catheter is passed. If this treatment is inefficacious continuous catheterization becomes necessary. For this purpose a large, soft rubber catheter, or a self-retaining one, is selected and the antiseptic solution introduced; if the catheter is properly introduced, the entire amount of the solution will return. Twice a day the urethra and bladder are thoroughly flushed with the antiseptic solution, the catheter being withdrawn far enough to allow the injected fluid to escape from the meatus, and then being pushed back into its former position.

The success of this treatment depends upon securing free and continuous drainage and this is incident to the permeability of the catheter and its retention in the proper position. When skillfully applied it is one of the safest and most successful means of treating cystitis, which so frequently complicates obstruction from prostatic enlargement.

Recent Literature.

Introduction to the Study of Malarial Diseases. By Dr. Reinhold Ruge of the Imperial German Navy. Translated by P. Edgar, M.B., C.M. (Edin.), and M. Eden Paul, M.D. (Brux.), M.R.C.S., L.R.C.P. Illustrated. New York: Rebman Company. 1903.

The author of this small volume of 138 pages modestly states that he offers little new to the student of malaria. His intention is rather to provide government officers with a brief compendium of important facts relating to this type of disease. The book is, therefore, eminently practical in its method of presentation, and discusses essentially those matters in the investigation of malaria which may lead to confusion on the part of the somewhat inexperienced. The book is well printed, adequately illustrated and should fill the place for which it is intended. Two plates of microphotographs are appended illustrating the endogenous development of the human malarial parasite and certain facts relating to the infecting mosquitoes.

The Complete Medical Pocket-Formulary and Physician's Vade-mecum. Collected for the Use of Practitioners. By J. C. Wilson, A.M., M.D., Physician to the German Hospital, Philadelphia, etc. Third revised edition. Philadelphia: J. B. Lippincott & Co. 1903.

As stated in the title, this small volume contains a series of prescriptions taken from various sources, together with many facts relating to the giving of drugs, and to their dosage, which cannot fail to be of value. Other facts and tests of various sorts are added, which may also be commended. The volume has reached its third edition. It makes no pretence to be anything more than it is. It is attractively bound in flexible leather, and may conveniently fit into a pocket or bag. Throughout the text various blank pages are left for personal notes.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 24, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

INTRACRANIAL SURGERY.

A matter of constantly recurring interest to practitioners of medicine, whether physicians or surgeons, is the question of the relief or cure of intracranial growths. The surgeon who has come to look for definite curative results from his operative procedures is apt to regard with a certain scepticism the possibility of relief in cases of brain tumor. The physician on the other hand is, if not sanguine of results, still often hopeful that the tumor may be successfully reached or removed, or at least that the symptoms may be so far benefited as to give the patient a relative degree of comfort. The attitude of the surgeon is no doubt in a measure justified by the facts of experience; and the hopes of the physician are not infrequently wholly disappointed by the outcome of surgical interference; nevertheless, this type of disorder demands for this reason the most painstaking study, both on the diagnostic and on the palliative side. Such study is being given as never before. Great numbers of cases are being reported, a few successful, many benefited, and some without material effect, or even fatal, after surgical intervention. It is certainly a branch of medical practice which requires the concentrated attention of surgeons, as well as neurologists, if the best results are to be attained.

We have been gratified and instructed in reading a discussion of the surgery of tumors of the brain by Dr. Charles H. Frazier of Philadelphia, published in a recent number of the *American Journal of the Medical Sciences*. Dr. Frazier finds that the statistics of the last five years give

renewed hope in the surgery of cerebral tumors, due to more accurate diagnosis, earlier recourse to operation, and to decided improvements in technique. On the surgical side the improvements in technique have as a common object the prevention of shock. Stress is very rightly laid upon the necessity of taking additional precautions in operations on the brain. To this end the avoidance of unnecessary exploration, or of prolonged operations, or of excessive hemorrhage, or of rough manipulations, are important. Furthermore, the anesthetic should be given by an experienced man, and circulatory conditions should be frequently observed during the operation. As to methods of opening the skull Dr. Frazier decidedly prefers the dental engine, armed with trephine and drill, by means of which an osteoplastic flap may be most quickly and easily made. The chisel and mallet, which had a brief period of popularity, the Gigli saw, and the recently introduced Stellwagen trephine, are all open to serious objections. The advantages of the dental engine, in Dr. Frazier's hands, are rapidity, ease of control of hemorrhage, and reduction in traumatism.

Precautions against hemorrhage from the very beginning of the operation are insisted upon. Even the blood lost from an extensive scalp incision should be considered, and to this end a tourniquet to the head is strongly advised. The problem of controlling hemorrhage from the brain or from a vascular tumor is a more difficult one. Two courses are open; either to pack gauze into the wound, or, as suggested by Crile, to close one or both carotids temporarily. This latter procedure is apparently not without danger, and in Dr. Frazier's opinion should be reserved only for extreme cases. As practiced also by Cushing, Frazier regards the observation of blood pressure during intracranial operations as of great importance, particularly since it affords information of practical utility as to the advisability of performing operation in one or two stages. The rather startling statement is made that about twenty-five per cent of patients operated upon died immediately from the effects of operation, variously attributed to shock, concussion or "unknown causes." It is now thought probable that the sudden withdrawal of intracranial pressure, leading to the breakdown of the vasomotor regulatory mechanism, is responsible for these too frequent deaths. The following rule is, therefore, worthy of consideration: If there be a very decided fall of blood pressure following the reflection of the dura after an osteoplastic operation, the operation should be temporarily discontinued and completed in a second stage from two to seven days later. This permits the circulatory equilibrium to be restored and removes the essential source of danger.

The discussion of the bulging or hernia of the brain after operation is also of much importance. The immediate bulging on opening the dura is sufficiently explained by the existing increase of intracranial pressure; the consecutive bulging, so often an annoying and dangerous feature of convalescence, is of more importance, since it is probably in a measure avoidable. If the experimental evidence as pointed out by Cannon is correct that cerebral edema is due to traumatism through certain chemical changes in the brain substance itself, it at once becomes of importance to recognize the fact that the various manipulations of the brain by the palpating finger, and by other efforts to discover the existence of a growth, are positively deleterious, since they lead to a swelling and subsequent hernia which might otherwise have been avoided.

Frazier is of the opinion, which must be shared by all who have had experience with this type of case, that palliative operations are wholly justified for the relief of the distressing symptoms when hope of cure is not to be considered. It is, perhaps, in these increasingly frequent palliative operations that special care should be taken by the surgeon to avoid risks of hernia and the consequences of over-much manipulation of the brain cortex. Lumbar puncture as a means of palliation should in the light of accumulating experience certainly be regarded as a dangerous procedure, and if attempted at all, an exceedingly small amount of cerebrospinal fluid should be withdrawn. In general it is concluded that the statistical study of the results of the last five years is encouraging; that the mortality, both immediate and subsequent, has been materially reduced; and that recurrence after removal of the growth is not to be expected more frequently than in other organs.

We have discussed this paper of Dr. Frazier at some length because it seems to us an admirable exposition of the surgical aspect of the general question. If the suggestions made by him could be put into active operation by all surgeons operating on the brain, we feel confident that results would be more satisfactory and the mortality much lessened. We are inclined from time to time to regret that surgeons do not take a more vital interest in the symptomatic course

of these cases, an attitude which would certainly induce a heightened appreciation of the necessity of devotion to the details of operation to which Dr. Frazier calls attention.

THE BOSTON DISPENSARY.

The managers of the Boston Dispensary are making an appeal to the public for money to enable them to add to their present buildings.

This institution has a long and very creditable history. It was started in 1796, eight years before the founding of the Massachusetts General Hospital, and sixty-eight years before the City Hospital, for the purpose of affording medical advice and relief to the sick poor of Boston. It is wholly a private charity entirely dependent upon popular support. In 1883 the present building was constructed, having been paid for by contributions from the charitable public of Boston. In 1900 an addition was completed at a cost of about $65,000, all of which, with the exception of $10,000 contributed by two friends, was paid out of invested funds. The capacity of the Dispensary was doubled, yet to-day it is badly cramped for room. The desired addition is imperatively necessary if the Dispensary is to properly care for the sick poor who come for aid. The estimated cost of the additional land and building is about $100,000.

In 1884 the total visits at the Dispensary were 31,725, or 103 per diem on the average, and the number of physicians was 39. The recipes put up by the apothecaries were 36,704. The total number of visits made by patients at the Dispensary in the year ending Sept. 30, 1903, was 89,207, which is an average of 295 a day. These patients were treated by the 77 physicians and surgeons of the Dispensary, who give their services without compensation. In addition, 20,501 visits were made at patients' homes by the 13 district physicians employed by the Dispensary, and 92,162 recipes were put up by the apothecaries. This indicates that the service has nearly trebled since 1884.

All those familiar with hospitals realize the great development in recent years of out-patient departments, both in numbers of patients and in importance in relation to the community and to the hospitals as a whole. The more modern medical methods, the growth of specialties, necessitate more equipment and more space than formerly. The buildings recently opened, or about to be opened, for the out-patient services of leading hospitals emphasize this proposition. The floor space of this new department of the Massachusetts General Hospital is nearly 80,000 square feet, while that of the Boston Dispensary is but 30,000, and yet very nearly the same number of patients is treated.

MEDICAL NOTES.

New York State Abandons Research on Cancer. — According to the *New York Medical Journal*, after spending $100,000 New York State has abandoned its attempt to find a cure for cancer. The Senate Committee on Finance has reported the annual appropriation bill, and from it has been stricken the provision of $15,000 for the cancer laboratory at Buffalo. The institution has had the benefit of State funds for six years. "We are convinced that no progress is being made in the Buffalo laboratory," said Senator Malby. "The state would gladly spend its money in the effort to find a cure for cancer if it could be shown that any advance had been made. My own impression is that if a cure for this much dreaded disease is ever found it will come through the work of some man who has devoted his life to scientific research and not through any state endowed institution."

This reasoning is of questionable validity, and savors rather of politics than of a progressive scientific spirit. We regret that New York is to be deprived of this relatively small sum of money in its attempt to solve the problem of cancer.

Panama Canal Commission's Sanitary Advisers. — Accompanying the Panama Canal Government Commission, which sailed from New York on the steamship "Alliance" for Colon on March 29, were Col. William C. Gorgas, M.D., and Major Louis La Garde, M.D., of the United States Army, and Dr. J. W. Ross of the Navy, who are to have supervision of the sanitary arrangements on the Isthmus. The Commission will probably remain at the Isthmus about two months and will inspect the entire route of the Canal.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon March 23, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 58, scarlatina 22, typhoid fever 9, measles 212, smallpox 0.

Medical Examiner, Yale Gymnasium. — The position of medical examiner for the Yale University gymnasium has been abolished. The last incumbent, Dr. Jay W. Seaver, held the appointment for twenty-five years.

A NEW TYPE OF LITIGATION. — Suit has been brought against the Boston Elevated Railway Company for damages because a passenger contracted a cold while riding on one of the company's cars. Plaintiff's claim is that during a rain storm she was exposed to wet and damp to such a degree that she contracted a cold therefrom. This exposure, it is claimed, was due to the negligence of the defendants. The defendants naturally set up a claim that the plaintiff assumed such a risk when she entered the car and that they were exercising due care. The judge before whom the case was presented reserved his decision, the importance of which is evident.

BOSTON MORTALITY STATISTICS. — The number of deaths reported to the Board of Health for the week ending March 26, was 237, as against 201 the corresponding week last year, showing an increase of 36 deaths, and making the death rate for the week 20.48. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 58 cases, 5 deaths; scarlatina, 23 cases, 2 deaths; typhoid fever, 8 cases, no deaths; measles, 194 cases, 2 deaths; tuberculosis, 51 cases, 38 deaths; smallpox, no cases, no deaths. The deaths from pneumonia were 32, whooping cough 1, heart disease 23, bronchitis 13, marasmus 4. There were 10 deaths from violent causes. The number of children who died under one year was 44; under five years, 61; over sixty years, 47; deaths in public institutions, 74.

NEW YORK.

OPENING OF MOUNT SINAI HOSPITAL.—The new Mount Sinai Hospital was formally opened on March 15, and among those who made addresses were Governor Odell, and President Fornes of the Board of Aldermen representing the mayor. In presenting the keys Joseph Fox, vice-chairman of the building committee, said: "Our greatest thanks are due to the Jewish community of this city, whose unprecedented liberality in providing the means for the erection of this group of buildings stands as an unequaled achievement in the line of communal work, an honor to our race and a credit to the metropolis." In the course of his remarks Edward Lauterbach, counsel for the hospital said: " These buildings have been erected, but there is the burden of an enormous expenditure that is still to come. There is a distressing spectacle in this city to-day, and it is that kindred institutions are threatened with diminution of their great services because of the lack of funds. That condition can never come to Mount Sinai Hospital as long as the pulse of the great Jewish community beats in unison with that of its directors, whose sacred duty it is to preserve and maintain it." The new Mount Sinai is unquestionably one of the finest and most perfectly equipped general hospitals in the world.

PRIVATE HOSPITALS IN NEED. — Nearly all the large private hospitals in the city (known as private by way of distinction from the municipal hospitals) are at present more or less crippled by a deficiency of funds, in consequence of the increasing demands upon them for the treatment of charity patients. Some of them have therefore been obliged to curtail their work, and retrenchment would seem to be a necessity as regards nearly all these institutions. The case of the New York Eye and Ear Infirmary has already been mentioned in the JOURNAL, and recently the Roosevelt Hospital has closed its special ward for diseases of women. If such retrenchments continue to be made, Bellevue and the allied public hospitals, which are now taxed to their utmost capacity, will be quite inadequate to care for the patients turned away from the private hospitals. During the past winter, however, there has been a very unusual amount of illness to contend against, and it is to be hoped that with the advent of spring the tension on all the hospitals will be materially relieved.

MOUNT SINAI HOSPITAL. — The Mount Sinai Hospital is having trouble in disposing of its old site, on Lexington Avenue, 66th and 67th Streets. On March 11 the Appellate Division of the Supreme Court rendered a decision, reversing the lower court's, to the effect that the corporation cannot give a marketable title to the property, the hospital first built upon the ground, which was in two plots, in 1871, holding the property under leaseholds from the city for ninety-nine years at one dollar rental per year for each plot. In June, 1898, in response to the corporation's petition, the commissioners of the sinking fund of the city granted the property to the corporation in fee simple absolute, with the right to dispose of it at best advantage for the maintenance of the institution. In view of the contemplated removal of the hospital to its new site, the corporation, in December, 1901, agreed to sell the property to David H. Hyman, who paid $20,000 on account when the contract was executed in the month following. Title to the portion recorded as Lot 1, Plot 2, passed March 1, 1902,

when $10,000 additional was paid, together with a mortgage for $51,500. When in July, 1903, the corporation tendered the deed for the remainder, Mr. Wyman refused it, claiming that it was invalid because the leases and deeds from the city were illegal and unconstitutional.

Correspondence.

MAMMEATA.

Suakim, Upper Egypt, March 2, 1904.

Mr. Editor: The enclosed photograph of the wet nurse of the Emperor Menelik's little grandchild may interest such of your readers as are trying to solve the problem of infant feeding.

We have no milk laboratories in this country.

Yours very respectfully,

Mantzaris Bey, M.D.,
(Paris, 1891),
Late Physician to the Imperial Household and at present Chirurgien en Chef of the Suakim-Berber Railroad.

CREDIT WHERE CREDIT IS DUE.

Manila, P. I., Feb. 11, 1904.

Mr. Editor: Vol. cxlix, No. 26, Dec. 24, 1903, on page 707, first column, a writer in the Journal gives a reference to an order of General Grant's Headquarters, Department of Texas, in regard to the protection of the command from yellow fever. The writer does not mention on whose recommendation this order was issued. Is it to be understood that it was of General Grant's own initiative or upon the recommendation of his medical officer? If so the credit for the steps belongs to the medical officer and not to General Grant, who only ordered that which the intelligence of another man had dictated. I do not think that General Grant would have cared to be put into the position of trying to steal another man's ideas, and equally difficult is it to think of him with expert medical knowledge.

Very truly yours,

J. S.

Miscellany.

BUILDINGS FOR THE INSANE.

According to *Charities* nearly a million and a half dollars is now being spent, or is about to be spent, in some nine different states for new buildings for the insane. This is exclusive of New York state where between $600,000 and $900,000 is annually expended for this purpose. It would seem pertinent to inquire whether there might not be an increase in efficiency and decrease in cost if the experience of the different states were in some way made available to one another. We have practically the same classes of patients to be provided for in all cases, and there is little reason why buildings which have been found suitable in Massachusetts should not be suitable in Oregon. The building operations now under way, or already planned, include entirely new institutions at Norwich, Conn., Allentown, Pa., and Parsons, Kans., and additions to existing buildings at Morristown and Harrisburg, Pa., Spring Grove and Sykesburg, Md., Dunning and Watertown, Ill., Lyons View, Tenn., Hopkinsville, Ky., San José, Cal., Eloise, Mich., Las Vegas, New Mex., Norfolk, Neb., and Pineville, La. The buildings include administration buildings, nurses' homes, cottages for convalescents and buildings for almost all other classes of patients. These buildings are probably designed in most cases by architects who have little familiarity with the requirements of the insane or with expert opinion on the subject of their accommodation. It is not customary for architects to specialize on institution construction, and the appointment of an official state architect has probably never been considered in most cases. Problems which have been solved only after many failures in some of the older states are, perhaps, worked out afresh without adequate data. In 1891 William P. Letchworth, a member of the New York State Board of Charities, wrote a valuable paper on "Poorhouse Construction," which was transmitted by the State Board of Charities of the Legislature and was afterwards reprinted and circulated for the information of the public. How helpful it would be if some expert in hospital construction would prepare a treatise on the construction of institutions for the insane, illustrated with plans and elevations and equipped with references to localities where successful exponents of sound theories of construction could be seen and studied.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 12, 1904.

Deaths reported, 4,249; under five years of age, 1,074; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 925, acute lung diseases 1,002, consumption 495, scarlet fever 37, whooping cough 14, cerebrospinal meningitis 17, smallpox 6, erysipelas 12, puerperal fever 19, measles 49, typhoid fever 65, diarrheal diseases 107, diphtheria and croup 78.

From whooping-cough, New York 7, Philadelphia 2, Baltimore 2, Pittsburg 1, Boston 2. From smallpox, Philadelphia 6. From cerebrospinal meningitis, New York 10, Pittsburg 1, Boston 3, Lynn, Brockton and Gardner 1 each. From erysipelas, New York 3, Chicago 1, Philadelphia 3, Baltimore 3, Boston 1, Somerville 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,475, for the week ending Feb. 27, the death-rate was 17.5. Deaths reported, 5,137; acute diseases of the respiratory organs (London) 180, whooping cough 163, diphtheria 58, measles 104, smallpox 2, scarlet fever 22.

The death-rate ranged from 6.4 in Hornsey, to 30.6 in Plymouth; London 16.5. West Ham 13.9, Brighton 20.2, Southampton 13.9, Bristol 18.2, Birmingham 22.7, Leicester 13.3, Nottingham 19.7, Liverpool 21.4, Bolton 16.0, Manchester 20.7, Salford 19.8, Bradford 14.4, Leeds 19.3, Hull 16.8, Cardiff 13.3, Rhondda 19.2, Merthyr Tydfil, 25.1, Tottenham 14.8, Bootle 22.8.

METEOROLOGICAL RECORD.

For the week ending March 12, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

THE PARTIAL PASSING OF NEURASTHENIA.[1]

BY CHARLES L. DANA, M.D., NEW YORK.

THERE have come of late years much clearer ideas of the nature and relationships of the insanities. The analysis of symptoms has been keener and clinical study has been pursued with scientific methods and with an especial enthusiasm. There has been, in fact, a kind of intellectual renaissance in psychiatry which has aroused deeply the interest and respect of neurologists to whom for many years alienism has stood chiefly for politics and stewardship.

This activity has perhaps excited in us a more careful study of mental states, and it has emphasized to us the fact that while insanity is a psychosis, or morbid mental state, there is a large number of such states that are not insanities, though showing a kinship to them. These non-insane psychoses come to the general practitioner, and perhaps especially to the neurologist, by whom they are put down commonly as some form of neurasthenia, perversity, hysteria or degeneration. It is my contention that a large number of these so-called neurasthenias and all the hysterias should be classed as prodromal stages, abortive types or shadowy imitations of the great psychoses. For in these cases it is the morbid mind that dominates the situation, not a weak eye-muscle, a poor stomach, a heavy womb, uric acid, arterial sclerosis or even an exhausted motor, nerve cell. They are not often, to be sure, pure psychoses; the body is also at fault, but the psyche is in main control and it gives the stamp to the syndrome, directs the prognosis and most acutely solicitates the treatment. Many neurathenias are only a kind of understudy of some particular type of insanity, or they make the forming stage of some major psychosis which, perhaps, under wise direction never fully develops.

With all this I think you will agree, and perhaps even say that it is both old and obvious.

But it is my particular task to try and show not alone that neurasthenia is often or usually a minor psychosis, but to indicate how we can often assign an individual case to its specific group.

For these purposes I must say something about the grouping of these psychoses.

I am not going to make any serious assault upon that mighty Gibraltar of nosology, the classification of the insanities. I have, however, tested some of my most meticulous alienistic friends with certain propositions, and they have yielded a satisfactory acquiescence. I hope they will be as well received by you. The propositions are these: There are, speaking broadly, five types of insanity, each representing a somewhat more instable brain upon which external or internal agencies of an injurious kind have acted. There is underlying all the chief non-accidental or functional insanities, an innate constitutional weakness, instability, or taint. This inherent structural weakness varies in intensity and seriousness with the character of the psychosis. Represent the normal human constitution by a horizontal line, and I think it will be agreed that the mental departures from this line are greatest in about the following order: precocious dementias; paranoia; manic depressive and melancholia; phrenasthenic psychoses; toxic and exhaustion psychoses; organic psychoses.

I am leaving out of consideration the idiocies, imbecilities, and the organic insanities from syphilis, epilepsy and gross-brain disease, for they present another problem.

There may be disagreement about the relative degrees of the teratological deviation in this scheme. I do not insist upon its absolute correctness. It is based mainly upon the different degrees in which the human mind deviates or disintegrates under the influence of the psychosis; and not upon the statistics of heredity.

It will be necessary for me to give some indication of my interpretation of those different forms, though it will readily be understood that I do it only in a most schematic way. I am following as you see in a general way the views of Kraepelin and his pupils, but also the admirable studies of Dercum; and I will confess to my indebtedness to this latter, as well as to the practical help I have got from the physicians of the Psychopathic wards at Bellevue Hospital, where for some years classifications have been put to vigorous tests.

THE PRECOCIOUS DEMENTIAS.

I do not suppose any one doubts that there are dementing insanities which attack people almost always before thirty, and very often before twenty; that they sometimes come on quietly, without noise, and with a long period of pseudo-neurasthenia, and that they sometimes remit and even cease entirely to progress. They are simple or primary dementias.

On the other hand, they sometimes develop with an outburst of violence, followed by confusion, stupor or a katatonic state, with remissions and relapses later. They sometimes come on with delusions and go ahead like a rather rapid type of delusional monomania. But they all, as a rule, tend to dementia sooner or later. We can use for them a multitude of qualifying names, but the main clinical facts are known, and generally agreed upon. They may some day be looked at in a different light, or grouped in a different way. Their present grouping is an easy and satisfactory one to the clinician, and is at the present day very widely accepted.

PARANOIA.

Paranoia is a form of the major psychosis about which there is practically no disagreement, and I need not take up your time with any description of its characteristics. It comes on after adolescence, has a tendency to a cyclical course in which there is at first depression, moodiness, suspicion, egotism and sense of being badly

[1] Read at the meeting of the Boston Society of Psychiatry and Neurology, Jan. 21, 1904.

treated; then follow systematized delusions, and sometimes active explosions of excitement under these influences. The course is long, but there is very little tendency to dementia.

MANIA-MELANCHOLIA, RECURRENT MELANCHOLIA, CHRONIC MELANCHOLIA.

The condition known as mania-melancholia is one much harder, perhaps, for the neurologist than the psychiatrist to accept. For we see much melancholia and very little mania; but there is undoubtedly a depressive insanity which begins early in life, often develops from slight causes, and recurs again and again with slight tendency to dementia.

On the basis of my own experience, I am inclined to out-Kraepelin Kraepelin, and place the chronic melancholia of middle and later life, *i. e.*, the melancholia of involution, in the same group. I cannot here present all my reasons for this view; but I believe it is a common experience to find a patient, who in the forties develops a mild melancholia or an agitative melancholy, to give a history of nervous prostration when in the twenties or a little later on sometimes, of attacks, ftve, ten or fifteen years previous to the one which is brought before me. We see analogies also in the neuroses, such as migraine. Migraine usually develops like dementia, before the twentieth year, and ceases at the climacteric, but often it does not develop until late in life, or having had a few years of display in early life, some new manifestations of migraine or some equivalent neurosis develops about the forty-fifth or fiftieth year. It can readily be understood that what is a pure psychosis as is manic depressive insanity in youth, may easily be made a chronic one by the complications and degenerative changes of later life. The late development of the psychosis suggests that the constitutional taint, which underlies it, is dying out, and hence, we would not get the violence of explosion or the occasional rapid tendency to dementia seen in the early and pure form.

PHRENASTHENIA.

The *neurasthenic* or *degenerative psychoses*, for which I use the term, *phrenasthenia*, form a well-recognized group also. I would make it include the perversions, hysterias, phobias, abulias, amnesias, as well as the compulsions and impulsions, the dipsomanias, morbid fears, and the psychic tics. In his work on the mental state of hystericals, Janet describes most of the phenomena of this group. The word, *hysteria*, however, conveys a different meaning to the minds of most, and the term "phrenasthenia" is one which implies little, and answers the purpose better.

I may be charged with using the term phrenasthenia as a kind of pathological catch-all for the psychopathic, but that is not my intention or view. In this group of persons, there are these dominant traits: (1) a tendency to psychical storms or explosions as in dipsomania, hysteria, or the psychic tics; (2) a tendency to psychical "tonus" or contracture as shown in obsessions, besetments and fixed ideas. There is with all a defect of inhibition which leads the instincts and the subconscious mind-stuff to play havoc with the conduct. The patients are often neurasthenic also, on the ordinary somatic side.

EXHAUSTION PSYCHOSES.

The *exhaustion and toxic psychoses* form a much divided group, but they can be, as Dercum states, classed pretty closely together under the delirium, confusion, stupor syndrome.

I presume that most cases of neurasthenia proper, occurring in adult and middle life, are exhaustion neuroses, with often some suggestions of the analogous psychosis. Thus the extreme nervousness is the nerve equivalent of mania, the inability to work and concentrate the mind often amounts to a confusion; and the absolute physical lassitude and weariness is the analogy of the stupor and dementia of a toxic insanity. This, then, is my schematic view of the great groups of insanities of which much of neurasthenia is a prodrome, a *forme fruste*, or an imitation.

Perhaps all that I ought really to assert is what you will readily grant, *viz.*, that among neurasthenics, currently so-called, we can find:

(1) Early stages and abortive types of dementia precox.

(2) Mild attacks of manic-depressive insanity, with exhaustion and retardation of thought, but not much melancholia.

(3) Many *formes frustes* of the neurasthenic insanities, with doubts, fears, impulsions, especially with obsessions and fixed ideas, drug and alcohol tendencies, and even sexual perversions.

(4) Mild forms of paranoia, in its depressive and hypochondriacal stage.

(5) Early attacks and mild attacks of the melancholia of involution.

(6) Early stages of paresis.

(7) Slight grades of the exhaustion psychoses, following typhoid fever, grippe, prolonged alcoholic indulgences, or non-paretic syphilis.

One might admit this much and yet be unwilling practically to grant that most neurasthenias are mental cases. But there are some general as well as specific and technical reasons favoring this view. It is notorious, for example, the number of "cures" that exist for the alleviation of the neurasthenic state. The patent medicines, suggestive and pedagogical therapeutics, like the New Thought, Mental Healing, Christian Science, Osteopathy, electricity, water cures. We all remember, also, the vogue at one time or another of specialistic cures by treatment of eyes, stomach, uric acid and the pelvic organs.

All this variety and excess of therapeutics certainly suggests either no disease or a mental one.

I have been watching for a case of neurasthenia due to excessive physical work alone, but I have never seen it. It does not occur, for example, as the result of long and hard athletic work, nor in bicycle racers, or six-day pedestrians, or in firemen and stokers. It is always the psyche that has to be hit in order to get a neurasthenia.

I am not, however, especially anxious to argue

this point, for I think the truth will be reached finally by a close study of symptoms.

I shall be very much disappointed if those who hear or read this paper should flippantly express their interpretation of it by saying, "Well, he just wants to make out that all neurasthenics are crazy people and ought to be locked up." Yet I can hear something of this in the air.

This is very far from my meaning. I would emphasize, rather, the fact that there are many important psychoses or morbid mental states that are not at all insanity, and never will be. Nevertheless, they are not perfectly healthy minds, and their maladies or sufferings are largely due to the mismanagement of their minds, rather than their bodies. *Mensa sana* means almost always *corpus sanum* so far as functional conditions go; and I say this at the risk of having Mrs. Eddy claim me for her own.

Furthermore, I would insist that these minor psychoses which make or keep up neurasthenia are generally manageable things. If one third of the major psychoses are curable, we can say that three fourths of the minor groups are so. But they are much more curable if we know which is the organ most in need of therapeutical attack.

And here is where the importance of recognizing the presence and nature of a psychosis comes in. We know that in phrenasthenia the trouble is a chronic one, with some tendency to a cyclic course. But in this phrenasthenia we need, above all, pedagogical treatment, isolation and a routine of regular life, while treatment makes them worse by intensifying the obsessions. In the early neurasthenias that suggest, at least, a precocious dementia, very prolonged rest is absolutely needed.

In melancholia-mania, the malady we know will run a course, and we can predict a cure, often in a short time; but we can also predict and try to avoid a relapse.

In the melancholic neurasthenia of later life, we have the hardest problem to meet, and must prepare the patient for it. Here recovery is likely, but it is slow, and not ever quite perfect.

Without going into further analysis, I should say that many neurasthenic psychoses can be recognized if we rememper these facts:

(1) Neurasthenia, strictly speaking, very rarely occurs under twenty. What we see then is pseudo-neurasthenia of dementia precox, or dementia precox itself; slight attacks of recurrent melancholia or manic-depressive insanity; or some early development of a phrenasthenia, showing itself in chronic headache, spinal irritation, hysterical seizures, fears and obsessions.

(2) Depressive forms of neurasthenia with mainly symptoms of exhaustion, and retardation of thought recurring, and coming on often without adequate cause or many bodily symptoms are forms of manic-depressive insanity.

(3) Neurasthenia in the luetic is often, not always, a precursor of paresis.

(4) The depressive and anxious types of neurasthenia occurring after forty or forty-five are usually mild forms of the melancholia of involution.

(5) The neurasthenias occurring after severe illnesses, toxemias and shocks, show sometimes signs of the confusional psychosis.

(6) So-called congenital neurasthenia or chronic hypochondria, is usually a dementia precox, paranoia or phrenasthenia.

Cut out all the foregoing, and one has cut out about 50% of neurasthenia. What is left is usually not a general neurasthenic state, but a local disorder. So that if one follows it up very closely we may yet end in finding that there is no such thing as neurasthenia at all. These are neurasthenic psychoses, and there are enfeebled nervous mechanisms, so that people have irritable or weak hearts, stomachs, legs or bowels. But this is not a general neurosis or neurasthenia.

I must confess that I may be charged with dealing disrespectfully with our one great national malady. You may say that if half our neurasthenics are just of fancy bred, and the other half not neurasthenics at all, America has been deleted of one of its most distinctive and precious pathological possessions. If no longer able to claim any disease as specially our own, or point with pride to a national and neurasthenical syndrome, there is removed, we may be told, an important stimulus to patriotism and racial solidarity!

I do not think, however, that I shall seriously jar the national pride. The removal of the term neurasthenia from the list of easy diagnoses will have its most tragic effect on the European professors whom our wandering plutocracy consults; and by whom the diagnosis of the "American Disease" is usually made as the patient is announced.

I am not, however, insisting that neurasthenia, *i. e.*, nervous exhaustion, is not a real thing. I think it is, and that the term will still have to be used.

But I specially urge that the mental state of these patients be carefully examined. The neurologist needs the help of the psychiatrist here, and I hope it will be given. I doubt if neurologists, as a rule, know enough of psychiatrical methods to make always the proper diagnosis of neurasthenia. This ignorance, however, will not last long and then there will develop a readjustment of our neurasthenic states with a knowledge of the psyche as a basis as well as of the *soma*.

It is in the hope of promoting this object that I have written this paper.

Appendix.

Description of the different types of psycho-neuroses.

The task of describing specifically the character of the different types of neurasthenic psychoses is difficult, and I do not pretend that I can accomplish it here. I shall in fact only try to point out some features of the more prominent groups.

A majority of the cases commonly called neurasthenia should be called "psycho-neuroses." This is a general term meaning nothing

much more definite than that the patient has a functional disturbance of the mind and nerves.

But a large number of these psycho-neuroses can be easily recognized as cases of phrenasthenia, of the explosive type like hysteria and dipsomania, or of the obsessive type.

A considerable number are cases of the mild or recurrent melancholia type, and they really belong to manic-depressive insanity, or to its allied form, chronic melancholia of involution. A smaller number of cases belong to the pseudo-neurasthenia that precedes or substitutes itself for dementia precox. A small number will be found to be really abortive types of paranoia. I have here arranged the psycho-neuroses in their order of frequency, at least, as I have observed them. Finally, most real neurasthenias are exhaustion and toxic neuroses or local neuroses. Thus we would have:

True neurasthenia: usually an exhaustion or toxic neurosis or local disease.

Psycho-neuroses: including: (1) pseudo-neurasthenia of dementia precox, (2) *formes frustes* of paranoia, (3) the same of the mania melancholia psychosis, (4) mild types of phrenasthenia, (5) mild types of exhaustion psychoses.

The *Pseudo-Neurasthenia of Phrenasthenia* — the most important and frequently seen psycho neurosis probably is that which have I called *phrenasthenia*.

This condition comes on in its hysterical and explosive form at the period of puberty and adolescence; but in its more chronic and obsessive form later in life, *i. e.*, after maturity. It occurs in women somewhat oftener than men. While congenital conditions are fundamental in the cause, the exciting causes are oftenest overwork, shock, worry and exhausting diseases and toxemias.

The condition is chronic, but tends to improvement and often cure. It runs a very variable, but not a regular or cyclical course. There is no tendency to dementia; and the patients are often active and intelligent; their social instincts are good, and they have not any deep or dominant melancholia. The memory is unimpaired, and the power of work often considerable, but concentration of mind is difficult, and there is a weakness of will and lack of initiative amounting to abulia. The hunger and sexual sense may be obtunded, or exaggerated; and there is usually an exaggeration of the sensations of pain, both physical and psychical. There are sometimes crises and prolonged conditions of what is called "nervousness"; this is a kind of pressure-activity, indicated by a feeling of restlessness and desire to do something or say something all the time. In the latter characteristic *place aux dames*.

Sometimes we get even suggestions of negativism, *i. e.*, a stupid refusal to react to sensible reasoning and advice, and the suggestion of any particular plan at once arouses antagonism and desire to do the opposite. Who has not met this person both in lovely woman and unlovely man? There is sometimes a marked diffidence and refusal to take part in ordinary social life. For the social instinct, though present, is crowded out by morbid self-consciousness and fears.

The phrenasthenic woman often shows an extremely morbid anxiety over her children, her husband and her household affairs, so that domestic peace is difficult and domestic service an especial trial. Affairs are run with a tremendous waste of energy; and, after all, not always well run, nor are the children well brought up, for the untrained phrenasthenic is over-rigid or over-indulgent, and in general makes a poor mother.

It is this class of people who get fixed ideas regarding their own malady or doctors, and become slaves to medication, or run off to Christian Science or some particular fad of treatment or diet. Sometimes the compulsion seizes them to go to bed, and they, on any excuse, run home, take off their clothes and soothe their fears between the sheets.

On the somatic side we find many of the ordinary symptoms of neurasthenia, such as periodical headache, occipital pain, and head pressure feelings of cerebral congestion, and a kind of subjective vertigo, which is really only a kind of crisis of apprehension. It is these patients who sometimes have long-standing and inscrutable headaches and local pains. They "never remember being without a headache" or pain in the back. No form of treatment has ever helped this. It is increased by exertion, mental or physical, and yet is not cured by rest or by anything but moral measures, including especially neglect.

Some cases of spinal irritation belong to this group, as well as that symptom which has been called topoalgia. It is not to be forgotten that some chronic headaches and spinal pains, however, are due to bad eyes, or to weak spinal muscles, or pelvic irritations. Nor do I deny that the soma may be the prominent defect in some patients who along with an obsessive brain, have small hearts, weak stomachs, and over-active thyroids, or perhaps a poor adrenal, and sphlanchniac system.

Naturally, these persons are sensitive to stimulants and rich foods, and are thrown into crises by moderate indiscretions. They are helped but not cured by washing the stomach, giving tonics, and so forth, but it is the "psyche" that really requires treatment.

The trouble is, in fine, a chronic non-dementing neuro-psychosis with tonic and clonic "seizures" affecting the intellectual field with fixed ideas, the emotional with crisis, fears, jealousies, doubts and morbid apprehensions; the instinctive with perverted impulses and the volition with periods of foolish action or actual paralysis.

I am not trying to describe that very easily recognized group of phrenasthenics who have serious phobias, doubts and almost insane obsessions and impulsions. Their characteristics are well-known and are sometimes so marked as to put them among the major psychoses. Mysophobia, doubting mania, belong most typically to this class.

It is the more subtle types that go often unrecognized as anything more than neurasthenic or

hysterical or hypochondriacal, though they really belong in the same great category.

The Pseudo-Neurasthenia of Melancholia. — The mania-melancholia syndrome is only an outfit of mental symptoms that may affix itself on any morbid and unstable brain. It occurs in the dipsomaniac and in the paranoic, it occurs as a phase of paresis, and in exhaustion psychoses. But it fits with particular purity of type a certain constitution coming nearest to that of phrenasthenia or the neurasthenic psychosis.

This syndrome does not always include a real melancholia or develop into a mania. Its principal underlying condition on the melancholia side, may be only exhaustion, retardation of thought, indecision and depression. There is a real and horrible melancholy, at times; at others, only an undercurrent of apprehension which stands for melancholia, and there are occasionally periods of nervousness, restlessness, and desire of action which stands for a mania. But the patient, on the whole, looks like a simple case of cerebral exhaustion, with inability to concentrate or use the mind, with simple " anhedonism," or loss of pleasure, sense and of interest in the work of the world, to which are added moods of melancholy, insomnia, pains and cerebral discomfort. The slightest effort seems impossible, and the smallest task a mountain of labor. The patient cannot read without fatigue or sense of nervousness, or even nausea.

Often the patients are girls or young women who break down at school, recover, and break down again in the twenties; perhaps during this decade they only have short periods of depression lasting a few weeks, but recurring every few years. Finally they become well, but sometimes develop new attacks at the period of the climacteric. These attacks are now more severe or, at least, more chronic, and are associated with many somatic symptoms due to arterial sclerosis, vasomotor and glandular disturbances, and the other frailties of the climacteric. Sometimes the attacks which occur late in life take the form of a hypochondriacal melancholia, because there are now real somatic disturbances which turn the mind upon the individual's own condition. The patient thinks he has a bad stomach, or liver, or heart, or is greatly worried over the parasthesias of arterial sclerosis and rheumatism that appear at this time. The characteristic of this psycho-neurosis in early life is a tendency to come on without much cause, and to recur without any marked physical disease or disability. The cases occurring at and after the climacteric are more obstinate and are associated with the somatic symptoms of the degenerative period of life.

The patients have no fixed ideas, or compulsions, nor much of the selfish egoism of dementing types of psychoses. There are sometimes periods of exalted feeling, of good health and spirits, with a flow of ideas and talk, and an exuberant delight in being well again. This leads sometimes to excesses that bring on exhaustion and depression.

Most cases perhaps are those which we see only in this later stage; and inquiries bring out the fact that at school or before marriage, she had one or two attacks of nervous prostration.

It is the fact that we see cases shading all the way from simple depression-exhaustion to real recurrent melancholia, that I consider these cases to belong to the psychoses.

The Pseudo-Neurasthenia of Dementia Precox. — These are neurasthenics of early life occurring under the age of twenty or twenty-five. There may be a bad mental heredity, and alcholism in the father is often noted. They include the cases of prodromal pseudo-neurasthenia, and the arrested and abortive types that pass later in life, perhaps, as chronic or congenital neurasthenia: Persons who achieve some success in early life, but have to husband their resources at every point or they break down.

The basis of all is a good brain originally, but one which at the time of maturity ceases to develop or to work well any more. It does not go to pieces, but its evolution ceases. It is not a short-lived, but an arrested organ.

Perhaps some cases get nearly well, for in a way, dementia precox is an exhaustion psychosis, and if the exhausting condition is quickly removed and long rest given, the brain may reassert its capacity to live. I am an optimist.

In pseudo- or prodomal, neurasthenic cases there is a period of two or three years in which a young man or woman shows symptoms of mental dulness or negligence. He does not do his work as well as formerly; and shows indifference to reproof and consequences. He has some ordinary neurasthenic symptoms, such as headache, insomnia, and cerebral parasthesia. He sits up late and sleeps very late. His conduct shows indecision and abulia, a loss of mental grasp and capacity to understand or do the work formerly attempted. The patient will spend hours in trying to finish a letter, or read a few pages in a book, or finish some calculation. He is often strong, physically, and will stand the work of a summer camp, of sports, or of hunting expeditions; eventually, however, this also tires him. The trouble may begin in a somewhat different way: A young man who has been working or studying steadily, rather suddenly finds he can't do his task. He goes home and lives with his family, simply refusing to work. He has not many complaints to make, but he simply cannot follow systematically any line of thought or industry. He sits at home a great deal, reads or pretends to do so, and lies in bed a great deal. His future depends on his situation in life, or the means, sympathy and affection of his parents. He is sent to travel, or to a life on a ranch, or in the woods. If urged too much, an explosion occurs, and his real malady is recognized. But if left alone, he continues his vegetative life, receiving casual treatment for his neurasthenia. After one, two or three years, perhaps, excitement or delusional conditions develop, and his trouble is recognized.

I am sure that there are types in which the

dementing condition is even slighter than this. The progress is really arrested for many years, and the patient is simply a rather useless homebody, doing nothing, not suffering much, helping a little about the house, showing aversion to real work however, complaining of his head, his stomach, probably sexually weak, developing some delusional ideas or vagaries. If he is originally serious-minded and brought up to ideals of duty and work, he makes a serious fight, but a little work causes profound exhaustion, and he has to give up. These patients do not have the egotism of paranoia. The malady runs a slow course; there may be periods of depression and apathy, suggestive to the watchful of a stupor, but there is not true melancholy. The great characteristic is the mental exhaustion and exhaustibility; the difficulty in attention and decision. It is an abulia from sheer weakness, however, not the hesitation of the doubting mania between two motives, or the indecision of fear and apprehension. The mental depression as stated is not acute, and if present is simply the psychic pain that comes from exhaustion.

To sum up: It is my contention, first, that many cases of dementia precox are in the early stages considered neurasthenics; but also that there are abortive types of dementia precox which pass through life or many years of it, with the dementia arrested, and are classed simply as neurasthenic. They are seen in college men and young professional men who break down suddenly after starting out brilliantly and are never heard of, becoming perhaps, breadwinners and fathers and mothers of families, but never amounting to anything, and always working at a disadvantage. They have no initiative; they break down often, and have to rest and limit their work.

Finally, neurasthenia occurring under twenty is rarely neurasthenia. It is a dementia precox, or a recurrent melancholia, or the exhaustion of a phrenasthenia, and it is rarely paranoia. Neurasthenia occurring at this early period with a bad family history, including family alcoholism, should make one very suspicious of a serious malady.

THE CYSTOSCOPE — ITS DIAGNOSTIC VALUE.[1]

BY A. M. WOSE, B.S., M.D., SYRACUSE, N. Y

By cystoscopy of to-day is meant the introduction of an instrument through the urethra for a visual examination of the bladder. This instrument, as you know, is called the cystoscope.

Like other articles of utility the cystoscope has its cycle of development. It is divided into two epochs:

(1) Instruments constructed on the plan of a tube passed into the bladder with the source of light reflected from a mirror without.

Bozzini at Frankfort in 1806 devised the first cystoscope. Then followed Segalas in 1826 with a modification, Bombolgini and John D. Fisher in 1827, Desormeaux in 1863, Cruise in 1865, Stein, 1873, and Gruenfeld in 1874. A question at that time was the choice of a light to be reflected; one advocated gas, another — petroleum, gazogen or magnesium — light. The open tube gave rise to difficulty from the fact that the contents of the bladder flowed out on introduction, and that the bladder-walls collapsed soon after, thus limiting the time and field of observation. The use of fenestrated tubes overcame this difficulty. All this, however, found its application in the female alone; for, at no time did this reflected light suffice to examine the male bladder.

This state of things changed on the introduction of the electric-light into therapeutics. Here commences the

Second epoch — that of the modern cystoscope.

Dr. Julius Bruck, Jr., of Breslau in 1867 was the first to use the platinum-light in medicine. He devised two methods for its use:

(1) What he called stomatoscopy, or direct illumination of a cavity oy a glowing platinum-thread.

(2) Diaphanoscopy — indirect illumination or translucency of a cavity by a glowing platinum-thread.

Ten years later Nitze returned to Bruck's method. For he believed that an organ like the bladder, connected by a long narrow canal to the outer surface of the body, could be satisfactorily lighted by passing the light itself into it. To accomplish this Bruck had already surmounted many perplexities for him as he had used the glowing platinum-thread, cooled by a stream of water, to investigate the aural cavity; and, as said, by introduction into the rectum to illuminate the bladder. Nitze then contrived an instrument not unlike an endoscopic-sound with Bruck's arrangement of lighting and cooling to be passed through the urethra into the bladder. On account of the narrowness of the lumen of the urethra, the field of vision of this cystoscope was no greater than the aperture of the sound used. On a suggestion from Nitze to enlarge this field of vision, an optician — Beneche in Vienna — constructed a tube with a combination of lenses comparable to those of a terrestrial telescope. After a thorough trial in Von Dittel's clinic, Nitze described and demonstrated this instrument at a meeting of the Medical Association of Vienna, March 9, 1879. So many were the difficulties in the use of his instrument, it found few adherents.

Dittel, however, added new life to this method of investigation. In place of the glowing platinum-thread, he believed he could substitute Edison's incandescent-light, which came to his notice for the first time in 1880. For the cystoscope this light was its greatest boon. Thus the former cumbersome stream of cool water became superfluous, and in 1886 Leiter of Vienna completed an instrument, which was small in caliber, simple in construction, and handy in use. In the beginning of the year 1887 the problem of the cystoscope was solved.

The fundamental principles, as you know, in the construction of all modern cystoscopes is: the arrangement of an electric light on the vesical

[1] Read before the Onondaga County Medical Society of New York State March 8, 1904.

end of a catheter-like metallic instrument with the optical enlargement of the field of vision by means of a prism, mirror and lenses. These instruments have a short Mercier curve with the lamps usually detachable, while the shaft of the instrument carries the optical apparatus, and a small wire to complete the electrical circuit. All the cystoscopes constructed by Nitze, Casper, Gueterbock, Berkley-Hill, Fenwick, Boisseau du Rocher, Leiter, Loewenstein, Lewis or Albarran are of the same principle. The improvements in the instruments in the hands of these experimenters have been numerous; each and all, likewise, precious adjuvants for the diagnosis or treatment of the great number of the maladies of the urinary tract.

The cystoscope of to-day is employed in two classes of cases:

(1) For diagnosis, by the ideas it gives of the character of the vesical mucosa and the products of secretions issuing from the ureters.

(2) For therapeutics, that intervention which it permits to effect directly on the ureters or the mucosa itself.

Thus there are simple cystoscopes, more complex ones, as those given to irrigation of the bladder or for the catheterization of the ureters, operating cystoscopes with a cold wire or a galvano-caustic loop, photographic-cystoscopes, and the cautery-cystoscopes employed in the operation of Bottini.

In spite of the perfection and the ingeniousness of the instruments themselves, cystoscopy remains a delicate and often difficult undertaking. A certain number of causes in fact may complicate its employment, and so introduce an error in the appreciation of the results obtained: First of all insufficiency in the brightness of the light always restrains one, which by too deep an introduction of the cystoscope obscures the view entirely, and if in contact with the bladder-wall may burn it with the consequent pain and movement of the patient (this latter property has been irradicated by the use of the new so-called cold lamps. These do not become heated). The arrangement of the apparatus — perhaps an imperfect contact in battery, or rheostat — diminishes the light or momentarily closes the circuit which prevents a just interpretation of that portion of mucosa observed. Immobility of the instrument after introduction, as rotation of the cystoscope on a longitudinal axis, or the movement of the ocular from side to side, forward or backward, limits the field of vision and a nicety of adjustment of the focal point to a clear image. Narcosis of the patient is generally necessary.

In order to investigate the bladder by means of the cystoscope the urethra must be passable. Strictures, a narrow meatus, or enlarged prostate must be calibrated or otherwise treated. In prostatic hypertrophy the use of the cystoscope becomes many times very difficult, and one should hold himself here to the strictest indications in its employment. The bladder must allow a moderate distention. Here a contraction or malformation embarrasses one. Likewise acute cystitis, tubercular cystitis must be given due consideration before any cystoscopic investigation. The bladder must contain a transparent medium to obtain a clear view of the intra-vesical relations. This medium is water or air, the former is at present most frequently used. Purulent and catarrhal secretions or conditions with hematuria must be repeatedly irrigated until the wash-water runs clear, otherwise one has a dim and imperfect reflection from the mirror.

It can but suffice to mention briefly the most important vesical observations by means of the cystoscope:

The cystoscopic picture of the normal bladder appears strikingly pale, whereas the mucous membrane after a suprapubic cystotomy is usually dark red in color. At the base of the bladder one finds the ureteral openings, which are often in diseases of the pelvis of the kidney or the kidneys, reddened, swollen, and edematous. In renal hematuria or pyuria the blood or pus can be detected coming from the ureter or ureters. The cystoscope is of the greatest aid to differentiate the origin of intermittent hematuria, whether the blood comes from the kidney, or its pelvis, the bladder, prostate, or urethra. In the male a question of import, many times, is the contour and relation of the prostate-gland. The cystoscope gives positive evidence in hypertrophic conditions of the median or lateral lobes.

It stands for reason that the cystoscope renders the greatest possible assistance in the differentiation of acute or chronic cystitic conditions, tumors of the bladder, whether they are infiltrated, papillomatous, carcinomatous, or papillary excrescences; and such plastic objects as foreign bodies or vesical calculi. In the search for a stone the cystoscope is always a valuable and often an indispensable diagnostic aid, as it reveals a vesical calculus, which by sounding may fail to be discovered. After litholapaxy, the cystoscope is used in search of remaining fragments. There may be a stone in a diverticulum of the bladder-wall, while the lithothrite is contra-indicated, the cystoscope leads one to the proper treatment. Also such rare conditions can readily be detected as: troublesome cicatrices or presence of ligatures after operation on the bladder; wounds or lacerations of the bladder-wall after contusions; the presence of a fistula; the point of perforation into the bladder from abscesses in the surrounding viscera, as in appendicitis, pyosalpinx, perinephritic abscess; and likewise in malformations as the remains of the urachus and the like. In gynecology the cystoscope gives additional insight to the pathology of displacements and malpositions of the uterus and adnexa, the striking appearance of the base of the bladder and ureteral openings in cystocele, the transformation of the bladder by a gravid uterus, and in uterine neoplasms, as carcinoma and the like.

In those rarer cases where the urethral cys-

toscope cannot be employed, an instrument has been constructed of late with a trocar, which allows a suprapubic puncture of the bladder, and at the same time a cystoscopic investigation of this viscus.

THE IMPORTANCE OF THE CYSTOSCOPE IN THE DIAGNOSIS OF DISEASES OF THE KIDNEY BY MEANS OF CATHETERIZATION OF THE URETERS.

For the progress in the surgery of the kidneys seen in the last ten years, we are much indebted to the use of the cystoscope in the catheterization of the ureters. A question often of first importance to the surgeon in contemplated renal operations is, whether his patient has one or two kidneys. Although the presence of only one kidney is a rarity, nevertheless, such cases are recorded and likewise not a few of them for the first time at the necropsy, after the removal of that kidney. Here the cystoscope with the catheter leads to positive evidence in diagnosis and for the subsequent treatment. One can determine the existence of this kidney, if it is healthy or diseased, or if its functional activity is impaired. As above mentioned one can differentiate by means of a simple cystoscope the diseases of the bladder from those of the kidneys by the changes taken place in the ureters or about the ureteral openings. With the catheterizing-cystoscope one is in a position to collect this urine from both kidneys, as it were, and separately subject it to the important microscopic, chemical and cryoscopical analyses.

For the collection and segregation of urine from each ureter, there are such instruments as those advocated by Harris, Downes, and more recently, those of Cathelin and Luys. These instruments are more applicable to the female, for the slightest enlargement of the prostate-gland lessens their value in the male; and likewise, in such affections of the bladder with purulent, catarrhal, and hemorrhagic secretions. Thus the problem to separate the urine of both kidneys in a complete and unobjectional method is solved only by the direct catheterization of the ureters; or, best of all, by the catheterizing cystoscope.

The catheterism of the ureters by the cystoscope is not infrequently crowded with difficulties, for one may deal with those rarer cases where the ureteral openings cannot be detected, for example: cases with a tumor-like swelling of the mucous membrane of the bladder in chronic cystitis, prostatic hypertrophy with excessive enlargement of the median or lateral lobes, a trabeculated bladder, and one with other deformation or deformity.

The combination of the x-rays with a catheterizing cystoscope mounted with a silver ureteral sound or a catheter loaded with a mandrin gives the following assurances in the radio-graphic plate: (1) absolute confirmation of course of ureters, (2) exact localization of an obstruction in ureter, (3) the exact topographical localization of pelvis of kidney, (4) solution of difficulty in diagnosis between biliary and renal calculi, (5) conclusion over size of kidney pelvis, (6) nature of a stopping of the ureter.

By the same method one can often differentiate between an abdominal tumor, wandering spleen, or a questionable wandering kidney on the left side.

As advocated by Dr. Howard A. Kelly, a ureter-stone can be revealed by the scratch marks on such a substance as a mixture of wax and olive oil on a catheter, after contact with the said stone.

When it is necessary to operate for calculus anuria it is often difficult to know upon which kidney to operate. The inquiry as to the side which gave localized pain is deceptive, and examination of the kidney region gives no assistance. Here the cystoscope clears up the scene.

Catheterization of the ureters is now employed with success in cases of tuberculosis of the kidneys, inflammation of renal pelvis depending on the presence of calculi or pyelitis itself. In these cases the common cure may remain resultless. Pawtick, Albarran, Casper and Kelly advocate the direct catheterization of the pelvis of the kidney. They employ this means in cases with increasing pyelitis or infectious forms, but not in primary affections of the kidney. Casper is of the opinion that in all cases of chronic pyelitis, which defy medical treatment, catheterization of the ureters is indicated; an operation is then in order if this fails.

Prior to an Edebohls or modified Edebohls operation for nephritis, the ureters should be catheterized. By this segregation of the urine one can determine the permiability of the kidneys, whether he deals with a unilateral affection, and that important question, whether his patient can sustain this operation. This latter factor would bring one to the consideratlon of the functional diagnosis of the kidneys. To allude briefly to this subject:

There is a comparable value between the permiability of the kidneys and the catheterization of the ureters. This value is in the Phloridzin test, the Methylene-blue test and the Cryoscopic test, in estimating the functional activity of the kidneys. Results of these tests are:

In the Phloridzin test: on segregation of the urine one obtains, from a healthy kidney, glycosuria, and from a diseased kidney no change whatever.

In Methylene-blue test: on catheterizing the kidneys, from a diseased kidney a pale barely-colored urine will be collected, while from a healthy kidney a pure green urine is obtained.

The Cryoscopic test: the freezing point of the urine lies between 0.9 and 2.3°. If the urine on segregation from the kidneys is below 0.9, an insufficiency of kidney or kidneys is shown.

Thus by the catheterization of the ureters one is able to estimate the functional activity of each kidney individually, by separately collecting the urine and subjecting it to the microscopical, chemical and cryoscopical analyzation.

In conclusion one can rightly say that the cys-

toscope of to-day affords an exactness in the diagnosis of urinary diseases, which as yet in comparison is unattainable by any other means. Likewise, one can safely conclude in the present state of our knowledge that the catheterization of the ureters offers a valuable and ever-widening field of usefulness in the just appreciation of nephritic affections.

LIGATION OF THE LACHRYMAL CANAL TO PREVENT INFECTION FOLLOWING CATARACT EXTRACTION.[1]

BY ALEX. QUACKENBOSS, A.M., M.D., BOSTON,

Surgeon, Massachusetts Charitable Eye and Ear Infirmary; Assistant in Ophthalmology, Harvard University.

Infection through the tear duct is one of the common causes of suppuration following cataract extraction. To overcome this difficulty, various means have been employed, in cases where disease of the tear passage exists; viz., probing, syringing out the sac, treating the nasal cavity, packing the sac with antiseptic ointment, obliteration of the sac or canal with the cautery and extirpation of the sac. Probing, syringing out of the sac, or treatment of the nasal cavity, entails a long course of treatment, and is often ineffectual. Personally, I have had no experience with packing the lachrymal sac with antiseptic ointment. Cauterizing the duct or sac has occasionally been followed by infection. Removal of the sac is undoubtedly the safest procedure, the only objection to it, in cataract operations, is that a great many of this class of patients are old and infirm. Dr. Knapp, in Norris and Oliver's "System of Diseases of the Eye," speaks of "ligating the lachrymal canal as a temporary or permanent means of shutting off infection."

At the meeting of the American Ophthalmological Society in 1902, Dr. Buller of Montreal advised the "temporary ligation of the canaliculi, as a means of preventing wound infection in operations on the eye."

During the past year, I have operated on two cataract cases in which there was trouble with the tear passage; I have also seen two other cases operated on. The canal was tied, and in each case was successful in preventing infection.

The report of one case will suffice to show the method employed.

Case. Female, age sixty-two; mucocele, O. U. staphylococcus; pressure over lachrymal sac causes muco-purulent discharge into eye.

The usual preparations for cataract extraction were carried out.

Operation under cocaine. Before operating for cataract, the contents of the mucocele were squeezed out, the eye washed out with corrosive (1–5,000), then a small probe was inserted into the upper puncta, and a suture passed around the canal, from the inside of the lid out. This was repeated on the lower lid. The sutures were passed two or three mm. from the puncta and were tied quite firmly.

Inserting a probe into the puncta aids in controlling your lid and in placing your stitches; this is especially so with the upper lid. The cataract was then extracted without incident, the usual dressing was applied, the dressing was changed daily and omitted at the end of six days. Healing process normal, very little injection being present at any time following the operation.

The patient complained of no discomfort from the stitches, and they apparently caused no irritation. The stitches were removed at the end of two weeks; before taking them out, pressure over sac failed to discharge anything into eye, but after removal, a probe was easily passed, and pressure on sac caused a small amount of muco-purulent matter to come through puncta.

I see no reason to keep stitches in, after the corneal wound has healed firmly, and in my second case removed them at the end of the ninth day. The advantages of this method are, its simplicity, the ease with which it can be done, its freedom from pain, that it can be done at the time of the operation, and that it can be used even in doubtful cases.

Clinical Department.

A CASE OF APPENDICITIS WITH GENERAL PERITONITIS.

BY CHARLES A. ATWOOD, M.D., TAUNTON, MASS.

L. M., schoolboy, age fourteen years. Has had four previous attacks of appendicitis within the last year. These attacks were of varying intensity and usually kept him confined to his bed about two weeks. Present attack began Dec. 24, 1903. I first saw him Dec. 28, 1903, at 9 P.M. Pulse 120. Temperature 103. Vomiting. Abdomen tense and distended. More resistance over the right lower quadrant. Diagnosis, appendicitis with probable general peritonitis. Prognosis decidedly unfavorable. Immediate operation advised as only chance. This was accepted. I immediately sent the boy to Morton Hospital and with usual preparation operated at 10.15 P.M.

Operation under ether. I opened the abdomen by an incision parallel with the fibres of the ext. oblique over the appendix. As soon as peritoneum was opened, there was found to be free pus in the abdominal cavity. The pelvis was full of pus, the intestines red and covered with masses of lymph.

Pus was washed away with normal salt solution. A short, gangrenous, perforated appendix was found, tied off, and removed. Salt solution was used in washing out the abdomen until the washings returned clear. Large gauze wicks were introduced around former site of appendix. A gauze drain passed up towards diaphragm and one into the pelvis. A long counter opening was then made in the left lower side of the abdomen and a long gauze drain introduced into the pelvis. The boy was in poor condition when removed from the table. Temperature next morning was 100.6° F. Pulse, 119. Dec. 30 temperature had come down to normal. His convalescence has been uninterrupted.

I report this case because it has been one of much interest and satisfaction to myself, also as it shows how much we may sometimes accomplish by surgery even under most unfavorable conditions, and lastly, as this was a case where

the whole abdominal cavity was infected, a case of general peritonitis. When the physician will call in the surgeon as soon as he even suspects trouble with the appendix, and not when his patient is moribund, then and not until then will these desperate cases cease to be so common.

The early removal of an inflamed non-perforated appendix, with its mortality so slight, is not to be compared with the deplorable results by any method of treatment of general infection.

Medical Progress.

RECENT PROGRESS IN GYNECOLOGY.

BY W. L. BURRAGE, M.D., BOSTON.

(Concluded from No. 12, p. 329.)

LARGE SARCOMA OF THE OVARY SITUATED IN THE LEFT KIDNEY REGION.

AGNES BLUHM [12] reports the case of a woman twenty-eight years of age who came into Czerny's clinic at Heidelberg complaining of pain and tumor in the left hypochondrium of eight weeks' duration. An elastic tumor the size of a child's head was found in the region of the left kidney, and partially under the edge of the ribs. The urine was negative. By bimanual examination the uterus was found retroflexed and the right ovary and tube normal. The left ovary could not be found. The clinical diagnosis was tumor of the kidney, probably hydronephrosis.

The tumor was removed after a difficult dissection and the wound drained with gauze. The patient made a good recovery. The growth proved to be a necrotic sarcoma of the left ovary, measuring 52 cm. in circumference and 19, 17 and 7 cm. in diameter. About three-quarters of it lay retroperitoneal and only the under fourth free in the peritoneal cavity.

The left kidney was displaced upward but had no connection with the tumor. A band ran downward behind the transverse and descending colon from the capsule of the tumor to the left broad ligament. The left ovary was absent. The author concluded that the tumor had developed in an undescended fetal ovary.

DISADVANTAGES OF THE TRENDELENBURG POSTURE.

Franz [13] has not observed a single case of serious circulatory disturbance in 745 abdominal sections performed in the elevated position, but from studies of the pulse and respiration curves he concludes that with the pelvis elevated the abdominal breathing is diminished and that there is little or no compensatory increase in the thoracic breathing.

As to the effect of anesthesia he noted 19 cases (2.3%) of bronchitis among 825 cases of ether narcosis in the dorsal position, while there were 44 cases (8.9%) among 493 cases in the Trendelenburg posture, 4 cases (2.7 %) of bronchitis among 150 cases of chloroform narcosis in the dorsal position and 9 cases (3.9 %) among 233 cases in the elevated position; showing much less difference between the positions in the case of the use of chloroform. Franz thinks the frequency of bronchitis after operations in the Trendelenburg posture is due to the escape of the infectious contents of the mouth into the bronchi after the patient has been lowered, and suggests that the mouth be carefully cleansed before the change is made to the dorsal posture.

He considers that the diminished oxygenation, which is present when the patient is in the elevated posture, probably has a deleterious influence on the central nervous system and that many disturbances which are referred to opening the abdomen are really due to this cause.

TELANGIECTATIC ANGIOMA OF THE BLADDER.

A. Berliner [14] adds a fourth case to the three cases of this rare affection already reported in literature.

A girl eleven years of age had suffered since her fourth year from hematuria. For the last weeks the hematuria had increased to such an extent that the anemia of the patient had become alarming. Since early childhood a pronounced asymmetry of the face had been noticeable. On examination a telangiectatic angioma the size of a walnut was found on the right labium majus. The urine contained blood in large quantity, had an alkalin reaction and contained pus but no tumor elements.

Cystoscopy revealed a number of circumscribed ridges or round elevations varying in size and bluish-red in color dispersed over the mucous membrane; between these the mucous membrane of the bladder was injected. Application of stypticin and douches being ineffective suprapubic celiotomy was performed. The telangiectatic areas were treated with the thermocautery and the bladder was drained through the abdominal wound with gauze. Cystitis followed and this was treated with instillations of nitrate of silver with the result that complete recovery finally occurred.

This is the first case on record in which a correct diagnosis was made and the proper treatment applied. The three other reported cases died, and it is probable that this girl would have gradually bled to death had she not had suitable treatment.

The diagnosis was rendered more probable by the simultaneous existence of an angioma of the labium and also by the deformity of the facial bones. Hypertrophy of the face concomitant with angiomas has frequently been observed.

Berliner points out that these angiomas consist of distended capillaries or radicals of veins; the connective tissue proliferates but little and there is no new formation of vessels. Angiomas, although frequently found in the epidermis, are rarely observed in mucous membranes.

Hematuria in young patients without cachexia,

[12] Archiv. f. Gyn., Bd. lxviii, H. 2.
[13] Centralbl. f. Gyn., No. 32, 1903.
[14] Deutsche. Zeitschr. f. Chir., Bd. lxiv, H. 5 and 6.

especially if inspection of the surface of the body reveals the presence of an angioma of the skin, should lead to the probable diagnosis of telangiectasis of the bladder.

ASCENDING RENAL INFECTION; WITH SPECIAL REFERENCE TO THE REFLUX OF URINE FROM THE BLADDER AND URETER AS AN ETIOLOGICAL FACTOR IN ITS CAUSATION AND MAINTENANCE.

Under this title John A. Sampson, Resident Gynecologist at the Johns Hopkins Hospital, publishes a lengthy article,[15] giving the results of a series of experiments and his conclusions arrived at from a study of the literature as to the anatomy, physiology and pathology of the ureter.

He states that he has previously described a radical operation for cancer of the cervix uteri, which consists in the removal of the lymphatics from the sides of the pelvis together with the uterus and carcinomatous growth *en masse*, this procedure being the reverse of the usual hysterectomy with a " digging out " of the glands subsequently. He has now done ten of these radical operations with three deaths and has resected one or both ureter in three cases.

He has found that if some 4 cm. of the lower end of the ureter are resected with the growth and the ureter implanted in the bladder there is danger of an ascending renal infection, and it was to study the cause of this infection that he undertook the study of the anatomy and physiology of the ureter.

A plate showing a longitudinal section of the vesical portion of the ureter with the bladder distended shows that the ureter passes through the bladder wall as a distinct organ, its course being very oblique. When the bladder is contracted, as shown by another plate, the course of the ureter is nearly at right angles to the internal surface of the bladder. The mucosa of the ureter is continuous with that of the bladder; it is smooth and the lumen of the ureter is flattened from before backward.

The ureteral orifice may be a slit with the labia close together, or an oval or even almost round opening, and sometimes the lumen of the ureter extends below the orifice, forming a pouch. That portion of the upper wall of the ureter which forms part of the bladder wall, that is to say, the V-shaped piece lying back of the orifice as seen in a longitudinal section of a distended bladder, is called the ureteral valve. Pressure on this valve by the fluid distending the bladder brings the anterior wall of the ureter in contact with the posterior wall and occludes the lumen, thus preventing reflux up the ureter. When this valve is injured by inflammatory processes the ureteral orifice remains patent and the valve cannot close the ureter. This is very clearly shown by a longitudinal section of the vesical portion of the infected ureter from a patient dying of unilaternal ascending renal infection.

Sampson points out that curettage of the trigonum is attended with danger of injuring the ureteral valve and thus making possible renal infection, also that ureteritis and renal infection are maintained by stricture of the ureter caused by pressure of the thickened bladder wall on the ureter.

As to the physiology of the ureter, the author made experiments on dogs, and also studied the ureteral orifices and the changes which they underwent during contraction of the ureter in ten women, using the cystocope with the patient in the Sims position. He concludes that the contractions of the ureter are dependent on the functional activity of the kidney and that the chief stimulus is fluid, without regard to its chemical constituents, running into or through the lumen.

The different avenues of infection of the kidney are discussed at length, *i. e.*, by the blood vessels, by the lymphatics and by the ureters. As to the blood vessels the infection may come through the general circulation; of this little is known except that one of the functions of the kidney is to excrete organisms which have gained entrance to the blood. Aside from the general circulation the blood vessels of the kidney communicate with those of the bladder through two other channels, the utero-ovarian vessels and the vessels of the ureter. The author's experiments on dogs to demonstrate lymphatics in the ureters were not successful and he quotes Sakata, who found lymphatics in the muscular and outer coats of the ureter, but not in the mucosa. He also found that the communication between the lymphatics of the bladder and kidney was not direct, but existed either by means of the local glands of the bladder and kidney or by means of the lymph-vessels of the ureter.

Sampson considers that infection generally occurs by an extension of an inflammatory process from the bladder through the ureteral walls, or along the lumen of the ureter. Reverse peristalsis in the ureter may occur, but the author is skeptical about it. Two etiological factors in renal infection are an injured kidney and general ill health.

In conclusion, the reflux of urine from the bladder into the ureters may be considered an etiological factor in the causation and maintenance of renal infection only when the intravescial portion of the ureter is diseased, thus impairing its function, or when some ureteral abnormality exists.

PAPILLOMA OF THE URETER.

Mackenrodt [16] reported a case of this rare affection before the Berlin Obstetrical and Gynecological Society.

A woman of sixty had passed blood in her urine and had had severe pain for a number of months. It was thought that the blood came from the kidney in all probability. Mackenrodt dilated the urethra and diagnosticated a tumor of the bladder and then inspected the tumor through a cystoscope. It projected from the

[15] Johns Hopkins Hosp. Bull., No. 53.

[16] Zeitschr. f. Geb. u. Gyn., Bd. l, H. 1, 1903.

orifice of the right ureter, the ureteral mucous membrane being continued on to the surface of the tumor.

At the operation, 5 cm. of the ureter together with the right half of the trigonum, were removed with the papilloma and the ureter implanted in the bladder. The patient made an uninterrupted recovery.

Eight days after this operation, Mackenrodt had the good fortune to see another case of large papilloma of the ureter. The woman was seventy-six years old. He operated on her and fourteen days after operation had obtained a satisfactory result.

In operating on the bladder from the abdominal side, the author advocates making the abdominal incision in the form of a horseshoe, the curve of the horseshoe being at the symphysis and the ascending arms along the borders of the recti muscles. The recti are separated from the symphysis. By this method access to the bladder is very free and manipulations in the pelvis easy. He also advocates a transverse incision into the bladder instead of a longitudinal one, as affording a better veiw of the bladder interior and as causing less injury to the blood vessels.

LATE RESULTS OF VAGINAL HYSTERECTOMY FOR UTERINE CANCER.

N. Flaischten [17] is an ardent advocate of vaginal extirpation of the cancerous uterus, affirming with Winter that early operation is preferable to, and accomplishes more, than extensive operation. He emphasizes the necessity of early recognition of the disease and prefers the vaginal to the abdominal route. He reports cases operated on by himself and by Ruge in which the patients have remained well from seven to eighteen years. Of the 17 women who were permanently cured, 12 remained well over ten years and 9 more than thirteen years. Nine of the patients had cancer of the cervix, 6 cancer of the uterine body and in 2 the cervix and endometrium were both involved.

TYPHOID SUPPURATION IN OVARIAN CYSTS.

P. V. Zantchenko [18] refers to three cases on record in which an ovarian cyst suppurated and the typhoid bacillus was found in the pus, accompanied by a diplococcus in one instance. The cysts were all of dermoid origin, but in a case he has personally observed pure cultures of the typhoid bacillus were cultivated from a pseudomucinous cyst — the only case of the kind of which he has knowledge.

THE SO-CALLED FUNDAMENTAL NERVE PLEXUS OF THE UTERUS.

S. Pissemski [19] having studied preparations of the uteri of cats, bitches, guinea-pigs, pregnant and non-pregnant women, children and infants, comes to the following conclusions: (1) In women and the animals examined the cervical ganglion as described by J. Walter, R. Lee and Frankenhauser does not exist. (2) At each side of the cervix, in the region where the cervical ganglion has been described as situated, is a network of nerves with a number of scattered ganglia. (3) This plexus is derived from branches of the second, third and fourth pairs of sacral nerves of the cerebrospinal system and receives nerves from the hypogastric plexus of the sympathetic. (4) At the junction points of these nerve fibers and along their course are numerous ganglionic collections of nerve cells, many of these ganglia being macroscopic, others to be discovered only with the microscope. (5) These ganglia and nerves form the sympathetic plexus of the pelvis. They may be described as uterine, vesical, vaginal and rectal. (6) The character of the plexus and the macroscopic size of the ganglia is the same in gravid as in non-pregnant women. (7) This plexus may be designated the fundamental nerve plexus of the uterus.

STREPTOCOCCI IN THE NORMAL MALE URETHRA.

Asakura [20] examined the secretions found in the fossa navicularis in 112 apparently healthy men and found the streptococcus pyogenes present in 14 (12.5%). This fact the writer regards as of especial interest to gynecologists, since it proves that streptococci may be introduced into the vagina during the sexual act.

INJECTIONS OF PARAFFIN AT THE NECK OF THE BLADDER IN INCONTINENCE OF URINE.

Hock [21] reports the case of a girl aged twenty-three years, who six years before had had a calculus removed per urethram, with resulting incontinence which resisted all treatment. After two operations for narrowing the urethra, and one in which torsion was performed, her condition was worse than before. A second torsion gave only slight relief. Two injections of paraffin (75 gr. each time) were made at the neck of the bladder, when the incontinence was speedily cured. Three months later the patient again began to have dribbling of urine, and the injections were twice repeated, with permanent relief. The paraffin remained unchanged at the point of injection.

THIRTY-ONE CASES OF DUDLEY'S OPERATION FOR ANTEFLEXION.

R. G. Wadsworth [22] analyzes the results in the cases of Dudley's operation performed at the Free Hospital for Women in the last two years.

The technique followed was the same as that described by Dudley, except that no wedge-shaped pieces were removed from the central portion of the edges of the divided posterior lip of the cervix, and, instead of excising an oval piece from the elongated and flattened anterior lip, as advised by Dudley, the operators did

[22] Bulletin of the Free Hospital for Women, vol. i, No. 3, January, 1904.

an operation which had for its object the lengthening of the anterior vaginal wall, operating as follows: A transverse incision is made in the anterior wall of the vagina, just in front of the anterior fornix, about an inch to an inch and a half in length. The incision is carried down to the areolar tissue between the vagina and bladder, and along this line of cleavage the bladder is separated from the cervix by the finger up to the level of the internal os, and from the vagina on each side sufficiently to avoid danger of wounding the bladder in placing sutures. The incision is closed at right angles to its original direction by a continuous chromicised catgut suture.

Dudley's operation was performed for the relief of dysmenorrhea in 21 cases in which anteflexion was the only discoverable cause of the symptoms. Of these six, or 28.5 %, were entirely relieved five to fourteen months after operation. Thirteen, or 67 %, were partially relieved in from four to twenty months after operation. Two cases, or 9.5 %, received no benefit. Two cases have become pregnant.

Reports of Societies.

BOSTON SOCIETY OF PSYCHIATRY AND NEUROLOGY.

The regular meeting was held Jan. 21, 1904, with the president Dr. G. L. Walton in the chair.

Dr. E. W. Taylor reported a case of

BRAIN TUMOR WITH ASTEREOGNOSIS.

The patient, referred by Dr. Vivian Daniel, was a man of twenty-nine, married, who had been ailing for seven months, dating from an attack of influenza. He was at that time ill in bed and made a poor recovery. He had persistent headache, chiefly frontal, at first unassociated with nausea. Four weeks before seen, on April 18, 1903, he gave up work on account of general weakness. Three weeks previous to his first visit numbness and weakness of the right hand developed. At the time of examination he was somewhat unsteady in walking; his eyesight was not impaired; his appetite and sleep were sufficiently good. He had lost some thirty pounds in weight, twelve in the last three weeks. The right pupil was slightly larger than the left; there was no defect in light reaction, or on accommodation. There was a suspicion merely of optic neuritis. The cranial nerves showed no paralysis; the speech was slightly thick, but there was no mental impairment; the right hand and arm were extremely weak without marked alteration in the reflexes. The sensibility of the hand was normal to painful stimuli and to contact, but showed a complete astereognosis. No object placed in the hand was rightly interpreted. The pulse was 140; respiration was rapid; knee jerks were lively; there was no Babinski. A few days later nausea and vomiting developed, together with spasms of the right hand and arm and increased mental irritability.

Electrical examination showed nothing abnormal. Treatment with iodide was unavailing. The temperature was at this time, and had been for many weeks, elevated several degrees. A later examination showed a marked increase of the symptoms given above, and in view of the fact that physical examination was otherwise negative, operation was decided on in spite of the elevation of temperature because of the evident localization of the new growth, and also because the patient was rapidly failing.

Operation was done May 1, by Dr. F. B. Lund. Several nodules of a hard tumor were easily extracted from the arm area, mainly anterior to the fissure of Rolando. Temperature at the time of operation was 103.5°. The patient made a good recovery from the operation; was relieved completely of his headaches; was without discomfort, excepting for the presence of a right hemiplegia. He died May 28, slight improvement in motility having taken place during the interval. Autopsy, May 28, showed an extremely active miliary tuberculosis, with a primary focus in the prostate. The brain, apart from the tumor, which on microscopic examination proved to be tuberculous, showed only a very slight tubercular basal meningitis. Other organs were thickly studded with miliary tubercles.

The interest of the case centers in the following points: The failure to determine the presence of tuberculosis, although it was suspected; the possibility of successful operation in the presence of considerable elevation of temperature; the localization of the tumor anterior to the fissure of Rolando, but associated with a definite astereognosis bearing out the work of Walton and Paul; and finally the significance of the symptoms as again pointing to the sensory motor character of the Rolandic cortex, as pointed out by Dana and others.

Dr. F. B. Lund described the operation and spoke of the resulting relief of headache.

EPILEPSY WITH PARALYSIS.

Dr. P. C. Knapp showed a man, aged thirty-nine, who five years before had suddenly lost power in the left arm for about ten minutes. Since that time he has had similar attacks at varying intervals, once in five or six weeks, even two or three in an hour. When the attacks occur frequently he does not fully regain use of the arm in the interval. With the attack there is a sensation of numbness, which extends over the shoulder and chest, and sometimes over the face. Once it extended to the leg and the leg muscles were slightly affected. In the attack there is no convulsive movement, no loss of consciousness, no flushing of the face, no change of temperature and no change in the pupils. There has been no headache, vertigo, nausea, vomiting, somnolence, mental disturbance or optic neuritis. The physical examination was absolutely negative, except that after an attack there was di-

minished sensibility to pain, touch, motion and position in the hand. The attacks were somewhat controlled by bromide. The long continuance of the attacks without other symptoms rendered a diagnosis of cerebral tumor or general paralysis improbable. Binswanger has cited cases of epilepsy in which the attack was attended with paralysis instead of convulsion, and that diagnosis seemed probable in this case.

DR. S. G. WEBBER recalled the case of a man who, without loss of consciousness, had sudden loss of power in one arm lasting only half a minute, so that he would drop whatever the hand held, but was immediately able to use the member perfectly. The attacks were deemed epileptic.

SPASMODIC TORTICOLLIS.

DR. W. E. PAUL showed a patient two and a half years after resection of the spinal accessory nerve by Dr. M. H. Richardson, and subsequent prolonged rest, for spasmodic torticollis. The muscles paralyzed by the operation have regained their tone and are under voluntary control. There is only rarely spasmodic twitching of sternocleido, or trapezius. The result seems satisfactory.

DR. J. J. PUTNAM thought that when spasmodic torticollis could be relieved without resort to operation it was preferable.

DR. C. F. FOLSOM reported a case relieved by non-operative treatment.

DR. H. C. BALDWIN referred to the lasting immunity from spasm in a severe case operated upon by Dr. M. H. Richardson several years ago.

TORTICOLLIS IN A MARE.

DR. KNAPP said that he and Dr. Putnam had recently seen a mare who apparently had spasmodic torticollis. The mare was out of a thorough-bred dam by a French bred coach horse and had won various prizes. She first came in season at the age of three, and at times after that, when in season, she would try to bite her tail. She was not nervous, although she was obstinate and would behave badly if not harnessed to her liking. She showed none of the equine stigmata of degeneracy. About a year ago, possibly after exposure, she began to turn her head toward the off side, the spasm recurring several times a day and lasting two or three minutes. She has had as many as nineteen of these spasms in an hour. They are usually worse when she is in season. The spasm can be felt by a person on her back to involve the muscles of the flank and rump, but it does not cause any change in her gait, either the walk, trot or canter. She does move her forward feet a trifle in the spasm to preserve her balance. There is no history of injury, no tender spot and no spot which seems by pressure to influence the spasm. Massage, electricity, ounce doses of Fowler's solution, and large doses of bromide and chloral had no effect. Absolute rest in a box stall had apparently made her worse. Breeding and the freedom of a paddock had been suggested. The spasm seemed to involve chiefly the levator humeri and the sterno-maxillary muscles, the analogues of the levator anguli scapulæ and the sterno-mastoid. The circular nerve of Willis, analogous to the spinal accessory, supplies these muscles in part, and in one place is quite superficial. The nerve is often divided at this point to prevent cribbing, and this operation is now proposed for this condition. The case is apparently unique. None of the veterinary surgeons here or in New York and no stable men have ever seen anything like it. Dexler in his "Nervenkrankheiten des Pferdes" describes a facial tic in the horse and other forms of tic, but nothing like this. Rudler and Chomel [1] describes various forms of tic in the horse, notably the "tic de l'ours" or "weaving," but no reference has been found to any condition such as this mare presents, which closely resembles spasmodic torticollis as observed in man.

DR. G. A. BLUMER, president of the Society for the ensuing year, assumed the chair, and called on DR. C. L. DANA of New York for his paper entitled

THE PARTIAL PASSING OF NEURASTHENIA.

The president, DR. BLUMER, in calling for the discussion of the paper, commented upon the essential unity of nervous and mental diseases. The latter, he said, were merely nervous diseases with greater prominence of the mental symptoms. He welcomed the commoner use of the term "phrenasthenia," which the French had found useful, and approved the essayist's attempt to popularize it as one that described more accurately, in the majority of instances, the symptom-complex which neurologists, as a sweeter morsel for the invalid's tongue, had described under the all-inclusive "neurasthenia," whose partial passing the distinguished visitor from New York had come to Boston to proclaim. He animadverted banteringly, and with an attempt at defence, as himself a recent comer to New England, on the pronunciation of the word "neurasthenia" as current in these parts and nowhere else, the adoption of which by the essayist would entitle him at once, despite his modest protest, to recognition in New England as to the manner born.

DR. J. J. PUTNAM said that he was glad to hear Dr. Dana lay emphasis on the mental element in neurasthenia, since from a practical standpoint, it was, perhaps, the most important element. On the other hand, there seems to be no sufficient reason for making the mental symptoms the turning point in classification. Many patients do not present such symptoms in any considerable degree, if at all, and their symptoms are often relieved to a greater or less extent by treatment and operations calculated to relieve some peripheral irritation. It would be just as reasonable to point out the relationships between neurasthenic conditions and quasi-normal conditions as between neurasthenia and more pronounced forms of mental disease. The

[1] Revue neurologique, xi, 541, June 15, 1903.

latter classification has a certain clinical advantage, but if it came into general use, it would cause unnecessary distress to many patients who were really not so very ill.

DR. G. L. WALTON agreed with the reader regarding the limitation of the diagnosis neurasthenia. In the neurological department of the Massachusetts General Hospital during October, November and December, 1896, this diagnosis was made 43 times, whereas it had been made during the same months of the past year only 11 times, which would have corresponded to about 16 times, if the number of cases had been the same. Most of the cases classed formerly as neurasthenia were now transferred to the "psycho-neuroses." He did not think they had often mistaken dementia precox, or paranoia, for neurasthenia.

DR. P. C. KNAPP believed there were many cases of true neurasthenia or irritable weakness — a condition of pathological fatigue. In uncomplicated cases the mental symptoms are not prominent. Study of a number of cases diagnosticated as neurasthenia showed definite mental symptoms in only a small percentage. A distinction must be made, however, between simple mental depression and true melancholy states. Every sick person is apt to be depressed. This is physiological and should not be classed as melancholia. In only a comparatively small proportion of neurasthenics are there insistent ideas, morbid doubts, morbid fears and other indications of the ideo-obsessive tendency. When a patient becomes weak, however, he begins to distrust his own powers and in this way, especially among the "deviates" and those of an unstable mental organization, morbid doubts and fears may develop. In other cases obsessions may arise in a person who is not neurasthenic, and the struggle against them may so exhaust the patient as to give rise to neurasthenia. We can usually distinguish, however, which is primary. Obsessions sometimes develop into actual delusions, akin to the delusions of paranoiac states; in fact, folie du doute is sometimes spoken of as abortive pananoia. His experience agrees with that of Dr. Walton, that as a rule we do not find any tendency to paranoia, or dementia, among neurasthenics.

DR. J. W. COURTNEY spoke of pathologic fatigue supposed to underlie the neurasthenic state. One is too prone to believe that because over-fatigued honey bees and humming-birds show changes in the nerve cells, analogous changes take place in the human species. Such assumption is unwarranted by clinical experience. In a neurasthenic who can barely crawl from home, yet who walks homeward with buoyant step, the conditions are psychical rather than physical. Whether called phrenasthenia or psychasthenia, it is to a limited extent a mental degradation, a pathologic state of nolition and the simulacrum of various forms of insanity.

DR. WM. MCDONALD regarded true melancholia and true paranoia as rare, the former falling generally under manic depressive, the latter under dementia precox. He coincided with the reader in limiting the use of neurasthenia. The term congenital neurasthenia, though scarcely permissible for the characterization of a special group, has been of some use in differentiating patients with congenital pathological tendencies.

DR. DANA said, in concluding, that cases of neurasthenia allied to or leading up to dementia precox were not very numerous, but their serious character made it very important to recognize them. They were in persons under twenty-five. There were relatively few cases of abortive types of paranoia passing around as neurasthenias; yet they did exist in the early depressed and moody stage. The largest number of cases miscalled neurasthenia, came under the head of phrenasthenia. The group in its well-marked forms was easily recognized as hysteria, doubting mania, morbid fears, obsessions, and so forth. It was the imperfectly developed forms that were unrecognized and which passed as "nervous exhaustion." A great many cases of mild recurrent melancholia or manic depressive insanity, were classed as neurasthenia. The speaker thought this would not occur if a more serious study of the mental state were made. He was inclined to favor the view of Dr. McDonald that paranoia should be classed with paranoid dementia. He would still recognize some cases as real neurasthenia; the others were 'psycho-neuroses," and these could be further distributed mostly as phrenasthenia or depressive psycho-neuroses.

THE AMERICAN SOCIETY OF CLINICAL SURGERY.

A REGULAR meeting of the Society was held in New York on March 18 and 19, under the supervision of the President, DR. GEORGE E. BREWER, assisted by DR. P. R. BOLTON and DR. J. A. BLAKE.

The two days were spent in visiting hospital clinics and laboratories.

At the College of Physicians and Surgeons Dr. F. C. WOOD, by invitation, in the pathological laboratory demonstrated specimens illustrating the pathology of tumors of the parotid; DR. CHURCHILL CARMALT, by invitation, demonstrated specimens showing the development and morphology of the salivary glands; DR. J. A. BLAKE showed his interesting modification of the Murphy button for gastro-enterostomy; DR. J. W. DRAPER MAURY, by invitation, showed a modified method of performing gastro-enterostomy with the McGraw ligature and DR. GEORGE E. BREWER demonstrated his ingenious method of treating wounds of the larger arteries by wrapping them with an elastic adhesive plaster.

In the afternoon, at the Presbyterian Hospital, DR. ELLSWORTH ELIOT, JR., gave an operative clinic and demonstration of cases, showing the x-ray plate of an open safety-pin in the esophagus; a patient operated upon for cancer of the tongue and another patient operated upon six years ago for cancer of the breast without recurrence; also two cases of hepaticptosis operated upon with relief of symptoms, by stitching up the round and falciform ligaments and denuding the liver and diaphragm. Dr. Eliot also operated upon a case of acute appendicitis, before the Society.

The members next assembled in the amphitheatre

of the Roosevelt Hospital where DR. R. F. WEIR, by invitation, showed two cases recently operated upon by hypoglosso-facial anastomosis for facial paralysis; a woman operated upon for hydronephrosis with a history of eleven previous abdominal sections: a case of pharyngeal tumor, a case of stone in the kidney and cases of foreign bodies in the trachea and esophagus. DR. J. A. BLAKE then demonstrated, in a case of bleeding ulcer of the stomach, the use and advantages of his modified Murphy button in an operation for gastro-enterostomy.

On Saturday, March 19, members assembled at 8.30 A.M. at the Hospital for the Ruptured and Crippled where DR. W. B. COLEY, by invitation, demonstrated three operative cases of inguinal hernia. DR. P. R. BOLTON then conducted the members over the Hudson Hospital illustrating "a type of an emergency hospital." After this visit Dr. Bolton operated at the New York Hospital, showing the transverse abdominal incision for pelvic disease. The afternoon was spent in visiting and inspecting, under the guidance of DR. HOWARD LILIENTHAL, the fine new Mount Sinai Hospital.

The Society then adjourned to meet next autumn in Buffalo and Cleveland.

Recent Literature.

Practical Handbook of the Pathology of the Skin. An Introduction to the Histology, Pathology and Bacteriology of the Skin, with Special Reference to Technique. By J. M. H. MACLEOD, M.A., M.D., M.R.C.P. Philadelphia: P. Blakiston's Sons & Company.

In the preface the author states that this handbook is intended primarily for students of dermatology, and is based on demonstrations given by him at Charing Cross Hospital.

Although the agents which affect elements of the skin in disease are described in detail, the book does not profess to be a complete treatise on the pathology of the skin, but rather a practical introduction to it. Most of the illustrations are drawn from his own specimens, a few from preparations lent him for the purpose, and there are several reproductions. The book certainly supplies a want, as the only other work dealing with this subject is Unna's large and much-involved "Histo-Pathology of Diseases of the Skin."

Macleod begins by a chapter on the apparatus necessary for histological technique, and follows with chapters on methods of examination, fixing, hardening, etc. These chapters, as well as those on staining, are exceedingly well written and clearly expressed. Various affections of the skin are then taken up in chapters dealing with the pathology of the epidermis, corium, blood vessels, pigment, etc. There are chapters dealing with bacteria, protozoa, etc. A little more space might advantageously be given to blastomyces and allied subjects. Altogether the book is to be greatly commended. The illustrations are clear and well printed. The paper and type are good, and the work, as a whole, will be gratefully consulted by those interested in dermatology.

Manual of Medicine. By THOMAS KIRKPATRICK MONRO, M.A., M.D., Fellow of and Examiner to the Faculty of Physicians and Surgeons, Glasgow; Physician to Glasgow Royal Infirmary, and Professor of Medicine in St. Mungo's College; formerly Examiner in the University of Glasgow and Pathologist to the Victoria Infirmary. Illustrated. Philadelphia and New York: W. B. Saunders & Co. 1903.

Another work on general medicine is before us, intended primarily for students and what the author is pleased to call junior practitioners. He considers that a manual of this size, which comprises about 900 pages, is needed, on the ground that many books are too small for the needs of the modern student, whereas others are too large. He compromises with a book of goodly size, but still in form and treatment by no means so inclusive as many of the standard works on the practice of medicine have come to be. We are inclined to think that books of this character are useful for the reasons specified by the author. The modern student is required to cover more and more ground in his medical studies without any very great addition to the length of time allowed, and it therefore becomes necessary that practical working textbooks should be of moderate compass, avoiding, however, the charge of superficiality. This, we should judge, Dr. Monro has accomplished in this new book.

It is printed in clear, good-sized type, with conspicuous headings, so that it should prove useful as a book of ready reference. We note that a section on diseases of the skin is included and also one on diseases due to animal parasites. The book is therefore rather more inclusive than many more pretentious volumes, and no doubt will fill the place for which it is designed. We note the almost complete absence of references to literature, a growing custom of textbook writers which in a certain sense is regrettable.

A Treatise on Orthopedic Surgery. By ROYAL WHITMAN, M.D. Second edition. Lea Brothers & Co. 1903.

It is a gratifying evidence of the interest taken in orthopedic surgery that a second edition of this valuable book has appeared so promptly. The work in the new edition has been enlarged and strengthened in many directions. The writer has the gift of clear statement and definite ideas founded on an extensive experience. A detailed, critical analysis of the different views advocated by Dr. Whitman, with an examination of the exact value of those of his ideas which differ from that of other orthopedic surgeons is to be left for the columns of special journals. It is sufficient to state here that the work is of the very highest character and is a standard of the best work in the specialty.

The book may be strongly recommended to all students and general practitioners who wish instruction in this important branch.

Lessons on Massage. By MARGARET D. PALMER, Masseuse and Manager of the Massage Department of the London Hospital, Instructor of Massage to the Nursing Staff of the London Hospital, Member of the Council of the Incorporated Society of Trained Masseuses. Second edition. Illustrated. New York: William Wood & Co. 1904.

We reviewed this book with commendation in its first edition. This second edition is slightly extended in scope. A brief chapter on the Nauheim treatment is appended and also one on bandaging. The book is, as was its predecessor, amply illustrated, and contains many facts with which those interested in massage should be acquainted. A lack of knowledge of human anatomy is a defect in many of those who give this type of treatment. This book should tend to overcome this deficiency.

A Manual of the Practice of Medicine. Prepared especially for Students. By A. A. STEVENS, A.M., M.D., Professor of Pathology in the Woman's Medical College of Pennsylvania; Lecturer on Physical Diagnosis in the University of Pennsylvania, etc. Sixth edition, revised and enlarged. Illustrated. Philadelphia, New York and London: W. B. Saunders & Co. 1903.

A sixth edition of this concise book on the practice of medicine attests its popularity and usefulness. We are pleased to see the distinct statement on the title page that the book is prepared for "students" without mention of the usual "practitioner." Evidently books of this description are essentially useful to somewhat elementary students, and if any distinction at all is desirable, we are glad to see it drawn as Dr. Stevens has seen fit to do. A complete revision has been made in this edition, the section on diseases of the digestive system entirely rewritten, as well as many other individual articles. The book, as heretofore, is very attractively bound in flexible leather covers, is capable of fitting into a good-sized pocket, is comprised in 556 pages and is altogether a vast improvement over the ordinary quiz-compend, and deserves general recognition.

An Atlas of Human Anatomy. For Students and Physicians. By CARL TOLDT, M.D., assisted by ALOIS DALLA ROSA, M.D. Translated from the third German edition and adapted to English and American and International Terminology by M. EDEN PAUL, M.D. (Brux.), M.R.C.S., L.R.C.P. Second Section, C, Arthrology. Third Section, D, Myology. New York: Rebman Company. 1903 and 1904.

Part II of this atlas, to which we have already alluded in some detail, concerns itself with the subject of arthrology. The same general plan is adhered to in this volume as in its very successful predecessor, and we have only words of commendation for the cuts, the accompanying descriptions and the generally systematic arrangement of the subject matter. The atlas idea is evidently kept distinctly in mind and is altogether to be commended since there is a certain tendency to advertise as atlases volumes which on examination bear but slight resemblance to our idea of that type of publication. Colors are sparingly used in this as in the preceding plates, but quite sufficient to make clear the different anatomical structures.

Part III is devoted to myology. The cuts, as in the preceding sections are very numerous, and executed in such a way as to express clearly the fundamental anatomical features. Muscles are, for the sake of contrast, colored an attractive brown, which serves to render clearer their finer relations. As a supplement to the general myology the inguinal and femoral canals are pictured with descriptive text and the customary use of red and blue to indicate arteries and veins.

Full indices are appended to each of these volumes, and every effort has clearly been made to render the books diagrammatic without being untrue to the facts, and convenient for purposes of quick reference. We can only repeat our commendation expressed in our notice of the first volume. We shall await the appearance of the three succeeding sections with much interest.

Manual of Practical Anatomy. By D. J. CUNNINGHAM, M.D. (Edin. et Dubl.), D.Sc., LL.D., D.C.L. (Oxon.), F.R.S. Two volumes. Third edition. Illustrated. Philadelphia: J. B. Lippincott Company. 1903.

This "Manual of Practical Anatomy" has reached its third edition with certain alterations of detail. Some of the material, which experience has proved unessential for a work of this sort, has been omitted. The descriptive matter has been rendered more concise, and the book has not grown in bulk in spite of general revision of the text. The chief changes have been made in those portions of the book which treat of thoracic and abdominal viscera. This has been rendered possible and desirable by improved methods of hardening fresh material, so that many errors have been corrected regarding the relationships of the viscera. The illustrations also have been modified and improved. In this edition they are certainly admirable. Colors have been used somewhat sparingly, but sufficiently to bring out important points. Particularly commendable are the excellent drawings of the nervous system. Although not very numerous, we have rarely seen better reproductions of sections through the oblongata and pons. The subject matter is arranged by regions rather than in the ordinary didactic fashion of the conventional textbook, and should, therefore, be of service, as is the intention of the author, to men engaged in the practical applications of anatomical knowledge. The volumes are small, attractively bound, and excellently printed. Particularly to be commended is this convenience in size, a striking contrast to the ponderousness of the ordinary work on anatomy.

The After-Treatment of Operations. A Manual for Practitioners and House Surgeons. By P. LOCKHART MUMMERY, F.R.C.S. (Eng.), B.A., M.B., B.C. (Cantab.). Demonstrator of Operative, Surgery, St. George's Hospital Late Senior House Surgeon, St. George's Hospital. New York: William Wood & Co. 1903.

This book is a small volume of 218 pages, compact and fairly well done. The author has evidently had a very considerable experience in the after-treatment of operations. The directions given are very simple and direct, but the minute details of the treatment are not given. In a future edition, which we feel confident will be called for, we believe that the author should add more details. An exception to this absence of detail is in the treatment of shock, which is given very fully. The after-treatment of laparatomy is considered at length. Operations in the various regions are touched upon. The appendix contains details on the different methods of feeding, diets, massage, exercises, artificial appliances, including limbs and belts and antistreptococcic serum injections. The cuts somewhat crude and the printing is only fair. There can be but little doubt that the treatment of the critically ill patient is a subject of vital importance.

The Practical Medicine Series of Year Books. Comprising ten volumes on the Year's Progress in Medicine and Surgery. Issued monthly, under the General Editorial Charge of GUSTAVUS P. HEAD, M.D. Vol. VI. General Medicine. Edited by FRANK BILLINGS, M.S., M.D., and J. H. SALISBURY, M.D., May, 1903. Chicago: The Year Book Publishers. Vol. X. Skin and Venereal Diseases, Nervous and Mental Diseases. Edited by W. L. BAUM, M.D., and HUGH T. PATRICK, M.D. Illustrated. September, 1903. Vol. III. The Eye, Ear, Nose and Throat. Edited by CASEY A. WOOD, C.M., M.D., D.C.L., ALBERT H. ANDREWS, M.D., and AUGUSTUS P. HEAD, M.D. Illustrated. December, 1903.

Volume VI of the "Practical Medicine Series of Year Books" on general medicine, under the editorship of Drs. Frank Billings and J. H. Salisbury, contains the usual concise review of important articles in this field during the past year. Attention should be called to the fact that this series of books is published primarily for the benefit of the general practitioner, hence the arrangement in separate volumes. The more specialized fields of medicine are, however, not neglected.

Another volume of the series on the skin, venereal, nervous and mental diseases for September, 1903, is also before us. This volume requires no special note beyond the general statement that the standing of the authors leaves no question of the correctness and value of the abstracts of current progress in their several fields.

Volume III on the eye, ear, nose and throat, bearing the date of December, 1903, discusses the progress made in these special branches.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 31, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE VISIT OF PROF. PAUL EHRLICH.

IT is no longer an unusual experience to be visited by distinguished men of science from Europe. We have in mind, for example, the very recent visits of Professor Foster, Professor Ewald and Professor Lorenz. This fact, however, should not abate our interest in the sojourn of Prof. Paul Ehrlich in this country. Professor Ehrlich occupies a wholly unique position in the medical world at the present time. It is to him more than to any other one man that we look for discoveries of moment in the now vital questions of immunity and serum therapy. These studies on immunity in the broad sense are in a way comparable to the discovery of the circulation of the blood, the cellular basis of pathology and the pioneer work of Pasteur in bacteriology. To prosecute this new research with success requires a peculiarly broadly trained mind and one in which the element of originality and the power of generalization are conspicuous. These attributes Professor Ehrlich possesses in unusual degree.

The immediate occasion of this visit to America is the delivery of the Herter lectures for the year at the Johns Hopkins University. It will be remembered that this lectureship was founded by Dr. Herter of New York for the purpose of bringing into closer touch medical scientists in this country and in Europe. A more opportune choice for this year's lectureship could hardly have been made, and, although Professor Ehrlich does not speak English, we can have no doubt that his remarks will be listened to by an attentive and appreciative audience. The University

of Chicago has already honored him by the degree of LL.D., and this week he is to be the guest of the American Association of Pathologists and Bacteriologists at its annual meeting in New York. It is hoped and expected that he will visit Boston in the course of his travels, although so far as we have learned there has been no arrangement for a formal address on his part.

In this connection it may be well to allude to the peculiarly favorable conditions under which Professor Ehrlich has been able to carry out his researches. In 1896 he was appointed director of the Institute of Serum Therapy in Frankfort-on-the-Main, a laboratory maintained by the German government. At this laboratory, with an adequate staff of assistants, untrammelled by the details of teaching and wholly independent of outside conditions, he is enabled to prosecute without restriction his chosen subject. The only limitation to the work is that it shall be directed toward the serum treatment of bacterial diseases.

This somewhat unique position, unfortunately, finds few parallels in other countries. Naturally a man of science, who willingly gives up the best and most active years of his life to the elucidation of an abstract subject, should be free from the cares and responsibilities which the necessity of procuring a livelihood demands. In spite of liberal provisions now made for research through the munificence of Mr. Carnegie and Mr. Rockefeller in this country, there is still apparently lacking that assurance of permanency which must be had if the best results are to be attained. Very recently the New York legislature has cut out the appropriation of $15,000 for the prosecution of cancer research in that state on the ground that nothing as yet has been accomplished. If such action be possible, for the reasons given, it is clear that the services of well equipped men cannot be obtained. The spirit of research is sufficiently active in this country and unquestionably the means to support it are equally abundant, but it is absolutely necessary that these resources be distributed in such a way that the greatest possible independence of investigation for long periods of time, regardless of immediate results, may be attained. It is perfectly clear that the questions now confronting scientific men in medicine are not such as may be answered in one or perhaps ten years, but that long periods of research, possibly discouraging alike to investigator and to the public, must be expected before final results of importance may be reached. The means of supporting such investigations should be wholly irrespective of results and until this is in some way attained, we may hardly expect to accomplish what our colleagues in Germany are doing. If Professor Ehrlich's visit, with its other advantages to us, may also result in directing the attention of our public spirited men toward the best way of encouraging and maintaining research, it will have accomplished a most beneficent end.

CATHETERIZATION OF THE URETER.

The danger attending indiscriminate catheterization of the ureter in women as practiced in the clinics at the present time is forcibly presented to us in a recent article on urinary tuberculosis by Hunner.[1] He shows that given bacteria in the bladder, as in the case of urinary tuberculosis, and the trauma which of necessity attends the passage of a ureteral catheter, be the catheter ever so deftly introduced, we have present two important factors in the causation of infection of the ureter and kidney. Furthermore in bladder tuberculosis in a cachectic patient it has been determined that when the woman is placed in the knee chest posture and air is admitted to the bladder through a cystoscope the ureteral orifices are apt to gape on the sound as well as the diseased side, and thus permit the entrance of air together with bladder contents into the ureters.

Bearing on this point are to be considered the researches of the resident gynecologist of the Johns Hopkins Hospital.[2] He instituted a series of experiments on animals and a cystoscopic study of the ureteral orifices in women, because it had been found that implantation of the ureter in the bladder after resection of the ureter in cases of advanced uterine cancer, was almost invariably followed by infection of the kidney belonging to the implanted ureter. According to these experiments renal infection is most often produced by the passage of microorganisms from the bladder up to the lumen of the ureter, and this passage of bacteria takes place under ordinary conditions only when there is present some injury to the vesical end of the ureter thereby preventing the valve-like portion of the vesical wall at this situation from maintaining the ureteral canal in a state of closure.

If, as would appear to be the case, urinary tuberculosis is almost invariably primary in the kidney, and in its early stages, at least, con-

[1] Johns Hopkins Hospital Bulletin, January, 1904.
[2] Ibid. No. 153.

fined to one kidney, the physician should be able to make a diagnosis without catheterizing the ureters. A history of pain in the back, side or inguinal region, together with a disturbance of bladder function, having led to a suspicion of some kidney disease, physical examination shows the kidney usually palpable and tender, and palpation over the course of the ureter as it crosses the brim of the pelvis elicits tenderness and a desire to void urine. Through the vagina the thickened bladder or the tender utero-vesical region is palpated, and the thickened ureter can nearly always be felt at its vesical junction just anterior to the cervix, and through the rectum it may be felt coursing outward and backward. A systematic search for tubercle bacilli in the urine, examining one or two slides a day for a week instead of many slides from one specimen as so often done, will verify the diagnosis.

If cystoscopy is resorted to it should be done with the patient in the elevated dorsal position. It is not necessary to catheterize the ureter on the supposedly sound side. Urine enough for microscopic examination and for an estimation of urea may be obtained from this side by inserting a ureteral catheter in the ureter of the diseased side and while it is in place washing out the bladder and then collecting the bladder urine. Suitable allowance can be made for the contamination from the bladder.

The danger which attends infection of a sound ureter and kidney in the case of urinary tuberculosis applies to other diseases in which the bladder is teeming with bacteria, so that too great care cannot be exercised in selecting cases for ureteral catheterization.

THE ETIOLOGY OF SPINA BIFIDA.

WHEN one considers the embryology of the spine and cord, it is easy to explain how a primary lesion of the former may mechanically act on the development of the rachis, alter its make-up and prevent the union of the vetrebral plaques. In some instances the medullary lesion, no matter what it may be, must appear at a very early embryonal period, because it existed when the cord was in the state of a sulcus and prevented the closure of this sulcus; such is the case, for example, in myelo-meningocele produced by an external hydrorachis.

If the causal lesion has acted at a later date, when the medullary sulcus has closed, one may admit that hydrops of the central canal of the cord has played the same part as an exostosis, or a foreign body, and from its size has opposed the union of the vertebral arches. It would appear that, in such cases, it is useless to search the why of the arrest of development of the osseous canal, the reason for the rachischisis, of spina bifida, properly speaking. The reason resides in the fact that hydrorachis exists, and it is only the cause of the hydrorachis that should be ascertained.

Beyond any doubt the cause producing the arrest of development of the neural sulcus may act likewise on the vertebral plaques, and this is so evident that, if in all cases of hydrorachis there is spina bifida, in all the instances of the latter affection there is not necessarily a hydrorachis. Let us explain. One sometimes meets with cases of spina bifida without tumor, the so-called spina bifida occulta, and this latter type appears to us to show the independent relationship of rachischisis and hydrorachis, and also the reality of this fact, namely, that a vertebral fissure is not enough to produce an hydrops of the cord or of its envelopes.

If in cases of spina bifida occulta, lesions are present which indicate a lesion of the cord, we are of the opinion that the medullary lesions are independent of the spina bifida, or, at any rate, are of earlier origin than those which are the cause of the rachischisis. Whatever the truth may be, the important point to retain is that spina bifida arises either from an arrest of development or from an hydrops of the cord or its envelopes.

The etiology of the affection is surrounded with mystery, and textbooks consider it unexplained. The pathogenesis of spina bifida has been little studied, but among the probable causes admitted, we would mention first Cruveilhier's opinion, according to which the inocclusion of the vertebral canal results from adhesions contracted by the fetus with the membranes of the ovum. Dareste believes that the inocclusion is consecutive to compression exercised on the dorsal aspect of the embryo by an abnormally narrow caudal fold of the amnios. On the other hand, Houel, Sulzer, Pilliet and Recklinghausen believe the inocclusion to be due to a mechanical cause, such as an exostosis, a pedunculated neoplasm of the ependymis, or a fibro-myo-lipoma, while Lebedeff considers the causal factor to be an exaggerated curve of the rachis.

None of these interpretations is quite satisfactory, and none explains the frequent coexistence of this anomaly with other various malformations, such as hare lip, club foot, etc.;

and still more they do not explain the intimate relationship which appears to exist between hydrorachis and hydrocephalus.

In 1883 Lannelongue offered the opinion that arrests in development might be due to a *virulent condition of the generators*, and in order to give weight to this hypothesis, he recorded four cases in which he considered that syphilis could be legitimately held responsible for the origin of spina bifida. Fournier also upheld the same doctrine, based on a number of personal observations.

It is far from our thought to uphold that in all cases of this affection syphilis is the causal agent, but we cannot refrain from believing that no other etiology is so fit to explain both the arrest in development and the medullary hydrops. Then again, among all the infections which might be incriminated as the primary origin of this malformation, there is hardly any which can be more legitimately suspected than syphilis, and, in point of fact, of all the infectious causes, is there one more intense or virulent in its effects than syphilis? Is there one that attacks the embryo more profoundly or at an earlier period of its development, or which better realizes the ensemble of lesions which so frequently accompany this developmental anomaly?

So many cases of spina bifida have been recorded in which syphilis in the parents has been found, that it is incumbent upon every medical man to study his cases with the view of ascertaining to what extent this potent virus may act in the causation of this congenital defect.

MEDICAL NOTES.

Undrinkable Alcohol. — According to *Science*, the Russian Government has offered a prize of about $25,000 for the discovery of some method to make alcohol undrinkable.

Anniversary Dinner of the Henry Phipps Institute. — The anniversary dinner of the Henry Phipps Institute was given by the staff at the University Club, Philadelphia, on Monday evening, the 28th. The delegates to the convention, which was called to consider the question of forming a national organization for the study of tuberculosis, were all invited as guests of the occasion. Sixty-two persons were present, among whom were many of the most eminent physicians of the United States.

The feature of the evening was the presentation of a silver pitcher to Dr. Lawrence F. Flick, the director of the Henry Phipps Institute, by the members of the staff as a token of their esteem. Mr. Henry Phipps, the founder of the Institute, was present and made the presentation in the name of the staff.

Among those who spoke after dinner were Dr. Abraham Jacobi of New York, Dr. William H. Welch of Johns Hopkins University, Dr. Vincent Y. Bowditch of Boston, Dr. John H. Prior, Dr. Charles L. Minor of Asheville, N. C., Dr. George M. Sternberg, former surgeon general of the army; Dr. John B. Huber of New York; Dr. Leonard Pearson, State Veterinarian of Pennsylvania; Dr. S. A. Knopf of New York; Dr. Ward of Albany, N. Y.; Dr. Henry B. Holton of Brattleboro, Vt.; Dr. John Musser and Dr. James Tyson of University of Pennsylvania and Dr. J. C. Wilson of Jefferson Medical College.

Dr. L. F. Flick acted as toastmaster and chairman and Dr. M. P. Ravenel spoke for the staff of the Henry Phipps Institute.

The Herter Lectures. — The first course of lectures on the Herter foundation will be delivered by Professor Paul Ehrlich, M.D., LL.D., director of the Royal Prussian Institute of Experimental Therapeutics, Frankfort-on-the-Main, Tuesday, Wednesday and Thursday, April 12, 13 and 14, 1904, at 4.30 P.M., in McCoy Hall, The Johns Hopkins University, Medical Department.

The lectures will be in the German language upon subjects relating to immunity. The special topics will be: (1) "The Mutual Relations between Toxine and Antitoxin;" (2) "Physical Chemistry versus Biology in the Doctrines of Immunity;" (3) "Cytotoxines and Cytotoxic Immunity."

Resignation of Sir Lauder Brunton. — It is announced that Sir Lauder Brunton has resigned his position at St. Bartholomew's Hospital, and has been appointed honorary consulting physician and a governor. He has been connected with the institution for thirty-three years in various capacities, but only nine years as full physician. Commenting on this resignation, the *British Medical Journal* makes the following remarks:

Recognizing that there are many young men at the hospital who are in the same position as he was fifteen years ago, and who would willingly devote a large proportion both of energy and time to hospital work and teaching and being conscious that for the last five or six years the claims of practice have tempted him to diminish the time spent in the hospital, he has taken the step now announced. Sir Lauder Brunton has expressed to us the opinion that the system of age

tenure as applied to the medical staff of St. Bartholomew's Hospital is bad, and nearly though not quite as bad as that of life tenure against which Abernethy inveighed after having been twenty-eight years assistant surgeon. We learn that before he was appointed full physician Sir Lauder Brunton suggested that the tenure of office should be altered to a time tenure of ten or twelve years as assistant, and ten or twelve years as full physician or surgeon, but this suggestion has not hitherto been adopted. We believe that but for accidental vacancies caused by the appointment of Dr. Southey to be a commissioner of lunacy, and by the creation of the appointment of a fifth physician to the hospital Sir Lauder Brunton would only have become full physician about six months ago; this is a *reductio ad absurdum*.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon March 30, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 43, scarlatina 29, typhoid fever 8, measles 195, smallpox 0.

DR. D. H. CRAIG HONORED. — At its meeting on March 23, 1904, the Massachusetts Medical Society, Suffolk District, Section for Obstetrics and Diseases of Women, elected Dr. Daniel H. Craig as its President. On March 24, 1904, after presenting a paper for their consideration Dr. Craig was given an Honorary Membership in the New Hampshire Surgical Club at its semi-annual meeting held at Concord, N. H.

NEW YORK.

POISONING BY OXALIC ACID. — Deputy United States Marshal John E. Thorne of Brooklyn was fatally poisoned on March 28 by a dose of oxalic acid which was accidentally administered to him by a member of his family for Rochelle salts.

COMMITMENTS FOR DRUNKENNESS. — In the annual report of the State Commission of Prisons, recently presented at Albany, it is stated that during the past year there were 28,519 commitments to the jails and 3,615 to the penitentiaries for intoxication, making a total of 32,134 commitments for the single offence of drunkenness. The total commitments during the year to the penal institutions of the State, for all offences, were 102,581. Thus it appears that nearly one-third of all commitments were for intoxication. While it may be necessary for the protection of the public that intoxicated persons should be taken into custody and receive treatment at the hands of the state, it is urged that this offence should not be treated strictly as a crime. "Drunkenness," the report continues, "has in it no element of malice — one of the usual and necessary elements of crime. Habitual drunkenness arises largely from mental weakness, and its treatment should partake of the characteristics which the state has deemed wise to use in other cases of mental aberration. There is a large distinction between the man who cannot control his appetite for drink and the man who wilfully and maliciously commits an offence agaist the person or property of another. The law should recognize this distinction. The present practice of sending him to jail or to a penitentiary, branded as a criminal, to cónsort with thieves, only depraves and discourages him, and at the same time inflicts punishment and privation upon his family. Some wiser method of dealing with this offence should be ascertained and adopted."

PART-TIME SYSTEM AT PUBLIC SCHOOLS. — By direction of the Board of Superintendents of the Department of Education, City Superintendent Maxwell has instructed the district superintendents to place the part-time system devised by Dr. William Ettinger, principal of public school No. 147, on trial generally throughout the city. It is stated that this system, which has been in use experimentally at a number of schools for several months past, will probably be adopted formally by the Board of Education in time for the autumn term for all schools where there are part-time classes, if it continues to meet with success. The system requires the two classes, which use one class room, to attend school twice a day. Class A occupies the room from 8.30 to 10.30 in the morning, plays quiet games under the direction of a teacher from 10.30 to 11.30, goes home for lunch between 11.30 and 12.30, and takes its second period in the class room from 12.30 to 2.15 P.M. Class B goes into the class room at 10.30 and remains till 12.30, when it goes to lunch. At 1.30 it returns, and, after playing games until 2.15 it re-enters the class room and remains until 4 o'clock. While it is at present to be employed only in schools where the excess of pupils has rendered the part-time plan necessary, the Ettinger system is believed to be actually more scientific for a considerable proportion of school children than the full-time system. The best pedagogical authorities are of the opinion that the smaller children should have shorter periods in the class rooms and longer recesses than are now provided in the regular courses.

Obituary.

AMBROISE A. LIEBAULT, M.D.

The death of Dr. Ambroise A. Liébault of Nancy, France, whose name is associated with the modern use of hypnotic suggestion as a therapeutic agent, is announced. He studied medicine in Strassburg, taking his doctor's degree in 1850. Soon after entering upon practice, he began the study of hypnotic suggestion and settled in Nancy, opening there a clinic for the treatment of the poor by suggestion. His reputation and experience rapidly grew, and, although for years he was looked upon as an imposter by the more conservative, his principles were later generally accepted and the Nancy School of Psychotherapy was established, with the co-operation of Bernheim, Beaunis and Liégeois. His work antedated Charcot's in the same field. During recent years, although differing widely from his more distinguished contemporary in the theory of hypnotism, he had a wide following, and undoubtedly has had a definite influence for good in the establishment of treatment by suggestion. He was honorary president of the first and second congresses of hypnotism and died finally at the ripe age of eighty years, having convinced the world of his absolute honesty of purpose and sincerity.

Miscellany.

DEATHS UNDER ANESTHETICS.

Commenting on a recent death from chloroform anesthesia, the *Medical Press* draws the following conclusions, which we imagine will not receive unqualified assent in this country:

Last week a tragic death took place under chloroform at the West London Hospital. The victim of the unfortunate accident was a kitchen maid, who died after the administration of one drachm of chloroform. As commonly happens, the amount of the anesthetic was small, so that the cause of death must be sought in other directions, such as shock and mental depression and fright. The theory that the danger of chloroform depends on the dose and the subsequent devices to measure and regulate the amount will be found to be advocated mainly by anesthetists and others who are interested in pushing some particular inhalation apparatus. A certain percentage of deaths must occur, at any rate in our present state of knowledge, whatever drug be used to procure general anesthesia. Chloroform is used so much oftener than ether that the absolute number of deaths from its use is naturally far greater. On Feb. 28 a woman died under ether at Blackburn Infirmary, when the main part of a serious operation had been performed. A death from nitrous oxide is reported in the issue for Feb. 20, 1904, of *American Medicine*. In short, the annals of medical science remind us that death may occur under wellnigh if not quite all known general anesthetic agents.

Correspondence.

A NATIONAL SOCIETY FOR THE STUDY OF TUBERCULOSIS.

Baltimore, March 29, 1904.

Mr. Editor: For the purpose of discussing the question relating to organizations for the study of tuberculosis in this country, the following met at the College of Physicians, Philadelphia, on the afternoon of March 28: Howard S. Anders, Philadelphia; J. M. Anders, Philadelphia; William M. Angney, Philadelphia; Henry G. Beyer, U. S. Navy; Herman M. Biggs, New York; Jonathan J. Black, New Castle, Del.; Oliver A. Blumenthal, Syracuse, N. Y.; Vincent Y. Bowditch, Boston; M. J. Brooks, New Canaan, Conn.; Herbert C. Clapp, Boston; J. Solis Cohen, Philadelphia; Solomon Solis Cohen, Philadelphia; W. M. L. Coplin, Philadelphia; Frank A. Craig, Philadelphia; Alex. H. Davisson, Philadelphia; B. H. Detweiler, Williamsport, Pa.; A. H. Doty, New York; J. W. Ellenberger, Harrisburg; W. B. Fetterman, Jr., Philadelphia; Lawrence F. Flick, Philadelphia; F. Forchheimer, Cincinnati; Albert C. Getchell, Worcester, Mass.; William B. Hackenburg, Philadelphia; H. A. Hare, Philadelphia; Charles J. Hatfield, Philadelphia; Henry D. Holton, Brattleboro, Vt.; A. Jacobi, New York; Henry Barton Jacobs, Baltimore; Edward G. Janeway, New York; Herbert M. King, Liberty, N. Y.; S. A. Knopf, New York; Alexander Lambert, New York; H. R. M. Landis, Philadelphia; Charles M. Lewis, Philadelphia; Daniel Lewis, New York; D. J. McCarthy, Philadelphia; James Alex. Miller, New York; Charles H. Miner, Wilkes Barre, Pa.; Charles L. Minor, Asheville, N. C.; J. H. Musser, Philadelphia; Estes Nichols, Augusta, Me.; George W. Norris, Philadelphia; William Osler, Baltimore; Jay Perkins, Providence; W. H. Peters, Providence; C. O. Probst, Columbus, Ohio; John H. Pryor, Ray Brook, N. Y.; Mazyck P. Ravenal, Philadelphia; DeLancey Rochester, Buffalo; Milton J. Rosenau, Washington; J. T. Rothrock, Mont Alto, Pa.; W. B. Stanton, Philadelphia; George M. Sternberg, Washington; Elwell Stockdale, White Haven, Pa.; Arthur K. Stone, Boston; J. Edward Stubbert, New York; J. M. Taylor, Boise, Idaho; James Tyson, Philadelphia; T. Mellor Tyson, Philadelphia; Josephus T. Ullen, Germantown, Pa.; Agnes C. Victor, Boston; Joseph Walsh, Philadelphia; Samuel B. Ward, Albany; William H. Welch, Baltimore; J. M. Willcox, Philadelphia; Francis H. Williams, Boston; J. C. Wilson, Philadelphia.

Prof. William Osler of Baltimore presided and Dr. Henry Barton Jacobs of Baltimore acted as secretary.

After a full discussion participated in by Drs. Daniel Lewis, Minor, Flick, Knopf, Solomon Solis Cohen, James Tyson, Stubbert, Pryor, Holton, Biggs, Rothrock, Jacobi, Janeway, Hare, Sternberg, Welch, Forchheimer, Ravenal, Rochester and Ward, Dr. Lawrence F. Flick of Philadelphia offered the following resolution which was seconded by Dr. Forchheimer and carried unanimously: *Resolved*, "That we here assembled do now organize ourselves into a United States society for the study of tuberculosis." It was then moved by Dr. George M. Sternberg of Washington and seconded by Dr. Hare of Philadelphia "that the Chair appoint a Committee of five to prepare a constitution and by-laws for such a society." This motion was carried unanimously. The Chair appointed Dr. Edward L. Trudeau, Dr. Herman M. Biggs, Dr. Lawrence F. Flick, Dr. William H. Welch and Dr. George M. Sternberg as that Committee.

It was farther moved by Dr. Sternberg and carried unanimously "that the Chairman and Secretary of this meeting be *ex-officio* Chairman and Secretary of the Committee." Dr. Ravenal then moved and it was unanimously carried, "that it is the sense of this meeting that the committee call us together for organization at Atlantic City during the week of the meeting of the American Medical Association."

Previous to the meeting an abstract of Professor Maragliano's lecture was read.

The meeting then adjourned.

Henry Barton Jacobs, M.D., *Secretary*.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 19, 1904.

CITIES.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from					
				Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Typhoid fever.

Plymouth . .	11,139	—	—	—	—	—	—	—	

Deaths reported, 4,111; under five years of age, 1,077; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 926; acute lung diseases 935, consumption 495, scarlet fever 44, whooping cough 11, cerebrospinal meningitis 22, smallpox 9, erysipelas 22, puerperal fever 14, measles 64, typhoid fever 53, diarrheal diseases 90, diphtheria and croup 81.

From whooping-cough, New York 5, Chicago 2, Philadelphia 1, Pittsburg 2, Boston 1. From smallpox, New York 1, Philadelphia 7, Pittsburg 1. From cerebrospinal meningitis, New York 16, Baltimore 1, Boston 1, Springfield 1, Brockton 1, Medford 1, Attleborough 1. From erysipelas, New York 13, Chicago 5, Baltimore 1, Boston 1, Cambridge 1, Somerville 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending March 5, the death-rate was 18.6. Deaths reported, 5,436; acute diseases of the respiratory organs (London) 202, whooping cough 176, diphtheria 71, measles 139, smallpox 2, scarlet fever 33.

The death-rate ranged from 8.7 in Handsworth to 29.8 in Norwich; London 17.9, West Ham 17.7, Brighton 18.2, Southampton 17.6, Plymouth 20.1, Bristol 17.6, Birmingham 21.1, Leicester 16.5, Nottingham 20.3, Liverpool 22.3 Bolton 13.4, Manchester 21.3, Salford 17.5, Bradford 18.8 Leeds 22.0, Hull 16.8, Cardiff, 18.9, Rhondda 27.7, Wigan 25.7, Hornsey 10.3, Plymouth 20.1.

METEOROLOGICAL RECORD.

For the week ending March 19, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

DELAYED PUBLICATION. — The strike, among printers and pressmen, is now over. And it is hoped to issue the JOURNAL on time from April 14th.

SOCIETY NOTICE.

AMERICAN NEUROLOGICAL ASSOCIATION. — The American Neurological Association has fixed the time of its meeting at St. Louis for Sept. 15, 16 and 17; and this will be immediately followed by the sessions of the various medical departments of the Congress of Arts and Sciences, beginning Sept. 19.

FRANK R. FRY, M.D., Secretary.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING APRIL 2, 1904.

J. M. EDGAR, surgeon. Detached from the "Wisconsin" and ordered to the "Monadnock," March 30.

J. P. TRAYNOR, assistant surgeon. Detached from the "Frolic" and ordered to the "Albany."

C. M. OMAN, assistant surgeon. Detached from the "Monadnock" and ordered to the "Frolic."

R. O. MARCOUR, assistant surgeon. Detached from the "Dixie" and ordered to duty with the Marine Battalion at Guantanamo, Cuba, March 31.

W. IE. G. HIGH, assistant surgeon. Detached from the "Constellation" and ordered to the Midway Islands for duty with the Marine detachment at that place, sailing from San Francisco, Cal., April 3, via the "Supply."

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED MARCH 31, 1904.

WASDIN, EUGENE, surgeon. Granted leave of absence for one month from April 1, 1904, on account of sickness. March 30, 1904.

ROSENAU, M. J., passed assistant surgeon. Detailed to represent service at meeting of Tuberculosis Committee, College of Physicians, Philadelphia, Pa., March 28. March 26, 1904.

CUMMING, H. S., passed assistant surgeon. Granted leave of absence for ten days from April 5. March 25, 1904.

LAVINDER, C. H., passed assistant surgeon. Granted leave of absence for two days from March 29. March 26, 1904. Granted three days' extension leave of absence from March 31. March 26, 1904.

GRUBBS, S. B., passed assistant surgeon. Granted ten days' extension of leave of absence from March 31. March 28, 1904.

BILLINGS, W. C., passed assistant surgeon. Granted leave of absence for two months and three days from April 30, 1904, with permission to go beyond the sea. March 23, 1904.

RICHARDSON, T. F., assistant surgeon. Detailed to attend conference of State Health Officer and County Health Officers of TEXAS, March 31. March 29, 1904.

AMESSE, J. W., assistant surgeon. Granted leave of absence for two months and fifteen days from May 1. March 26, 1904.

BOGGESS, J. S., assistant surgeon. Granted leave of absence for two days from March 30. March 29, 1904.

Original Articles.

INFECTIOUS ARTHRITIS.[1]

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

THE following paper is presented without apology, however unusual it may be for an orthopedic surgeon to write upon a subject belonging so largely to the realm of general medicine, since it is only by the most exact knowledge of the various aspects of such diseases that the treatment of the disabled joints which result from them can be intelligently carried out. It was in this spirit that the work was originally undertaken, and it is my hope that the results may be of as distinct service to others in the treatment of the acute disease as they have been to me in the treatment of the results of the disease. It is my hope at the same time that the confusion which exists in regard to the various non-tubercular joint diseases may be somewhat less as the result of this communication.

The term here used may not be above criticism, but it is simple and represents a reasonable mode of approach to this large class of disease which includes many of the cases of "rheumatism" and many of the other conditions which have been variously classified. Subdivisions under the term will undoubtedly follow, based upon the organism which may be present in a given case, or upon the results of the presence of that organism, but as the principles underlying all these conditions are the same it is thought wise to consider the whole subject in this form, allowing the individual observer to make the special application. For the opportunity to study the acute cases, especially the so-called acute rheumatism, I am indebted largely to the medical staff of the Massachusetts General Hospital, all of the members of which have been most kind and helpful in the work.

The term infectious arthritis is used to designate a joint disease resulting from the presence within the body of some infectious organism, the symptoms being due either to the presence of the organism itself within the joint or to some toxine produced by that organism in some other part of the body. The condition is rarely primary, but usually appears as a sequela of some other disease, representing in all probability the extension of an infection. The primary disease may be mild and attract but little attention, so that in a large number of cases, especially the so-called acute rheumatisms, the few symptoms of the primary disease are often considered to be prodromata of the joint lesion. Upon careful inquiry it will be found that in the majority of cases definite symptoms did precede the trouble in the joint and that these are too varied both in character and location to be fairly considered prodromata, especially as with the majority of persons having similar symptoms no joint disease develops. It seems more reasonable therefore to consider the joint condition as a sequela of the original disease rather than that the joint disease itself is an entity. This is exactly the position that is held in regard to much of the disease of the middle ear or the mastoid cells, and as with these and other analogous conditions the same thing is true with this type of joint lesion, that the secondary is frequently more serious and annoying than the primary disease.

Infectious arthritis may result from practically any of the infectious or pus producing organisms and the type of the lesion or its character will naturally depend upon the special organism involved. The disease may be mild and of short duration with complete recovery, or it may be very severe with much suffering and at times fatal termination. One joint may be affected, and if so the disease in this joint may be very slight or may go on to considerable destruction of the articulation; on the other hand, many of the joints may be involved, — at times all of the joints in the body, — and, as when the single joint is affected, there may be severe permanent changes or the disease may soon be over, leaving little to show for its presence.

In this type of disease the onset is usually abrupt, at times symptoms of great acuteness resulting within a few hours. At other times the process is more insidious and gradual, some weeks being required for its development. It is, however, characteristic of this general class of disease, whether mild or severe, of abrupt onset or gradual development, that all of the joints that are to be affected become affected at practically the same time. With those organisms which have but a short period of active life the joints which are to be affected become so at once and there is no farther extension to the other joints. With some of the other organisms, such as the gonococcus, which may live in the various tissues for many weeks, while the beginning of the joint disease may be abrupt, other joints may develop symptoms later at any portion of the time during which the organism is active, but even under these conditions, the progression is confined to a few months at most, and is in marked contrast to the type of disease described under the head of "atrophic or rheumatoid arthritis," in which, although many or all of the joints may be involved, the extension of the disease is very gradual, joint after joint breaking down at long intervals, so that the complete extension of the disease is not reached until many years have elapsed.

With infectious arthritis the symptoms depend upon the severity of the infection; if it be mild there may be little if any temperature, the pulse but slightly accelerated, the glandular enlargement not marked, with only a serous effusion into one or more of the joints which subsides in a few days, with or without treatment, leaving no permanent impairment. If the infection is more profound the temperature is more elevated, the pulse is much accelerated, the blood count shows a definite increase of the leucocytes, the lymphatic glands are enlarged

[1] At about the time this paper was completed a paper by Dr. T. J. Harrington appeared in this JOURNAL Jan. 28, 1904, emphasizing some of the features here described. In spite of the danger of repetition the paper is still published, as too much attention cannot be attracted to this subject at the present time.

throughout the body and there is marked effusion into the affected joints which frequently goes on to the infiltration of the membranes and ligaments about the joint.

In the exposed joints, especially in the fingers, the swelling produces a distinct spindle shape, and at first glance may be mistaken for the spindle joint of the atrophic or "rheumatoid" arthritis. At first the swelling is simply a distension of the synovial sac, but unless this is absorbed within a few days the membranes and periarticular structures become infiltrated and the swelling persists, but not from fluid within the joint, but from the swelling of the membranes and the soft structures about the joint. In the healing or organization which follows such a condition, the membranes if left to themselves usually adhere so that the joint motion is restricted either wholly or in part.

The joint lesion in infectious arthritis is, in the majority of cases, of the nature of a toxemia. The organisms are not found in the joint, but the marked hyperemia of the membranes, the rapid increase in the joint fluid, with the general aspect of the case in its onset, clinical course, and its behavior under treatment, all suggest the result of an infection.

At times the organism itself may be present within the joint, and whenever this is the case the symptoms are much more severe, and not infrequently marked destructive changes result. Here, as with practically all of the other features, the extent of the destruction depends upon the organism present. Occasionally, in a given case many of the joints may show the changes, suggesting a toxemia, while in some one or two joints the organism itself may be present producing in those joints the more serious destructive changes, while the other joints in which the symptoms were those of a toxemia recover with less, or entirely without, impairment of the joint function.

The origin of the infection or the point from which the absorption has taken place, is, of course, of considerable importance and at times can be definitely determined and the organism isolated. At other times this is not possible, but it is not, however, unreasonable to consider such cases as infectious, since the pathological appearance of the joints is in keeping with this theory, as well as the entire clinical aspect together with the fact that the cases are in every way similar to those in which the nature of the infection can be definitely proven. The same reasoning is used in many of the ordinary infectious diseases in which the nature of the infection has not as yet been demonstrated.

It is, it seems to me, only in this way that many of the cases can be understood, and when such a theory is once accepted, it serves to connect and to make comprehensible the various opinions which have at times been advanced in connection with rheumatism or the rheumatoid diseases. It explains at once the reports of the finding of organisms in the joints of certain cases of rheumatism, as certain cases of infectious arthritis undoubtedly have organisms in the joint, but as in only a few of the cases is the infection severe enough for them to be present it is easy to understand why the organism is found so infrequently and why in many cases even those who have urged the germ theory most strongly are unable to detect them. It also makes comprehensible the fact that the organisms which have recently been reported by two or three groups of men are distinctly different in their characteristics. It explains the fact that some of the cases of rheumatism are mild and some are severe; that some of the mild cases are of short duration while others last for a much longer period; that some of the severe cases are of much longer duration than others; that some of the cases which are severe may have little elevation of temperature (this being particularly true of the gonococcus infection) while with other cases, really no more severe, the temperature is very high, the so-called "rheumatic fever;" that some of the acute cases become chronic, or do not recover promptly; that with some of the acute cases which become chronic one joint may be troublesome, or the chronic condition may persist in all of the joints; that with some the heart is affected, since the endocardium is not infrequently involved in the general septic processes, but this feature would naturally be expected only when the infection is quite severe. It makes comprehensible, also, the type of disease originally described by Still as simulating rheumatoid arthritis but being more rapid in its onset with glandular enlargement and other evidences of infection and, according to Still, ending fatally, but it also explains why some of the cases of Still's disease are now being reported as going on to complete recovery, the recovery or the general course of the disease depending naturally upon the severity of the infection.

The result of the infection in a given case must necessarily depend upon the organism from which the infectious element is absorbed. If due to the typhoid bacillus, the joint process may consist simply of a toxemia with a slight increase of temperature, with a serous exudate into the joint, and with recovery in a short time leaving no permanent change in the joint function. The same organism may, on the other hand, be present in the joint in pure culture causing severe destructive changes. In the first case, the process, if seen in the spine, would ultimately show nothing abnormal, while in the latter case the evidences of the more serious condition would at once be apparent, with the limitation of the motions and in the extreme cases when there had been bone destruction, a true kyphos.

That which is true of the typhoid bacillus is true also of the other organisms. The pneumococcus, the streptococcus, the staphylococcus, the gonococcus, the influenza bacillus, dysenteric bacillus, etc., may all produce a toxemia with joint changes which would be in keeping with such a condition, or they may be present in a given joint in pure culture, producing more

FIG. 1.— Showing the swollen and distorted fingers of Infectious Arthritis without bone or cartilege change. Case 16.

FIG. 2.— The hand of Fig. 1, showing no atrophy of the joint structures, although all of the joints of the fingers and wrist are stiff. Case 16.

FIG. 3.— Atrophic or Rheumatoid Arthritis, showing the atrophy of both bone and cartilage, with fusion of the carpal bones and actual telescoping at the metacarpo-phalangeal articulations.

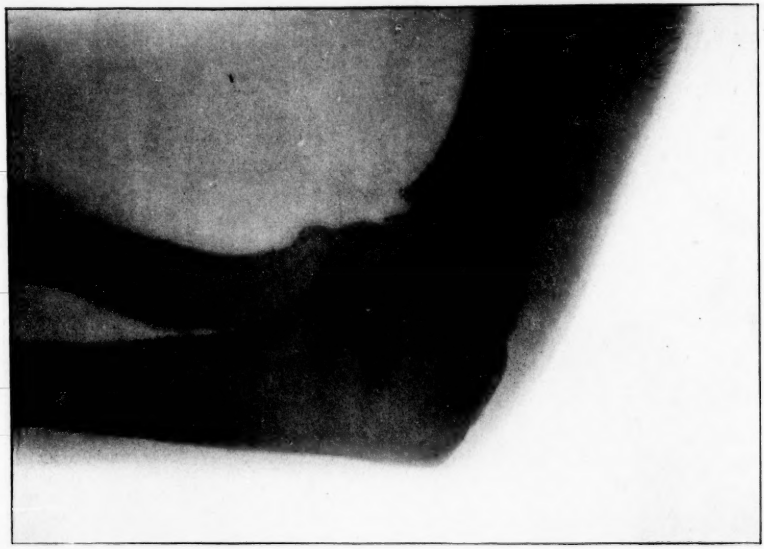

FIG. 4.—Hypertrophic or Osteo arthritis, showing the elongation of both the coranoid and the olecranon processes due to the hypertrophy of the edge of the articular cartilage, without the fusion of the bones. Some motion is present, but is limited by the thickened cartilage.

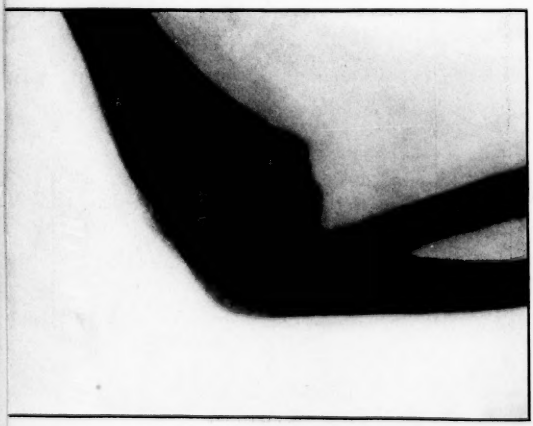

FIG. 5.—The result of Infectious Arthritis with suppuration and bone destruction, showing the character of the bone thickening. The bones are fused together, causing complete anchylosis. Case 7.

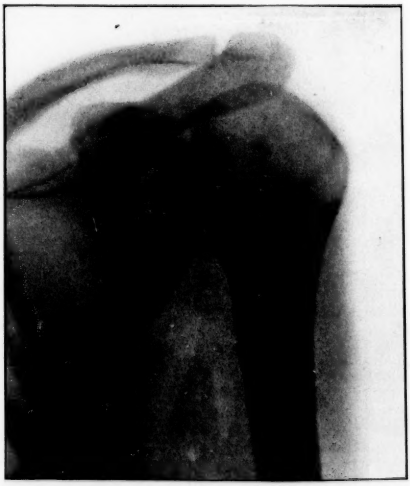

FIG. 6.—Infectious Arthritis without suppuration, but with a perfectly stiff shoulder due to the infiltration of the capsule and the consequent obliteration of the joint. There is no bone or cartilage atrophy or hypertrophy. Case 7.

serious lesions. The pneumococcus and the streptococcus, as is true with the typhoid bacillus, may cause marked destructive changes of the bones as well as of the soft parts. The gonococcus, on the other hand, rarely leads to bone changes, but is associated with much thickening of the capsule and interference with joint function. It is possible that a similar condition may result from the tubercle bacillus, but it seems more probable in the tubercular cases that the joint symptoms suggesting "rheumatism" are due to toxines which result from some of the other organisms which are almost always present with the tubercle bacillus (the so-called mixed infection) in the last stage of tuberculosis, the stage when the so-called rheumatic symptoms are most seen. It is also possible, and indeed probable, in the light of recent reports, that organisms have been found or will be found which will explain some of the cases which, up to the present time, have been shown to be undoubtedly infectious, but in which the definite organism could not be found.

The character of the onset with the different organisms varies. With the typhoid bacillus the onset of pain is sudden, but the temperature requires a few days before the maximum is reached, this lasting a few days, after which the decline also is slow, suggesting at once the character of the chart of typhoid fever as it is usually seen. The streptococcus and the pneumococcus usually have a more abrupt onset with the sudden rise of temperature and with a rather rapid fall if the symptoms represent a toxemia, or continuing at the height until drainage is obtained or until the abscess is walled off if the organism is present. With the pneumococcus the joint symptoms may follow the process in the lung or may develop without other signs in the body. With the gonococcus the onset is usually very abrupt, frequently within a few hours, with marked swelling, pain and tenderness, but with only a moderate elevation of temperature. With this organism the condition is rarely grave unless the infection becomes more general (the organism has been found in pure culture in the heart), but means in the severe cases without treatment a long period of suffering with the ultimate loss of function of the joint, due to the changes in the membranes and periarticular structures.

In the differential diagnosis of infectious arthritis from the other types of rheumatoid disease, in case the history, the general appearance of the patient, and the local lesion is not distinct, the x-ray is of the utmost importance. In infectious arthritis the process is a local inflammation; the joint is swollen; the capsule, if the inflammation has lasted for any length of time, is thickened, giving the spindle shaped swellings (Fig. 1) in any exposed joints, with practically no change in the bone or cartilage (Fig. 2) unless the process is of the destructive nature, in which case the mere extent of the destruction would make the recognition of the condition easy.

In atrophic arthritis, with which the condition will be most often confounded, from the very beginning of the disease, atrophy takes place, at first showing in the cartilage between the bones, but ultimately in the bones themselves. (Fig. 3.)

In infectious arthritis, the bones are of normal density; the cartilage is present and of normal thickness (Fig. 6), and although the joints may be ankylosed, the ankylosis is due to the adhesions which have resulted as a part of the inflammation. In atrophic arthritis, the ankylosis, if it takes place, may be due either to adhesions formed from the disintegrated material resulting from the atrophy or there may be actual fusion of the bones together.

In case the infectious arthritis goes on to more destructive changes in the repair there may be new bone formed about the joint and true ankylosis result, but the appearances are entirely different, as shown in the illustrations, from the atrophic or rheumatoid arthritis, and also the hypertrophic or osteo-arthritis with which, because of the marked thickening, the condition in this stage would be most apt to be confounded. In hypertrophic arthritis the thickening is always primarily at the edge of the articular cartilage growing outward from this line as is shown in Fig. 4. The joint motion may be much impaired, but except in the spine and in a few rare instances does complete ankylosis take place. In infectious arthritis the new formation of bone is similar in every way to the new formation of bone which follows a septic periostitis. It is not a thickening of bone at the edge of the cartilage, but thickening of the bone at the point of infection wherever the periosteum is present as is shown in (Fig. 5).

The blood in infectious arthritis in the beginning and during the active stage shows a marked increase of the leucocytes with usually a high percentage of hemoglobin. As the disease progresses and the acute symptoms subside the increase of the leucocytes gradually disappears, and the percentage of hemoglobin becomes less so that in the later stages of the disease a secondary anemia is almost invariably present. In atrophic arthritis the leucocytes are not increased and the secondary anemia does not develop. The extent to which the changes in the blood occur naturally depends upon the severity of the infection, but even in the comparatively mild cases, the increase of the leucocytes is quite marked.

The lymphatic glands in infectious arthritis are almost always somewhat enlarged in the beginning of the process, and this enlargement remains until the toxemia has been overcome, when it gradually and entirely subsides. If any one joint develops symptoms more pronounced than the others or in case suppuration develops, the glands which would be affected by that joint naturally are larger than those in other parts of the body, and at times, in the particularly virulent cases, may go on to suppuration.

The urine of infectious arthritis is not peculiar unless the infectious process be quite profound, in which case the characteristics are

simply those of a septicemia, and what is true of the kidneys is true also of the other organs.

The treatment of infectious arthritis must be considered in two parts, that which pertains to the general condition and that which is required for the local process. It is of the first importance to keep up the general health as much as possible, and for this purpose all the details of general care should be observed, as they would be carried out in a case of septicemia. In the very beginning, if the disease be acute, with much fever, naturally the diet should be restricted, but after this period has passed, the diet should be wholesome and generous, with the idea of increasing the general strength and nutrition as much as possible. In the mild cases with good general care recovery may take place entirely without the aid of drugs, but if drugs are to be used tonics and reconstructives are indicated. In the early stages in many of the cases salicylic acid or some of its compounds will be of distinct help to relieve pain, but in case this drug is to be used it should be borne in mind that in many of the cases it affords no relief whatever, and also that if it is to be of help that the improvement is noticed at once. It should also be borne in mind that although it relieves pain it is a distinct depressant, disturbing both the action of the heart and the digestion, and if continued for any considerable length of time is distinctly harmful, as it lessens the resisting power of the patient. For this reason in case salicylic acid is to be used it should not be continued for more than a few days, after which in the majority of cases it is possible to entirely dispense with it, using instead some of the simple alkalies with at the same time the use of large quantities of water internally.

It is undoubtedly essential that the eliminative functions, both from the kidneys and the bowels, should be kept as near the normal standard as possible. For the former the large quantity of water with the simple alkalies, such as the bicarbonate of soda or potassium, the phosphate of soda or the salts of lithium, are usually sufficient, and any tendency to the increased acidity, due either to the presence of the formic or uric acid, which are a result of the condition and not the cause, is entirely overcome. For the intestinal elimination cathartics should, of course, be used if needed, and frequently olive oil in half ounce doses once or twice daily is helpful to improve or correct this feature. Aside from this the medication should be planned with reference to the infection, and tonics and reconstructives should be used freely with fresh air, stimulating bathing, and any such measures as improve the body tone.

It is probable, in the light of the pathological and clinical nature of the disease, that as the condition represents so probably an infection, that some anti-toxine may be discovered, the use of which will control the disease. At this time observations are being made with the anti-streptococcus serum, but as yet the results of this treatment are too recent to report definitely.

For the local treatment in the active stage there is comparatively little to be done other than to protect the affected joint, and by means of hot applications, either moist or dry, liniments and such remedies, to relieve the discomfort as much as possible. If the process be acute, fixation will undoubtedly give relief, and this can be accomplished by the application of some form of splint, or a pillow folded about the leg and held with straps is oftentimes enough. At times complete fixation is necessary, in which case the plaster of Paris bandage is the most satisfactory. In arranging the position of the joint during this active period, the danger of contractures or dislocations should be borne in mind, and after the inflammation has passed, in case any stiffness or impairment of motion remains, passive motion, manipulation, and massage should be used in order to restore the joint to its normal function as soon as possible. In case the joint lesion represents a toxemia the recovery is rapid, so that within a week or two the acute symptoms have passed and motion should be encouraged. If the infection prove to be of the more serious type in which the organism itself is present in the joint more radical measures are frequently indicated and the joint should be opened and thoroughly irrigated. The infiltration of the capsule seen in this more severe type of the disease and which is responsible for the impairment of motion in many of the cases, particularly those due to the gonorrheal infection, does not take place to any marked degree until after the first three or four weeks. Up to that time the infection and swelling is confined largely to the joint itself. For this reason, if the improvement is not marked at the end of the first three or four weeks, in case only one or two of the joints are involved, they should be opened and thoroughly washed out. The same principle holds in the cases of this nature in which many joints are involved, but as in these cases the virulence of the process is less severe, measures as radical as incision are rarely necessary. In some cases, especially those due to the presence of the pneumococcus or the streptococcus, the symptoms may develop so rapidly and indicate so definitely an active septic process in the joint that there can be no question but that the joint should be opened at once and thoroughly drained, it being frequently possible in this way to prevent the marked destructive changes which otherwise would take place.

In operating the joint should be as thoroughly explored as possible, and in the exposed joints, such as the knee or elbow, the opening should be made on both sides, so that the irrigation may be thorough. In the gonorrheal cases, which are probably those in which the operation is most commonly needed, simply flushing the joint with water at the temperature of 120° F. is sufficient to destroy the organism. With the infections due to other organisms, definite antiseptics will be required and any of them in proper strength may be used. In the gonorrheal cases the wounds should be closed tightly except for one or two strands of silk which are allowed to

remain in the joint for twenty-four or forty-eight hours. After that it is customary for the healing to take place rapidly, and the function of the joint to return almost as rapidly. The marked relief from pain in these gonorrheal cases which follows such an operation is at times very striking. If the organism present is a more active pus producing element, such as the pneumococcus or the streptococcus, the joint should not only be flushed out, but drainage of some sort should be inserted so that repeated irrigations may be possible, and any accumulations of pus which may form, easily escape.

With the pneumococcus infections, if the joint alone is affected, the prognosis is good and healing takes place rapidly after the joint is once thoroughly opened. With the streptococcus the healing is apt to be more delayed, requiring a longer course of treatment, and the end result almost invariably shows some impairment of function of the affected joint. As both of these organisms, and several of the others, if allowed to remain in the joint for any considerable length of time attack the bone as well as the soft parts, naturally the operation should be performed at the earliest possible moment after the diagnosis is made.

In many of the cases of infectious arthritis and even those which are quite mild after the acute swelling and sensitiveness has passed, instead of the joint returning to its normal size and function, some swelling persists and the joint remains sensitive, weak and uncertain for an indefinite period. This condition is due usually to the fact that as a part of the original inflammation the membranes are swollen, and instead of contracting to their normal size as the inflammation subsides, the swelling remains and leads to the formation of folds and fringes, so that a villous arthritis results. It is also true that in certain cases the fibrin in the synovial fluid is precipitated, so that after the swelling goes down these masses of fibrin remain and act within the joint, as a foreign body, producing irritation and symptoms exactly as would any other foreign body. Both of these conditions should be definitely recognized, and if after a reasonable length of time, with stimulating bathing and local tonic treatment, the part does not return to its normal size and function the joint should be opened, and these features removed. This undoubtedly explains the persistence of symptoms in many cases which are at first supposed to be simply acute rheumatism, but in which the symptoms do not entirely disappear, and what is considered as chronic rheumatism develops.

If, as is not infrequent in a considerable number of cases, the patients are seen for the first time after the acute symptoms have passed and after the thickening of the capsule has resulted, and the contractures or the other undesirable features have taken place, an effort should be made to improve the condition. If there are dislocations attempts should be made to reduce them; if contractions, they should be overcome; and every possible effort made to restore the joint to as near as possible its normal condition. In practically any case, no matter how extreme the condition may be, improvement is possible, but, of course, in varying degrees; in some the joints can be made nearly normal; in others the improvement is necessarily less marked, but an attempt should be made in any such case, no matter how severe the crippling may be, to improve the condition of the patient.

During all of this late period of the disease the rheumatic remedies are naturally not of the slightest use and should be carefully avoided, the whole plan of treatment, both internal and external, being to improve the patient's general health as much as possible.

The following cases are reported, as offering suggestive evidence to the conclusions presented above. It is to be understood that they are only suggestive, and do not pretend to offer positive proof:

Case I. Mr. C., a man thirty-five years of age, was seen at the Massachusetts General Hospital, giving the following history: Having previously been well, one week before entrance he started in with what apparently was a hard cold. There was general feeling of malaise with cough and considerable muco-purulent expectoration. The day before entrance several of the joints became swollen and tender, supposed to be rheumatism. One wrist and several of the other joints were involved. The temperature was but little elevated, the glands could be felt all over the body, and the blood count showed over 20,000 leucocytes. Under rest in bed with local warmth to the affected joints, and with salicylic acid the condition entirely cleared up, so far as the pain and swelling was concerned, in four or five days.

The case suggests an influenza or severe cold with a toxemia following in which the joints were involved.

Case II. A child of five years was seen at the Children's Hospital with trouble with the shoulder joint of two weeks' duration. At the time of the first examination the general condition was very poor, and the joint was swollen and reddened. A diagnosis of septic arthritis was made and the joint opened, the pus showing the pure culture of the pneumococcus. The recovery was rapid with a fairly good functional result.

In this case the joint symptoms were due to the pneumococcus which was present in pure culture.

Case III. Mrs. E. D. R. was seen at the Massachusetts General Hospital with Dr. F. C. Shattuck. She had a typical severe attack of lobar pneumonia with pleurisy, with a gradual subsidance of symptoms until two days before she was seen by me. At that time she began to have joint symptoms referred to the knees, left shoulder, hand and elbow and to the right elbow. There was swelling and marked tenderness on motion. The white count was naturally high during the penumonia, but had fallen so that at the onset of the joint symptoms it was 12,200. There was moderate glandular enlargement and a serous exudate into the joints. In a few days with nothing more than good care the joint symptoms subsided and the normal function returned, the condition probably representing a toxemia following the pneumonia.

CASE IV. E. E., a physician thirty years of age, was seen by me several years ago in reference to an attack of supposed rheumatism in several of the joints, particularly one knee. The onset had been abrupt and the symptoms in all of the joints but one knee soon disappeared. The swelling and pain in the knee persisted for two or three weeks and then disappeared leaving a normal joint. A few days before the onset of the joint trouble the patient had had a sharp attack of pharyngitis and the culture taken at the time of my first visit showed a pure culture of streptococcus.

The treatment consisted chiefly in tonics, with a splint for the knee, followed by a bandage for a short time after the swelling subsided.

The joint symptoms in this case were of the nature of a toxemia and probably came from the throat where the streptococcus was found in pure culture.

CASE V. J. H., a physician thirty years of age, had a sharp attack of dysentery from which there was marked prostration with much septic absorption. During the recovery, after the acute intestinal symptoms had subsided, when the patient was still very weak, symptoms developed very abruptly in one knee, one foot, and one sternoclavicular articulation. The joints were swollen and tender. The joint condition gradually improved under moderate protection during the stage of swelling, with active use as soon as this had subsided. The internal treatment consisted of the use of large quantities of water with tonics and stimulants. The sternoclavicular articulation and the knee recovered in a few weeks under protection but several months elapsed before the sensitiveness about the foot at the attachment of the tendon Achilles disappeared. Several years have now elapsed since the trouble developed, and no further trouble has followed.

The joint symptoms represented undoubtedly a part of a general toxemia, following the dysentery.

CASE VI. L. H., a woman forty-five years of age, was admitted to the Massachusetts General Hospital in August, 1903, and was under the care of Dr. J. J. Minot, at whose request she was seen by me.

The patient having previously been well, had had, three weeks before entrance, a sharp attack of pain and swelling in the right knee. One week later the right wrist and the joints of the fingers became red, swollen and painful and a few days later the left hand developed symptoms similar to the right, only less acute.

The condition presented the appearance of an acute articular rheumatism, and with good general care steadily and rapidly improved except the right wrist which remained swollen and gradually grew worse. The redness and swelling increased until suppurative changes were evident, when the joint was opened, thoroughly cleaned out, and drained. After this the healing went on rapidly and steadily. Before the operation there had been a moderate elevation of temperature. The case represents a toxemia with rapid recovery in all but one joint in which the suppurative changes indicated the presence of the organism itself. There was no growth on the ordinary culture media employed in this case.

CASE VII. Mrs. H. A., thirty-one years of age. The patient, the wife of a physician, was seen in September, 1902, giving a history of having been perfectly well up to a year and a half before, at which time she had an attack of erysipelas about the head. A short time after her recovery from this, the right shoulder, the left elbow, both knees and the right ankle became swollen and painful. Abscesses formed at the right shoulder, the right ankle and the left elbow, which discharged and rapidly healed. She was kept in bed for seven months and was considered very ill.

At the time of the examination, the left elbow was firmly ankylosed with no swelling or evidence of active joint disease; the right foot was stiff and in the position of valgus; the ankle and shoulder were completely ankylosed, and one knee was quite stiff. The condition undoubtedly represented a profound toxemia probably resulting from the erysipelas, associated with suppurative changes in some of the joints. There had been no extension of the disease and the type, as illustrated in the x-ray, Fig. 5, does not suggest atrophic arthritis or hypertrophic arthritis. In the joints in which the suppuration occurred, there is considerable formation of new bone, not the thickening confined to the edge of the cartilage, as is seen in hypertrophic arthritis, but the general thickening following an inflammatory process in which the periosteum or the general joint structures are involved. In the joints which did not suppurate there is no evidence of cartilage or bone atrophy. (Fig. 6.)

CASE VIII. Mr. J. B., twenty-eight years of age. In 1896, patient had an attack of gonorrheal arthritis, both knees, the right shoulder, the toes, the back and one finger being affected. After a few months the condition entirely cleared up except the lumbar spine and the left knee which continued to pain and have remained troublesome ever since. The knee joint has been aspirated several times and he has received much treatment at the various baths, none of which have yielded more than temporary relief. During periods of quiet the swelling and irritation of the joint subside but they are always made worse by active use.

On examination, the joints were normal except the lumbar spine which was quite stiff with some pain on motion, and the left knee which showed considerable thickening of the capsule with such a definite villous arthritis that the fringes could be palpated and readily demonstrated on motion. The condition is undoubtedly one in which for some reason following the toxemia of a gonorrheal process a few joints became more involved than the others. The condition in the affected joint at the present time is not a gonorrheal process, but the result of that infection, the symptoms at the present time being due entirely to the presence of the synovial fringes or villi and the mechanical irritation which their presence represents to motion. Naturally in such a case on any considerable amount of use, the fluid in the joint would increase, and aspiration or such other treatment as has previously been tried would give relief but would not cure the condition. The treatment which offers hope of cure must naturally be the thorough opening of the joint and the removal of the villi which are responsible for the irritation. The patient is awaiting operation.

CASE IX. J. L. Q., machinist, aged twenty-five years, admitted to the Massachusetts General Hospital Jan. 6, 1904. About one week before onset of the joint symptoms he had an acute attack of urethritis. The joints first involved were the feet, a few days later the elbows, both knees, back and several finger joints. The shoulders were unaffected. Some of the joints were not swollen at all; several of the others showed periarticular thickening with apparently no increase in the joint fluid. The spindle shaped swelling of the second phalangeal joint in the index finger of the right hand was very noticeable. The glands all over the body were moderately enlarged. During the stay in the hospital the temperature ranged from 99° to 100°; pulse was quickened, reaching 122. Hemoglobin 70°; whites 18,600; urine shows slight trace of albumen with occasional

casts and round cells. The improvement under good, general care was rapid.

The case represents an infectious arthritis of moderate severity following a gonorrheal arthritis, with little to produce permanent changes.

Case X. Mr. A. B., forty years of age, was seen in consultation with Dr. E. C. Boland. Shortly after a definite attack of gonorrhea, he developed symptoms in the left knee. The onset was abrupt; the swelling marked; the suffering very great, with no relief from the rheumatic remedies or from protection of the joint which was kept up for four weeks. Large doses of morphia were necessary to control the pain. After waiting four weeks without improvement the joint was opened and irrigated with water at the temperature of 120°; the wound closed, except for a strand of silk and sterilized dressings applied.

The pain was at once relieved by the operation and motion was possible within a few days, and function gradually and steadily improved.

The examination in this case of the fluid confirmed the diagnosis of gonorrheal arthritis.

Case XI. V. Y., a man forty-five years of age, was seen with Dr. H. F. Vickery at the Massachusetts General Hospital with what appeared at first to be an ordinary but severe case of acute rheumatism. The onset of joint symptoms and the early history was not noted so that the nature of the early infection is not known. The patient seemed quite sick with a moderate elevation of temperature, with a rapid pulse, and with the general enlargement of the glands, besides the swelling and pain in most of the large joints. With good general care the excess of the joint fluid was gradually absorbed leaving the periarticular structures considerably infiltrated. The patient's general condition did not improve and later on symptoms of valvular disease of the heart developed, which increased in severity and death followed in a few days. The pathologist's report was that death was due to a "septic endocarditis."

The case represents a profound toxemia with a final lesion involving the heart.

Case XII. Miss I. M. P., twenty-nine years of age. Patient entered the Massachusetts General Hospital in the service of Dr. James J. Minot in June, 1903. Three months previous she had an attack of typhoid fever, and three weeks after the onset of the disease severe pain developed in the back, relieved only by morphia. This continued for three weeks and then largely disappeared, and the patient was able to be about until five days ago when the pain in the back recurred with such severity that the patient was put to bed. For a week her temperature ranged about 101° and after that gradually fell to normal and remained there during the balance of her stay in the hospital.

At the time of the examination the motions of the lumbar and low dorsal vertebræ were much restricted with marked tenderness over the spinous processes in the region of the upper two or three lumbar vertebræ. All motion of the spine was so painful at this time that it was with difficulty that a thorough examination was made. The heart and lungs were negative; the urine was normal; the hemoglobin was 70%; there were 10,600 whites in the blood count and the widal reaction was positive.

At that time a diagnosis of typhoid spine was made and a plaster of Paris jacket applied to immobilize the spine until the active inflammation subsided. The patient was kept in bed with the jacket on for about a month. During the first part of the use of the jacket the pain continued, the only benefit from the support being the greater ease in moving from side to side. After that the pain gradually disappeared and a leather jacket was substituted for the plaster one. The patient then left the hospital with the understanding that the leather jacket was to be gradually discontinued. The spinal motions at that time were distinctly limited in the region of the inflammation, and undoubtedly much of this will be permanent.

The spinal process represented undoubtedly a definite infection due to the typhoid bacillus with enough inflammatory change and thickening to cause permanent thickening and thus limit the spinal motions. In the simple toxemias which undoubtedly do at times affect the spine the relief from the pain would probably have followed the application of the jacket, while in the case reported with the organism itself probably present, in spite of the fixation, the pain persisted, as is usual in such infections until the temperature disappeared and the evidences of the active life of the organism had passed.

Case XIII. Pauline W., ten years of age, seen in January, 1903, in consultation with Dr. T. M. Rotch, had the following history: Until four years ago the child had been so unusually well as to be considered a model of health by the people of the neighborhood. At that time the child had some trouble with a tooth which was followed by acute disease of the cervical glands. Shortly after this she began to have trouble with the feet so that it was difficult to pull on her boots. With this there was some lameness, and a short time afterward the neck became suddenly sensitive and the head was drawn to the right. Soon after the knees and then the hands and wrists became swollen. All the joints which are now involved or which have been involved became so during the first six months. Under the supposition that the condition was rheumatism the patient was treated with the ordinary rheumatic remedies, was taken to the Hot Springs in Virginia for some time without benefit and under the various forms of anti-rheumatic treatment she ran down in health steadily.

At the time of the examination the tarsal and ankle joints were swollen and boggy but the motion was not much affected; both knees were swollen, and also the wrists with but little restriction of motion; the cervical spine was stiff with very little apparent swelling and the inguinal, axillary and cervical glands were moderately enlarged. The x-rays taken at that time showed no atrophy of the bone or cartilage, the joint swelling being due apparently to the infiltration and relaxation of the membranes. The child was put upon a course of general stimulating tonic treatment, and the father, who is a physician, reported three months later that she was much better and was continuing to follow the same general directions.

This case represents quite typically the disease described by Still, except that it was of a milder type than the cases reported by him. From the most careful study of the disease it suggests an infectious process, the infection most probably having been absorbed from the abscess about the tooth. Unlike the atrophic form of arthritis the disease has not progressed since that time, nor has the swelling of the individual joints subsided and gone on to ultimate atrophy. At present the swelling of the various joints is undoubtedly due to the hyperemia of the mem-

branes and the villous arthritic change which results from this. In case the general stimulating and tonic treatment does not effect a material improvement in the condition, an operation with the idea of removing the villi which represent the mechanical irritation to the joints must be considered.

CASE XIV. Miss E. M. S., a patient of Dr. W. W. Pillsbury, having previously been well and with a good family history, in March, 1903, met with a slight injury to the left knee. This was followed by a synovitis, and shortly afterward pain developed in the joint so that motions were restricted, and gradually during the next four or five months the process extended from joint to joint until at the present time practically all of the joints in the body are affected. In the individual joint there is comparatively little increase in the joint fluid but much infiltration of the membranes and periarticular structures, giving in the exposed joints a marked spindle shaped appearance. All during the developmental stage of the disease there has been a slight increase of temperature, from one to two degrees, and the pulse has been much accelerated, from 120 to 130 most of the time. The glands throughout the body are much enlarged. While at first there was comparatively little abnormal in the character of the blood, a profound anemia has developed.

The case suggests in all its appearances a typical chronic rheumatism, undoubtedly resulting from some organism, the exact nature of which we do not at the present time know. It seems probable that it is in such a case that the organisms which have been recently recognized in cases of rheumatism will be found to represent the causative factor.

CASE XV. Mr. R. W., twenty-one years of age. Four years previous to the time of the examination in July, 1903, the patient had an attack of pneumonia which was followed by an empyemia, for which a radical operation was discussed, but which for some reason was not performed. The convalescence from this condition occupied a long time and in that time pain developed in one hip. Shortly afterward the other hip, both knees, one ankle, shoulder, elbow and jaw became affected. Two years later the patient had scarlet fever, following which all of the symptoms were worse. The condition at first was considered an acute articular rheumatism which has gradually gone on to a chronic condition.

At the time of the examination many of the joints were involved as stated. The spine was stiff, both hips allowed only a slight amount of motion, the knees were flexed with considerable stiffness, the right ankle was swollen and stiff, the jaw was practically ankylosed and the left shoulder could be moved but little. The other joints were practically free. None of the joints showed any changes of atrophy and there had been no progression or extension of the disease since the original trouble began. The patient presents the typical appearance of chronic rheumatism and in the light of similar cases probably represents a toxemia following upon the pneumonia and the empyemia, the organism probably responsible for the infection being the streptococcus. A pneumococcus toxemia does not as a rule last so long, and for the organism to have been present itself would have undoubtedly been followed by suppuration in some of the joints.

The treatment with this patient, as the active disease was over when he was first seen, has consisted of regular manipulation of the joints, tonics to improve the general nutrition, and has been followed by considerable improvement in the function of the affected parts.

CASE XVI. Mr. F. R., twenty-one years of age, having previously been well, two years ago developed suddenly an attack of what was called rheumatism, confined at first to the right knee. The joint was red, hot and considerably swollen. In three months the other knee became involved, then gradually the neck, elbows, feet, hips and shoulders. Each joint behaved in the same way, showing swelling with much sensitiveness which gradually subsided leaving in almost each instance some restriction of motion. At the time of the examination the cervical spine was stiff, the motions in the left shoulder restricted about one half. The left elbow, which had been more seriously affected than the other joints, was completely ankylosed. Both knees were flexed to about 45°; the wrists were stiff, and the fingers of both hands were flexed and distorted (Figs. 1 and 2); the feet were quite flat and the right one stiff at the ankle. The case represented undoubtedly the so-called chronic rheumatism, and at the time of the first examination there was very little evidence of active disease. The glands, however, were still somewhat enlarged; there was practically no elevation of temperature, but the anemia was quite marked.

For treatment the patient has had regular and repeated manipulations of the various joints with the idea of improving their function as much as possible. He is, at the present time, able to walk about with his legs straight; the hands are used more perfectly, and in all the joints there has been some improvement. The degree of helplessness as the result of treatment has been materially lessened.

CASE XVII. Mrs. B., thirty-five years of age. Two years previous to the time of her first being seen the patient had a severe attack of what was called articular rheumatism, many of the joints being swollen and acutely painful, the right hip being especially involved. The symptoms of acute suffering lasted for several weeks, during which period the patient was kept upon her back, the leg raised and supported upon pillows with considerable adduction. This position was maintained throughout the period of active inflammation, and after the acute symptoms had passed and the patient began to get about it was found that the right hip was dislocated, the dislocation having undoubtedly resulted from the distension of the joint during the inflammation together with the position of flexion and adduction which would make dislocation easy.

There was at the time of the examination no apparent destruction of bone, and accordingly the leg was manipulated under ether, and with comparatively little difficulty the head of the femur put back into place. The position was maintained with fixed dressing for a few weeks, after which motion and weight bearing were allowed. The bones remained in the proper position and the function of the part improved so that except for some limitation of motion in the extremes there was little to show for the previous condition.

This case illustrates a result which may follow a comparatively simple inflammatory process unless the position of the part is carefully considered.

CASE XVIII. Mr. A. O., a young man twenty-two years of age, was seen in July, 1903, in consultation with Dr. J. J. Whoriskey. Having previously been well, he developed following the wearing of an imperfectly fitted shoe a blister upon the heel, which was

followed by a small pustule at that point. Twenty-four hours later symptoms of acute infection developed, with high temperature, rapid pulse and glandular enlargement. The pustule was promptly opened with temporary relief, but one parotid gland became infected and went on to suppuration. One or two other points of infection developed, and finally a few weeks after the first onset of the disease the left hip became acutely sensitive. From the beginning of the infection the patient was very seriously ill, and with the development of the symptoms in the hip the condition was so grave that a rapid incision was made into the joint for drainage as an operation of last resort. The hip joint was filled with pus, as had been all the other parts in which the infection had manifested itself. Under gradual, stimulating tonic treatment, with protection of the joint, and with such treatment as would tend to lessen the suppuration in these parts, the patient gradually recovered with a moderate restoration of function in the affected part.

The case represents an infectious process starting in the subcutaneous tissue, followed by joint suppuration, the specific organism not being determined as the culture was lost. In such a case, it is, of course, impossible to expect normal recovery because of the amount of destruction of tissue which has taken place.

SOME POINTS ON THE DIAGNOSIS AND TREATMENT OF CERTAIN NEGLECTED MINOR SURGICAL LESIONS.[1]

BY E. A. CODMAN, M.D., BOSTON.

THE subject on which I have chosen to speak to you is not remarkable for its brilliancy, as you may guess by the title. I think that we may justly criticise ourselves as surgeons, for our tendency to pay too much attention to the cases on which we may obtain brilliant and striking results, rather than to endeavor to do our best for every surgical case which is presented to us. In the cases which I shall describe, as a rule, the results are not very good and even when intelligently treated, the patients are apt to think that doctor so and so made some error because the limb is not more useful. The material which I have used for this paper I have obtained mainly from my service in the Surgical Out-Patient Department of the Massachusetts General Hospital. In my work there, the cases in which I am not able to make a satisfactory diagnosis are always more interesting to me than those in which the diagnosis is clear and the treatment sharply indicated.

Among the lesions which have been most troublesome, are certain unrecognized fractures which we have only lately learned to distinguish from sprains. It used to be said that a sprain was worse than a break, but from my experience of the last four or five years, I feel quite certain that the majority of sprains which do not promptly recover are in reality breaks. Among the most common of these unrecognized fractures is that of the scaphoid bone of the wrist. The history of the following case is quite typical:

H. S. F., aged twenty, injured his wrist in playing football at Cambridge. He was seen by the surgeon of the football squad and the wrist was put in splints for several days. The swelling and tenderness subsided to a certain extent. No crepitus was obtained, no ecchymosis, and the patient could use his fingers and wrist a certain amount. There was no abnormal mobility. In football practice it is found that a sprain does better if the use of the limb is kept up, and this wrist was treated on this principle. While there was some improvement, the joint still remained sore, forced motions beyond a slight angle were very painful and the gain in strength was slow. About six weeks after the original injury the patient consulted me at my office. I made a diagnosis of fracture of the scaphoid and confirmed it by an x-ray. Feeling that it was too late to endeavor to obtain union between the fractured ends of the bone, I only kept the wrist on splints for about two weeks and then had it massaged. The rest on the splints improved the joint to a considerable extent but it still remained somewhat swollen and gave pain if extreme motions were forced. The young man was prevented from doing any sort of athletics with the wrist, he could not play football, and frequently found that he hurt it in scrapping with the other fellows. This condition has lasted over two years with a very gradual gain, so that even now the wrist cannot be extended beyond an angle of 25° without giving extreme pain; flexion is less painful, but in the extreme position almost as bad as in extension. There is marked tenderness over the scaphoid bone which is best obtained by adducting the wrist and pressing with the thumb just in front of the styloid process of the radius in the anatomical muff box.

This history is typical of fracture of the scaphoid and while at first I found the x-ray a necessity in making the diagnosis of this fracture, I can now in a large proportion of cases diagnose it from the clinical side alone. With the assistance of Dr. H. M. Chase, I have collected about 15 cases which have been at the Massachusetts General Hospital and obtained their detailed histories. We hope to publish these cases soon. In addition to these there are perhaps twenty-five more of whom we have x-ray plates, but whose clinical histories we have not been able to obtain.

Prof. Dwight has offered the suggestion that these fractures are perhaps due to a congenital condition of the scaphoid bone which is characterized by the forming of two centers of ossification instead of one, so that a lamina of cartilage is left between the two halves of the bone and that it is through this weakened area that the fracture takes place. Be this as it may, fracture does take place and in my opinion the assumption that such a weakened portion of the bone exists is entirely a theoretical one. To sum up the diagnosis of fracture of the scaphoid: There is no deformity, no ecchymosis, no crepitus, no abnormal mobility — in other words the classical signs of fracture are absent. What we do have is localized swelling and tenderness in the region of the scaphoid bone, *i. e.*, in the radial half of the wrist joint; limitation of active joint motion and sharp pain called forth by efforts at

[1] This paper was prepared to be read at a meeting of the Worcester District Medical Society on March 9, 1904. A number of anatomical preparations on the bursæ about the wrist, shoulder and ankle were demonstrated, and lantern slides illustrating this paper were shown. Owing to lack of time, the formal reading of the paper was omitted.

forced passive motion. The joint protects itself from such efforts at forced flexion or extension by muscular spasm, which is particularly evident in extension. The diagnosis should be confirmed by the x-ray, the best position in which to take the x-ray being an antero-posterior view in adduction. As I have said the above history is very characteristic of this fracture and the reason for the continued impairment of the wrist is that the bone being in such delicate relation with the other bones any deformity of it prevents the other bones from going through their normal arcs of motion.

In most of the cases as shown by the x-ray, union does not take place and in those in which it does take place, the bony callous is so large as to destroy the accurate contour of the bone, which is necessary to secure a perfect mechanical action of the joint. In some cases, though, the displacement of the fragments has been very little and a union has at length taken place. These cases are as a rule, more comfortable than those in which union has not taken place or a large callous has formed. The treatment indicated, therefore, would be to prevent motion of the joint while there is still a hope of the fragments uniting. In other words, if we treat the case as a sprain and continue active and passive movements of the joint, the union will be prevented; we must, therefore, keep the joint in a fixed position for at least three weeks in order to obtain union. It is impossible for me to tell just how long such fractures should be kept fixed, but I am inclined to think that three weeks is a fair amount. If this has not been done immediately after the injury, I doubt if union can be obtained for the fracture is on both sides open into the wrist joint, the inter-space is filled with synovial fluid, and the adjoining synovial membrane, I am inclined to think, spreads over the raw edges of the bone and a false joint is formed.

As to the treatment of the condition when union has not taken place and a considerable period of time has elapsed, although I have never done it, I should advise excision of the proximal half of the bone. In two cases of compound dislocation of the wrist where this bone was also broken, one-half of it was excised, in one case by one of the house officers, in the other by Dr. Greenough. Both these cases have now fairly good wrists in spite of the great severity of the original lesion. I am inclined to think that if the proximal half of this bone were absent, the permanent condition of the wrist would be better than if the bone remained un-united, in which case one half of the bone constitutes practically a foreign body. I should, of course, not advise this operation unless the condition of the wrist was so troublesome as to interfere with the occupation of the individual.

Another injury of the wrist which should be spoken of in this connection is dislocation of the semilunar bone. This often occurs with fracture of the scaphoid, although in two cases I have seen it the only lesion. One of these I was able to reduce by manipulation without open incision. In the other case I was obliged to make an anterior incision and with the aid of a tenaculum easily reduced the bone. The result in both the cases has been very nearly perfect.

The method of reduction of the semilunar bone is to forcibly extend the wrist; an assistant then makes pressure with his two thumbs over the flexor tendons of the wrist on the semilunar bone, while the surgeon with the assistant's thumbs still in position, flexes the wrist completely. The os magnum slips over the posterior horn of the semilunar and the latter pops into its position on the radius.

Another lesion which must be considered in the diagnosis of fracture of the scaphoid, is early tuberculosis of the wrist joint. This condition is sometimes found confined to the region of the scaphoid so that the swelling, tenderness and spasm, closely resemble the condition in fracture. In the diagnosis, the absence of history of injury, the slow onset, the extreme grade of spasm of the muscles and local temperature, are important aids. The x-ray by showing the focus of bone destruction from the disease is the decisive test. By the kindness of Dr. J. G. Mumford I am able to show you an x-ray of such a case in which the focus was successfully excised.

Rheumatoid and osteoid arthritis may also be confusing although in both, other joints are apt to be implicated in the disease. The former is characterized in the x-ray by the absorption of cartilage so that the bones approach each other very closely. The latter shows the characteristic enlargement of the articular margins typical of osteoid arthritis.

I have never known syphilis to affect the wrist joint except in one case of Charcot's disease. In this case the great mobility and anesthesia characteristic of a Charcot's joint left little doubt of the diagnosis, although the deformity was characteristic of a Colles fracture.

Another lesion in this region which should be considered, is teno-synovitis of the tendons of the thumb and long extensors of the wrist. You may or may not recall from your study of anatomy that the bursæ surrounding the tendons of the extensor ossis metacarpi pollicis and extensor primi internodii pollicis communicate with one another and that the bursæ of the extensor secundi internodii pollicis and those of the extensor carpi radialis longior and brevior have a common sheath. Teno-synovitis of these bursæ is very common and is characterized by the anatomical location of the swelling and the well known tendon crepitus. These bursæ overlie the scaphoid bone and swelling and inflammation of them is quite confusing.

Another point which is not generally known (and I have never seen it mentioned in the books) is that in fracture of the lower end of the radius, as in Colles' fracture, and the various fissures which occur through the lower end of the radius, bleeding is apt to take place into the common bursa of the radial extensors. When I see this bursa enlarged and fluctuant after an injury to the wrist, I feel almost certain that a fracture of

the lower end of the radius exists even if no displacement of the bone is seen and no other deformity is present. This is generally borne out by the x-ray.

Another region which is interesting from an anatomical standpoint in diagnosis is the shoulder joint. No surgeon can practice long without seeing certain puzzling cases of lesions in this region which defy his diagnosis and treatment. Unrecognized fractures are not uncommon in this vicinity, especially in the greater and lesser tuberosities. Cases which show neither crepitus, abnormal mobility nor deformity may prove to be fractures of the facets of insertion of the short rotators of the humerus. The x-ray is particularly useful in indicating fractures of the greater tuberosities which appear like laminæ torn from the head of the bone. Unfortunately the fracture of the lesser tuberosity is apt to oe unrecognized in the x-ray because the facets pulled off by the subscapularis fall in the shadow of the rest of the oone. The same is true of the supra and infra-spinatus. Some weeks after the injury the fossæ of the supra and infra-spinatus show great atrophy, due to the inability of these muscles to perform their functions. This may occur in other conditions, however. The importance in treatment of recognizing these lesions early, is so that the shoulder can be immooilized for a continued period in order to allow the facets of bone torn away by the muscles to form new attachments. As in the wrist, if motion is allowed, it is unlikely that we will get union. I am sorry to say that it is unlikely even with treatment, and such cases usually fall into the class which we call peri-arthritis for want of a better term.

We all know how often the shoulder remains crippled for life and the patient complains that he is unable to get his hand to the back of his head. This term, peri-arthritis, is a sort of surgical waste basket in which we throw our diagnostic failures. We manage to keep our self-respect by telling the patient that rheumatism has set in or that he has a gouty joint, but I believe that such lesions, when we know more about them, will be separated into more distinct anatomical entities. In the diagnosis of such lesions we must not forget a simple impacted fracture of the shoulder joint. It is extraordinary how little displacement such fractures present.

We are apt to depend in our diagnosis of fracture on the presence of abnormal mobility, crepitus or deformity. Personally, I think that local tenderness and ecchymosis are of as great importance. The more I see of fractures about the shoulder joint, ankle joint or wrist, the oftener do I find that where ecchymosis is present, there is bleeding from a broken bone. In speaking of ecchymosis, I refer to the discoloration which takes place in adjoining parts which were not directly subjected to the forces causing the injury. In the instances of fractures about the shoulder joint the bleeding may travel under the fascia and appear on the inner and posterior surfaces of the arm just above the elbow. In the ankle such hemorrhages appear just above the sole on either the outer or inner side of the oscalsis. When ecchymosis is present in these situations, I seldom fail to find fracture of some bone, and if I do fail to find it, I regard it as more than likely to be present in spite of my efforts. As in the neighborhood of the wrist joint, so in the shoulder joint, we may confuse fracture with teno-synovitis of the bursæ.

About the shoulder we find numerous bursæ, the most constant of which are: the deltoid or subacromial lying just under the fibers of the deltoid muscle and extending between the acromion process and the capsule of the joint; the trapezoid, lying over the little triangular area at the posterior end of the spine of the scapula; and the coracoid, lying under the tip of the coracoid process and between the tendons of the coraco-brachialis and the supscapularis. The diagnosis of inflammation of these bursæ is not difficult if their anatomical situation is borne in mind. In raising the arm over the head, the first third of the motion may be accomplished by the rolling of the head of the humerus on the glenoid cavity but to move beyond this if the scapula be fixed, the great tuberosity and the capsule of the joint must also roll under the acromion process. This would bring into play the two surfaces of the acromial bursa which, if inflamed, gives great pain and causes the muscles about the joint to fix the humerus at this point, and the remaining arc of motion is carried by the movements of the scapula on the thorax. Hence to make a diagnosis of deltoid bursitis, the scapula should be held by an assistant and the arm moved upwards by the examiner. Somewhat less than one third of the motion can be made without causing pain, but effort beyond this will cause great pain referred to the region of the acromion process. Often there is tenderness at a joint just below the tip of the acromion extending backward and forward along the edge of the process. Where the bursa is filled with serous effusion the contour of the shoulder may be rounder than on the other side. Inflammation of the coracoid bursa is characterized by local tenderness just below the tip of the coracoid process and pain on muscular efforts which call into play the coraco-brachialis; for instance, if the patient with extended arms tries to press his palms together in front of his chest. I have sevefal times seen this lesion in truck drivers who had pulling horses. The trapezoid bursa is particularly apt to be inflamed where for some reason there is fixation of the shoulder joint from disease or injury. In this case the scapula is obliged to take part in all the motions of the arm, and the bursa between the trapezoid and posterior edge of the scapula does more than its normal share of work. There is not infrequently a crackling fremitus when the two surfaces of these bursæ roll over one another. This crackling we are all familiar with in the pretapella bursa, although I find that most surgeons imagine that this crackling is inside the joint.

The treatment of these bursæ is the same as in inflamed serous cavities in other portions of the body, *i. e.*, mechanical rest and counter-irritation. The form of work which has produced the inflammation must be stopped, and the motions of the joint which call the bursæ into play must be restricted. A very effective form of treatment of the mild cases of the shoulder joint I have found to be the simple pinning of the coat sleeve to the coat. This allows a certain amount of rotation in the joint cavity, the free use of the forearm, but restricts the motions of the upper arm. As a counter-irritant, it has seemed to me that I have often seen benefit from using a light stroke of the actual cautery. Some of my colleagues are very enthusiastic about the high frequency electric current. It certainly is helpful in ruling out neurasthenics and malingerers.

Another region of the body which is interesting in the diagnosis of obscure lesions is the ankle joint. We have learned lately to detect fractures in this region too, in which the old signs failed, and which used to be called sprains. One of these, which is not at all uncommon, is impacted fracture of the oscalsis.

The salient points for diagnosis in this lesion are: (1) The history of a fall on the feet or heels. (2) Tenderness over the oscalsis. (3) Ecchymosis just above the sole on both sides of the foot. (4) Shortening of the distances between the malleoli and the floor as compared to the other foot. (5) No crepitus, abnormal mobility or obvious deformity. This fracture is very common, particularly in working-men, and the ultimate result sometimes leads to considerable incapacity. The direct result is flat foot, the impairment of the motion of the joint through formation of bony callous and the alteration of the lines of weight bearing on the bony and ligamentous structure of the foot. I have never seen one of these cases as a late result, who did not complain of some soreness in his foot on unusual exertions, such as extreme flexion of the ankle, walking on rough ground, long standing, etc. The treatment in these cases should be directed to preventing the patient from walking on his feet before bony union has taken place. This has the double result of preventing a further impaction of the bone causing shortening of the distance of the malleoli from the floor and of lessening the degree of permanent callous, which in any fracture is greater if it is continually disturbed while healing. When the acute symptoms have subsided, and the patient commences to walk, he should wear a flat foot plate to prevent increasing pronation of the foot.

Perhaps the commonest fracture about the ankle which is overlooked, is oblique fissure of the external malleolus. In this, also, we fail to find crepitus, abnormal mobility and deformity, we rely for our diagnosis on local tenderness, ecchymosis and the x-ray. This fracture is the badly sprained ankle, which we used to see before the x-ray. The line of fracture takes place just above and through the external malleolus from behind, forwards, downwards and inwards. What little displacement there is, is a tilting or rotation of the lower fragment which produces a slight irregularity on the posterior surface of the fibula at the point where the upper edge of the lower fragment is located; tenderness at this point is usually acute, and by careful palpation, the tenderness will be found to follow the line of the fracture downwards and forwards. The ecchymosis takes the form of a bloody sac which falls over the tip of the external malleolus and spreads along the outer side of the foot. The ecchymosis has almost a characteristic shape, so that I am inclined to think it is due to the filling with blood of the peroneal bursa which lies just behind the external melleolus. As in the radial bursa the base is directly on the bone and must be torn by a fracture.

At first I was always in doubt about these cases and relied wholly on the x-ray to detect them, but now-a-days I am able to recognize them at a glance, and while I always have the x-ray taken, I am seldom mistaken in the character and position of the lesion from my "snap diagnosis." This fracture should be treated as a fracture, not as a sprain. As in the other forms which I have spoken of, the rule that callous increases if the fracture is continually moved, is true in these cases too, and patients who have had this insignificant fracture, and have been treated for sprain in the ankle, will often tell you that it is of considerable annoyance when it has been used more than a moderate amount, even years after the injury.

There are in the ankle other fractures which the x-ray has taught us to recognize which are important from a point of view of prognosis and treatment and which I should be glad to dwell on at length, if time permitted. Among these I may mention the fracture of the posterior facets of the astragalus, of the facets of insertion of the lateral ligaments of the ankle joint, etc.

In making these fragmentary remarks I have confined myself to the wrist, shoulder and ankle; but let me say that the same general principles apply to the other joints too. You will be astonished to find how often the presence of ecchymosis and accurately localized tenderness are proofs of fracture where no crepitus, deformity or abnormal mobility can be obtained. You will also be astonished to find how a little brushing up of your knowledge of the anatomy of the bursæ will help you in your clinical diagnoses. "House-maid's knee" and "weavers' bottom" are not the only ones.

RADICAL CURE OF INGUINAL HERNIA.

BY JOHN O'CONOR, M.A., M.D.,
Senior Medical Officer, British Hospital, Buenos Aires, S. A.

I WISH to invite the attention of my American colleagues to a method which I have recently practiced in 50 cases with very satisfactory results.

A four-inch incision is made over the line of the inguinal canal. The sac is thoroughly isolated from cord, opened, and its interior carefully in-

spected, and palpated right into abdomen. Any intestinal or omental adhesions which may be present are separated and occasionally it is necessary to excise some omentum before the contents of sac can be returned into abdominal cavity.

An assistant next draws the sac downwards by a forceps applied to its distal extremity and retaining my left index finger within sac nigh to internal ring in order to prevent intestine or omentum getting caught, I transfix and ligate sac with fine silk, then divide it about half an inch below ligature; the stump recedes into abdomen, and the distal portion is removed.

The conjoined tendon and Gimbernat's ligament are next differentiated from surrounding structures, and with left index finger introduced into canal as a guide four "strong" fishing gut sutures are passed from within outwards by means of a full curved hernia needle, about one-third of an inch apart, through the projecting ledge of Gimbernat and external oblique, the ends of sutures are retained outside external oblique and the needle withdrawn.

The free ends are next threaded on a hernia needle with an opposite curve and are carried upwards from within outwards into substance of, and through conjoined tendon. The ends of these sutures are similarly retained outside sheath of tendon, and the needle withdrawn.

A straight Reverdin needle, or sinus forceps, is next entered through each suture hole in tendon, passed across just beneath aponeurosis and made to emerge at corresponding suture hole in external oblique, the end of this part of suture is caught in needle or forceps, drawn across and out through suture hole in conjoined tendon, thus both ends of each suture emerge from the same aperture in tendon, and form a most efficient submuscular stitch, excepting the fourth or lowest suture which is only partially submuscular in that it crosses in front of external ring. These sutures are tied with sufficient force so as to approximate the tendon and Gimbernat, care being taken on adjustment of lower suture so as not to unduly compress the cord. I generally allow enough room for the insertion of my little finger.

The ends of sutures are snipped off and the knots retreat into substance of tendon and each little stitch aperture in sheath of latter is closed by a fine catgut suture.

The operation which takes from ten to fifteen minutes to perform is concluded by uniting the skin wound with a continuous blanket suture.

The advantages which I claim for this method are, (*a*) its simplicity; (*b*) the two strongest and most suitable structures in the inguinal region for effective barrier formation are utilized; (*c*) there being no interference with the position or structure of cord, orchitis, with subsequent atrophy of the testis, does not supervene; (*d*) there is no splitting up of structures which experience shows are never anatomically replaced, not to mention the fact that all cicatricial barriers tend to weaken in time.

To any surgeon wishing to put this method to the test might I suggest, to perform it on a cadaver and then make an inspection from inside abdomen.

In conclusion I wish to mention that full use must be made of the left index finger introduced into inguinal canal during the application of the sutures, which not only protects the structure of cord, but differentiates the projecting ledge of Gimbernat, and so obviates the danger of injuring the external iliac vessels.

In my 50 cases no accident occurred, no orchitis supervened, and only in one instance did sepsis take place, which promptly ceased on opening up lower angle of wound. The silkworm gut sutures being buried in the substance of conjoined tendon, and covered over by sheath, are practically out of the range of contamination.

Iodoform gauze dressing is applied, the skin suture is removed on seventh day and the patient allowed out of bed on the fourteenth day.

Clinical Department.

A CASE OF OVARIAN TUMOR WITH TWISTED PEDICLE. THREE REDUCTIONS WITHOUT OPERATION. OPERATION; RECOVERY.

BY CHARLES ALLEN PORTER, M.D., BOSTON,

Assistant Visiting Surgeon to the Massachusetts General Hospital,

AND WILLIAM CARTER QUINBY, M.D., BOSTON.

WITH Dr. Herman Baldwin, of Chestnut Hill, on Jan. 11, 1904, the following case of ovarian tumor, with twisted pedicle, was seen, which, owing to a definite history of reduction by manipulation, previous to operation, is of sufficient interest to report.

A. P., age thirty-five, had a healthy child in May, 1900. A year ago, she complained of bearing-down sensations in the pelvis, and discomfort in this region on lifting the baby, and on pushing the baby carriage uphill. She had gynecological treatment by tampons, but was not informed of the condition found. Her last treatment was in October, 1902. Since then, she has been well, except for occasional pains in the back, until her present illness.

On Dec. 22, 1903, after eating some bad steak, she was taken sick in the night, and vomited violently all day. On Dec. 23, after an especially severe attack of vomiting, she was seized with a sudden, sharp pain in the right iliac region. She states that she saw and felt a lump there, the size of a small orange, which after massage and manipulation, disappeared. The pain ceased immediately. She vomited daily in the morning, but was up and about, and free from pain until Jan. 5. On this day, after carrying the baby upstairs, she had another attack of severe pain, similar to that on Dec. 23. On Jan. 4, the catamenia began, with more flowing than usual, and severe backache.

On the morning of Jan. 5, she was found crying and groaning, evidently in great pain. Temperature was normal, pulse 68, abdomen lax, not distended, tender in the right iliac region, but without muscular spasm. Examination was unsatisfactory, owing to the patient's rather hysterical condition. At the end of an hour, the pain suddenly ceased, the patient said that she was well, refused further examination, and wished to get up. Occasional vomiting was still present. Bowels

moved normally, no distention, no fever. Although at work, she did not feel well.

On Jan. 11, in the morning, she had another sudden attack of pain, similar to the other two. Flowing was still present, although usually it lasted only three days. Temperature 97.8, pulse 66, vomiting about every fifteen minutes, with continuous pain. At four in the afternoon, after another attempt at palpation of the abdomen, the pain suddenly disappeared.

When seen with Dr. Baldwin on the afternoon of Jan. 11, about five o'clock, she had no fever, pulse was 72, and she was apparently free from pain. There was no distention. The abdomen was soft, with considerable fat between the umbilicus and pubis. No tenderness in the epigastrium. She did not appear sick. On careful examination, a globular tumor could be felt in the hypogastrium, which slipped readily from side to side. The tumor was about the size of a large grape fruit, irregular in contour, elastic, not tender to pressure. It could be pushed to the left for several inches, when further pressure caused a sensation of tension and pain in the right iliac fossa. It could also be pushed upward, so that it occupied the right hypochondriac region. Attempts to push it further were again resisted by an apparent attachment in the right iliac fossa, and caused pain and tenderness in that region. When the tumor was pushed into the right iliac fossa, no pain was caused. On making deep pressure on the inner side of the right pelvic brim, there was slight tenderness. On coughing, there was no evidence of a hernia in either the femoral or inguinal canals. The right kidney was not palpable, and the tumor could not be pushed below the ribs. No blood count was made, nor was a vaginal examination proposed, owing to the flowing.

In view of the vomiting, apparently of a reflex nature, the absence of constipation or distention, and the presence of a tumor, movable to a certain degree, as if attached on the right iliac fossa; also in view of the absence of fever, tenderness or spasm suggesting appendicitis, the diagnosis of an ovarian cyst, the pedicle of which had become twisted, causing these three attacks of pain, seemed assured. That in one instance, the abdominal manipulation had righted the twist, did not seem improbable, in a tumor of such marked motility. The other two reductions were apparently more spontaneous. The tenderness at the point of origin of the pedicle, which was most probably the right broad ligament, appeared to indicate where the twist had occurred, and that here thrombosed vessels might be found. In view of the ease with which reduction had occurred, with relief of all symptoms, except slight tenderness and vomiting, it seemed as if the cyst could not have twisted more than once or twice. Immediate operation was advised, on the grounds that the tumor might be infarcted, or further twisted at any time, with consequent gangrene, that nothing could be gained by delay, and that if thrombosis occurred, it might become progapated to the vena cava, or to the internal iliac vein.

Operation was done on the morning of Jan. 12, 1904. The previous night had been fairly comfortable. She vomited once, but in the morning felt well enough to walk upstairs, and was free from pain, though the abdomen was somewhat tender. For the first time, she had a temperature of 100 F°.

On opening the abdomen, just inside of the right rectus, the intestines were found collapsed, and an infarcted ovarian cyst at once presented, in a moderate amount of fluid, containing a few fibrin flakes. The tumor was dark purplish, tense and shiny. It was seen to spring from the right broad ligament, the tube being continued over it. The twist had occurred immediately after the tube and ovary left the uterus. The round ligament was slightly involved in the rotation. The tube had also been twisted, and was of a deep violet color. It was found that the tumor was rotated one and three-quarters times on its axis, the rotation being towards the median line. The ovarian vein was ligated, and the tube and ovary removed, cutting the narrow pedicle close to the uterus. The ovarian veins, and those in the broad ligament were found thrombosed, at the site of the twist.

On examining further, a similar tumor, about as large as a medium-sized orange, was found to involve the left ovary. This tumor was the color of an ovarian dermoid, and was not infarcted. The tube was not enlarged. It was decided, owing to the age of the woman to leave a small amount of ovarian tissue, which was dissected off from the base of the ovary. No ligatures were used, but the few bleeding points were controlled by a continuous chromic catgut suture. The uterus was small, and in normal position.

Recovery from the operation was entirely satisfactory, and the patient made an uninterrupted convalescence. Had a vaginal examination been possible, the left ovarian tumor, which lay beneath the one with the twisted pedicle, could easily have been discovered. Of especial interest in this case are the repeated reductions of the torsion, which, together with the physical examination, gave a perfectly definite clinical picture, on which to base the diagnosis.

Pathological Report of Specimens sent to Dr. W. F. Whitney, consisting of a cystic tumor of each ovary:

First, a tumor the size of an orange, with a thin wall; the sac containing sebaceous material and hair, and the inner surface lined with a cutaneous membrane.

Second, a cystic tumor, the size of a grape fruit, of a dark blue color, with evident infiltration of the walls with blood. On section, it was found to be chiefly composed of a single cyst, with papillary projections from one side.

Diagnosis: Simple dermoid cyst of one ovary, and papillary cysto-adenoma, with infarction of the other.

Medical Progress.

PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D., BOSTON.

MANAGEMENT AND CONTROL OF INFECTIOUS DISEASES.

TUBERCULOSIS IN ENGLAND.

NEWSHOLME[1] notes the following as the measures which are at present contributing to the extinction of tuberculosis in England,

A. Means of ascertaining the existence of the disease.
   (1) Bacteriological diagnosis.
   (2) Notification of cases, voluntary or obligatory.

B. Direct preventive measures.
   (1) Law against expectoration in public places.

[1] Journal of Hygiene. Vol. iii, No. 4, 1903.

(2) Disinfection and cleanliness.
(3) Sanatoria.
(4) General Sanitary Improvement.

C. Education of the public and of patients in the importance of the foregoing measures.

The author also discusses the relation of the food-supply to the prevalence of tuberculosis, and shows that while the price of wheat diminished from 775 pence per quarter in the five years (1838–42) to 343 pence in the five years (1896–1900), the death-rate from phthisis declined from 3,880 per million to 1,321 per million in the same time.

ORIGIN OF PULMONARY TUBERCULOSIS.

Behring[2] insists upon the identity of human and bovine tubercle bacilli, and urges that the chief source of pulmonary tuberculosis occurring at any time during life is from infection through the milk taken in infancy, whether the tubercle bacilli in the milk are of human or bovine origin. The presence of a coughing consumptive in a family often results in the infection of the infants by inhaling the germs, or by their getting into the milk, or upon the vessels used. This is the secret of the so-called heredity and predisposition to tuberculosis in the members of a family. The infection is post-genital, not inherited. It may remain latent for years or for life, but under predisposing conditions it may develop into pulmonary tuberculosis which is thus traced to infection in infancy.

TUBERCULOSIS IN PRISONS.

Schaefer, of Munich,[3] found in a Bavarian prison that 13% of the prisoners admitted were suffering from tuberculosis. Almost half of the prisoners were also suffering from some form of tuberculosis. Schaefer lays special stress on the food as a vehicle for the transference of the bacilli into the body. He found cultivable tubercle bacilli in the cooking dishes, even after the dishes had been washed. He recommended the isolation of the sick from the healthy, the provision of country colonies for tuberculous prisoners, together with absolute cleanliness.

Theodor, commenting upon the same topic, states: (1) that prisons favor a rapid form of phthisis. (2) The tendency to spontaneous cure found outside is not noticed in prisons. (3) They favor in a high degree the continuance of epidemics of tuberculosis.

INFECTION BY THE BREATH.

Koeniger[4] refers to the projection of bacilli from the mouth while in the act of speaking, such bacilli having been placed in a fluid with which the mouth had been washed. The higher the note uttered the more bacilli were found in the air of the room used for the experiment. No bacilli were found in the air of the room, one hour after speaking.

[4] Deutsche Vierteljahrs. f. off. Gesundheitspflegen Supplement, 1902.

ADVANTAGES OF TREATMENT IN SANATORIA.

Parkes[5] enumerates the advantages of sanatoria treatment for consumptives as follows:

(1) The public health would benefit by the withdrawal from among the general population of active foci of disease. A reduction in the prevalence of consumption would ensue when the system is thoroughly established.

(2) The sanatorium treatment made available for sufferers in the early stages of the disease would restore to health and activity a certain proportion of those who under present circumstances succumb.

(3) In the event of a patient being discharged relieved, but uncured, or in the event of a recurrence of the disease after discharge, the precautionary habits acquired by the patient whilst under treatment would largely tend to prevent during his illness the diffusion of infection which would otherwise occur in his own home and place of occupation.

THE SOURCE OF INFECTION IN TUBERCULOSIS.

In a paper upon this subject presented by Dr. S. Davies[6] of Woolwich, England, at a meeting of the Society of Medical Officers of Health, much stress was laid both by the author and by those who took part in the discussion, upon the excessive prevalence of tuberculosis among drunkards, and the probability that infection among them often occurred in consequence of the exceedingly filthy condition of the floors of public-houses or saloons which they frequented, where spitting upon the floor was a very common practice.

PROPHECIES RELATIVE TO THE EXTINCTION OF TUBERCULOSIS.

Dr. Hillier[7] in a paper entitled "The Probable Extinction of Tuberculosis," predicts its extinction in England and Prussia, within "about a generation," and shows, by means of a chart, the rate of decrease in each country.

Dr. Newsholme[8] also in a paper entitled "Public Health Authorities in Relation to the Struggle Against Tuberculosis in England," says, "There is, I believe, more hope of the almost complete extermination of tuberculosis than of any of the acute infectious diseases, with the possible exception of typhus and smallpox."

Again Professor Von Behring[9] expresses "his firm hope and belief that all hospitals and homes or shelters for consumptive patients will become unnecessary in future through the same means which Jenner used to render smallpox hospitals superfluous in the past."

At the present rate of decrease in the mortality from phthisis it does not seem at all improbable that in the next half century, the many sanatoria now peopled with consumptives may be needed for a different class of sufferers, possibly those who are suffering with cancer, since cancer

[9] Report of Seventy-fifth Annual Meeting of Philosophers and Biologists at Cassel, 1903.

appears to be steadily increasing, while phthisis is tending towards extinction.

These facts, however, should only be the incentive to greater exertions to hasten the eradication of a disease which has produced and is still producing a large share of the general death-rate of the population.

After the crusaders had returned from the East in the twelfth and thirteenth centuries, there was scarcely a town in continental Europe in which leprosy did not exist, but great numbers of lazarettos were established in which the sick were isolated, and now the disease is almost unknown in Europe, except in Norway.

EBERTH'S BACILLUS IN THE BLOOD IN TYPHOID FEVER.

Courmont and Lesieur [11] demonstrated the presence of Eberth's bacillus in the blood in 37 cases, in all of which the attacks were of moderate severity, from the first few days up to the end of the third week.

OYSTERS AND TYPHOID FEVER.

In an examination of the population of the English district of Southend-on-Sea, Nash [12] found in a population of 33,000 that 250 were regular shellfish-eaters all the year round, this number increasing in the oyster season to 1,500. Among the shellfish-eating portion the typhoid attack-rate was 51.25 per 1,000, and in the non-shellfish-eating portion it was only 0.75 per 1,000. Among employees of shellfish dealers the percentage of attack was 160 per 1,000.

THE BACTERIOLOGY OF BANK-NOTES.

On account of the liberal use of bank-notes of small denominations in Greece, Cumulis [13] submitted bank-notes to experiment, and came to the following conclusions: (1) When the cholera spirillum was scattered upon a dirty bank-note and exposed to dry air, the spirillum died in fifteen to twenty minutes. (2) On a clean note, covered with glass, but exposed to daylight, it lived forty minutes. (3) On a note placed in an envelope the life of the spirillum may be prolonged to sixty minutes, but not more. Koch and Kitasato found that the cholera spirillum lived as long as three hours when dried in air. Cumulis explains this by the fact that their experiments were made on glass and not on paper, and in air moister than that of Greece.

FLIES, TYPHOID FEVER AND SUMMER DIARRHEA.

Martin [14] says: "Each succeeding year confirms my observation of 1898 that the annual epidemic of diarrhea and of typhoid is connected with the appearance of the common house-fly, which becomes very numerous at the beginning of July, and breeds chiefly in privy-middens. The increase and decrease of the annual diarrhea and typhoid epidemic can be foretold with a great degree of accuracy, an increase in the diarrhea cases occurring in a week, and typhoid notifications in three or four weeks after an increase in the number of flies is observed. The annual epidemics of these two diseases begin and end with the appearance and disappearance of the domestic fly."

HOSPITAL ISOLATION OF SCARLET FEVER PATIENTS.

The practice of isolating patients ill with scarlet fever in hospitals designed for this purpose, having been vigorously attacked by three British medical officers, Drs. Marriott, Millard and Fraser,[15] the subject was discussed by the Society of Medical Officers of Health, and the following resolution was adopted by the Society, at the suggestion of Dr. Fraser:

"That in the interests of public health, and in view of the large sums expended annually upon the hospital isolation of scarlet fever, it is, in the opinion of the branch, advisable that a full and searching inquiry into the whole system be held."

The general opinion of the sanitary officials who participated in the discussion was in favor of such hospitals, and opposed to the statements of Dr. Fraser. In Portsmouth, to which most of Dr. Fraser's statements had reference, about 60% of all reported cases are isolated.

The editor of *Public Health* also, in commenting upon Dr. Fraser's address, differs in opinion from him, regarding the isolation hospital as a necessity *pro bono publico*, and any failure of the system is due "largely to defective administration. . . . We must confess to surprise that this was not made the basis of the demand for an inquiry. To our mind, that is the true conclusion to which all the papers on the subject point. But what does it mean? It means the indictment of the local authorities and their advisers for faulty construction and mismanagement. Hospitals play a very important part in the methods at our command for dealing with infectious diseases, and the sooner the administration of those which are defective is put on a proper and efficient basis the better it will be."

[No reference appears to have been made in this discussion to the matter of improper or inefficient notification. In every large city where hospital isolation is provided, a considerable percentage of those attacked, living in well-to-do families, are treated in their own homes, and while isolation is required it may be of a very different character from hospital isolation. Again, very many cases, mild in character, but still quite as infectious as severe cases, are treated in families without the attendance of a physician, no notification being made. (But the law requires it as much of the householder as of the physician, in Massachusetts.) And, lastly, cases are not rare in which the disease is entirely unrecognized. All these classes may, and undoubtedly are, fruitful means of the spread of infection, so that it is difficult to estimate the actual value of a system

which is from the nature of the case imperfect in its application.]

CONFIRMATORY CULTURES IN DIPHTHERIA.

Dr. J. S. Billings, Jr.,[16] finds that, while in a certain percentage of cases the diphtheria bacillus fails to appear in the first cultures, the failure is generally due to a conjoined infection with the septic micrococci. Aside from these cases, the statement that the case is probably not diphtheria can be made on one negative culture up to the tenth day of the disease. Valid reasons for requesting a confirmatory culture in negative cases are: (1) When there is no growth whatever on the culture media. (2) When there is complete contamination and liquefaction of culture media in cases which are clinically diphtheria. (3) Cases where there are suspicious bacilli. (4) In croup cases where the membrane is limited to the larynx and the duration of the disease is less than five days. Dryness of culture media, scanty growth, and the recent use of antiseptics with satisfactory growth of other organisms than the diphtheria bacilli, do not alone furnish sufficient grounds on which to request a confirmatory culture.

CEREBRO-SPINAL MENINGITIS.

In two German regiments at Homburg and at Darmstadt, there were 1,900 cases of epidemic cerebro-spinal meningitis. The diplococcus of Weichselbaum was found in three cases, once in the nasal mucus, once in fluid obtained by lumbar puncture, and once in the post-mortem exudation. At Homburg the barracks were overcrowded. Emptying them, disinfecting and cleansing them, seemed to stop the epidemic. The disease was also prevalent among the civil population at the same time.

UNCINARIASIS IN MINERS.

The International Congress of Hygiene at Brussels [17] voted in favor of: (1) Complete medical inspection. (2) Declaration of cases. (3) Provision of suitable latrines, both above and below ground, and of dressing-rooms and baths. (4) Cleansing of the soil and ventilation. It may be noted that disinfection — in Germany with milk of lime (whitewash) and in Belgium with cresols — has been used with partial success as secondary to the hygienic regulations as to the care of excreta, water-supply, baths, change of clothing, and supervision.

THE CONFLICT WITH MALARIA (ROBERT KOCH[18]).

It is stated that when, ten years ago, the author was face to face with the combat with cholera, it was recognized that the preventive measures must be directed against the germs which could in every case be demonstrated by bacteriology to be the active agents in the spread of the disease. When he had time to turn his attention to the diagnosis of malaria, he found in a similar way that the blood was infected with a parasitic organism easily destroyed by quinine, which, although it was wholly different from that of cholera, might be attacked and dealt with on a similar principle; and, by means of his experiments at New Guinea, he satisfied himself not only that it was possible to destroy the malarial parasite in human blood, much in the same manner as in the case of the cholera germ; but also that the active agent of malarial diseases was capable of existing only in man and in certain insects of the gnat tribe, and was not to be found in any other organism. This rendered it possible to undertake the necessary preventive measures which have been adopted with complete success. Accounts are then given of the conflicts with malaria at Brioni (Istria) by Prof. P. Frosch, and at Puntacroce by Dr. Bludau. A report is printed of the malaria-expedition to German South West Africa by Dr. Vagedes, and descriptions follow of the conflicts with this disease at Daressalam by Dr. Ollwig, and in the Tuscan Maremma by Dr. B. Gosio. This last investigator declares that only time and a sufficient supply of quinine are needed to stamp out the disease. Dr. E. Martini treats of the precautions taken to avert an outbreak of malaria at Wilhelmshaven, and Mr. Dönitz gives an account of the various species of the anopheles which serve to spread the disease in the different countries where the question has been actively studied. All these essays are illustrated with maps and diagrams.

CAISSON ILLNESS AND DIVER'S PALSY. MODES OF PREVENTION.

Hill and Macleod [20] report the results of experiments and observations relative to this form of illness.

They believe that by proper choice of men (healthy young men, eighteen to twenty-six years old, and not too stout) and regulation of the shift and decompression period, work can be carried out without loss of life at a depth of even 200 ft., *i. e.*, about seven atmospheres, or +100 lbs. pressure.

They also conclude : that the circulation is unaffected mechanically by compressed air, that the cause of caisson disease is the escape of gas bubbles in the blood-vessels, and tissue fluids on decompression. An animal exposed four hours to eight atmospheres of air and quickly decompressed is like an opened bottle of soda-water. The fluids of the body generally effervesce. Recompression causes the bubbles to go into solution, and if applied quickly enough the circulation recommences. The varying symptoms of caisson-sickness are due to the varying seat of the air emboli.

Young men escape caisson-sickness owing to the elasticity of their tissues, and greater facility for collateral pathways of circulation.

Animals can be safely exposed to eight atmospheres of air for four hours, if two hours be spent in gradual decompression. Such exposure can be safely repeated three times a week. By the

choice of suitable men, and proper regulation of the period of compression and decompression, caisson and diver's sickness can be avoided.

One of the earliest American papers upon this subject was presented by Dr. R. T. Davis of Fall River at a meeting of the Councillors of the Massachusetts Medical Society, Feb. 2, 1876.[21]

DISINFECTION.

THE DISINFECTING POWER OF HOT SODA SOLUTIONS.

According to Simon [22] the bacteriological methods of research have rendered it possible to assign very definite limitations to the activity of a number of substances employed as disinfectants, and have made it evident that, owing to the varying degrees of resistance possessed by different species of bacteria, there is a wide range of usefulness for many of the materials which have been proposed for this purpose. The author thought, therefore, that it might be expedient to ascertain how far the common washing soda, used in nearly every household, was capable of being employed for disinfecting the dwelling-house. Reference is made to some previous experiments by Jaeger, Förster, Behring and others. The present tests were mainly directed to ascertain the action of hot solutions of soda of various degrees of concentration on the pathogenic organisms likely to be encountered in dwelling-houses; as, for instance, the diphtheria bacillus, the different kinds of cocci (Staphylococcus, Streptococcus, etc.) and tuberculous sputum. Bouillon-cultures of all these germs were dried on to silk threads and were exposed to the action of 2%, 5%, 10% and 20% solutions of soda. The threads were steeped in the solutions which had been raised to various temperatures from 22° C. to 62° C., for periods which ranged from one minute up to sixty minutes. Tests were also made by infecting different polished surfaces of furniture, flooring, leatherwork and linoleum, which were then treated with a 5% solution of soda at a temperature of 60° C. In a similar way experiments were conducted with tooth-brushes, combs, hair-brushes, kitchen utensils, etc.; also with secretions, such as sputum, pus, etc. Full details are given of all the tests, and the results are tabulated. The author states that even in dilute hot solutions (60° C. to 62° C., such as are employed in the kitchen and laundry), soda is a safe and reliable disinfectant and it is also extremely cheap.

THE STANDARDIZATION OF DISINFECTANTS.

Rideal and Walker [23] say the makers of genuine disinfectants have to compete with others whose preparations are not only worthless, but actually dangerous, while the use of such products gives rise to a false sense of security. The public should know that disinfection — the killing of disease germs — is by no means a simple operation, and the control of disease by this means should form a part of the routine work in every sanitary area under the direction of the board of health. He therefore argues for a bacteriologic test, the details of procedure to be agreed upon beforehand by different investigations, the following factors to be considered: (1) Time; (2) age of culture; (3) choice of medium; (4) temperature of incubation; (5) temperature of medication; (6) variations in vital resistance of same species; (7) variations in vital resistance of different species; (8) proportion of culture to disinfectant. He suggests pure phenol as a standard, since it has marked advantages over a metallic salt. Similar work [24] has been accomplished by the American Public Health Association.

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE.

STATED meeting, March 17, 1904.

THE President, ANDREW H. SMITH, M.D., in the chair.

The meeting was under the auspices of the Section on Ophthalmology of the Academy, DR. ALEXANDER DUANE, Chairman. The subject of the evening was

THE EYE IN ITS RELATIONS TO FUNCTIONAL NERVOUS DISEASE.

DR. CHARLES L. DANA read a paper on

MENTAL DISTURBANCES PRODUCED BY EYE-STRAIN.

He said it would perhaps be more strictly accurate to announce his title as "Eye-strain and the Psychoses." The term eye-strain was not found in works on psychiatry, but it was a convenient word and one which had become popular. There were two forms. The first, which was eye-strain proper, was of mild gravity and sub-cerebral in its operation. The second was more serious in character, and the cortical centers were involved. This effect might not be distinctly recognized, but it really constituted a brain-strain. It seemed to him that it was only this kind of strain that could work any serious injury. The possible disturbances attributed to ocular defects, he thought of no serious import, since nature provided ample compensation, just as in the case of a leaky heart.

Two groups of psychoses were recognized. In the first were the grave cases, insanity. In the second were included all the minor psychoses, such as hysteria, impulsive acts, sexual perversions, hypochondriacal manifestations, melancholia, etc. At the St. Lawrence State Hospital for the insane the experiment was made of treating the patients by attention to eye defects, but without success. So also at the Willard State Hospital, and here, likewise, no benefit resulted. Dr. Dana then referred to the negative results of the investigation, sixteen years ago, by the Stevens Commission of the New York Neurological Society, of which he was a member. In certain secondary schools for boys he had found cases of a kind of exhaustion psychosis resulting from close application to study. The scholars appeared to be markedly apathetic and depressed, and lost their interest even in out-door sports. No serious results occurred, however, and prompt cures were reported. We believed that such instances were rare and that ordinarily eye-strain was attended only by such mild manifestations as headache, etc.

After watching carefully for twenty years, he had

found scarcely any cases in which eye-strain has proved a source of any serious trouble. When the mind of the individual was a good one, the eye-strain had but little effect. Perhaps, after all, the most interesting psychosis connected with it was that which had prevailed among a certain class of oculists. It was a fact, however, that psychoses are increasing in a marked ratio among the community, and new combinations were constantly arising which ought to be carefully studied and wisely prescribed for.

Dr. Colman Ward Cutler read a paper on

HEADACHE, MIGRAINE, AND OTHER SENSORY DISTURBANCES PRODUCED BY EYE-STRAIN.

It was principally devoted to a consideration of migraine, or sick headache, which, he said, was considered a distinct disease by some. In the *modus operandi* of its production great stress was laid by some writers upon the agency of the eye, while by others this element was practically disregarded. Perhaps the true solution of the question was to be found in a happy medium between these two views. Among the characteristics of the affection were periodicity and heredity. In different members of a family in which it was present it was attended by the same special phenomena. It naturally presented some features which were common to it and epilepsy, and it had been regarded by some, more particularly the French authorities, as practically identical with that disease. It could easily be shown, however, he thought, that such was not the case. Thus, while epilepsy was unquestionably more common in families with a bad history, such as alcoholism, etc., the opposite of this was apt to be true as regards migraine. Again, while many cases of migraine were relieved or cured by appropriate eye treatment, this was not the fact with epilepsy.

The influence of heredity should be fully recognized in migraine as it was fairly constant. At the same time it was undoubtedly true that it was often a reflex neurosis of ocular origin. It had been contended by many that there was such a thing as idiopathic migraine, but as a rule the affection could be traced to some peripheral irritation, and, in the treatment, should be approached from the periphery. There were a certain number of cases, however, which were of unknown origin, and which persisted in spite of all treatment. In these it was often necessary to depend on morphine as a palliation at the time of the attack. Still, in some instances, after persisting for a long time, the disease finally yielded to treatment. Migraine being then, for the most part, a reflex neurosis, all avenues should be tried in turn in order to discover, if possible, the source of difficulty. Not infrequently cases were met with in which the objective symptoms were found to be not dependent on the eyes. The site and character of the headache, it was to be remarked, was of little diagnostic value. Often a dull pain followed upon eye-work.

Migraine, he thought, should be studied from a statistical point of view. Recognizing the tendency in some quarters to associate migraine with the graver forms of nervous trouble, such as epilepsy, Dr. Cutler had made inquiry of Dr. Spratling of the Craig Colony for Epileptics, as to the prevalence of migraine among the patients at that institution, and he had received the reply that it was exceedingly rare.

Dr. B. Sachs read a paper on

THE RELATION OF EPILEPSY, CHOREA AND OTHER MOTOR DISTURBANCES TO EYE DISEASE.

He said that the branch of the subject assigned to him had to do with motor phenomena principally. He might quote statistics almost indefinitely, but statistics could be juggled so as to mean almost anything that one wished. In the first place, he could assert with positiveness that the dependence of the motor neuroses on the eye had been greatly exaggerated, and that however few the instances of this might be, the cases that had been cured by oculists were fewer still. This dependence, it was well known, was chiefly maintained by a certain variety of oculists and pseudo-oculists. By the Stevens Commission of the New York Neurological Society fourteen test cases were thoroughly investigated, and not a single one of them was a case of epilepsy. His experience since that time had borne out the conclusions arrived at by the Commission. The advocates of this doctrine had written and talked a great deal, but such evidence as they had presented seemed to him wholly unsatisfactory. Their great aim seemed to be to impress the general practitioner with the importance of their views, and the general practitioner had too often fallen a victim to them. In an article published in a prominent medical journal Dr. A. L. Ranney had reported a series of cures by eye muscle cutting in cases of grave nervous disease such as epilepsy, and one of the patients, according to the writer, presented the symptoms of cerebral softening. Yet there was not a single one of these reported cases which would stand the test of scientific investigation.

In a recent annual report of the Craig Colony for Epileptics, Dr. Spratling stated that under the advice of Drs. Gould and Bennett 68 of the patients (all but one of whom suffered from astigmatism) had been fitted with glasses, and it was hoped that much benefit might be derived from this treatment. Yet in the next annual report of the institution it had to be acknowledged that in all the 68 cases there had been improvement, and that but slight, in only one. Notwithstanding this brilliant result, Drs. Gould and Bennett still persisted in their opinion that epilepsy might be successfully treated by proper attention to the eyes of the patient. All authorities were agreed that true epilepsy is a serious affection of the central nervous system, that it persists for years, and that it shows a tendency to become aggravated and end in grave degenerations. Only a small proportion of cases could be cured by any known method of treatment. At the Craig Colony it had been demonstrated that, as a rule, the mode of life there enforced was more successful than anything else in bringing about an amelioration of the condition.

In order to show that ocular disturbance had any relation to epilepsy it would be necessary, for one thing, to prove that such disturbance had existed as long as the nervous disease. It was quite conceivable to suppose that some peripheral irritation, such as that from a phimosis or a nasal lesion, might cause a single convulsion, or perhaps more than one, but there was no ground whatever for believing that such irritation was a cause of true epilepsy. If the ocular treatment of epilepsy were entirely an innocent affair it might be regarded with composure, but, unfortunately, this was not always the case. In illustration, Dr. Sachs mentioned the case of a gentleman suffering from nocturnal epilepsy who was advised to consult a certain oculist. He did so, and the result of the treatment he received was to give him double vision, which he found to be far more annoying than the epilepsy itself. So general had grown to be the opinion that nervous troubles are dependent on ocular disturbance that private patients were almost universally found to be wearing glasses, and he thought it would be a great advantage to the patient when such erroneous views had been relegated to their merited oblivion.

Again, as regards chorea minor, or Saint Vitus's dance, this was an evidence of very severe disorder of the nervous system, and it was absurd to suppose that ocular or other peripheral irritation was its cause. He had yet to see a single case of chorea cured by eye treatment. A different variety of the affection was what is known as *habit chorea*, in which the choreic manifestation is a twitching of the eye, the sudden elevation of the shoulder, or other similar movement. In all cases of this kind he believed that a careful examination of the eye and the nasal passages should be made. But even here the eye business had been over-done, and too many of the patients were wearing glasses.

Convulsive tic was not unlike habit chorea, but it was a much more serious affection. In this, as in other motor disturbances, the burden of proof was on those who desired to establish the etiological relation of eye trouble. Such relation might be perfectly clear in the minds of some faddists, but they have as yet entirely failed to present any evidence that would have any weight with those who had no axes to grind nor any special field of medicine to exploit.

DR. WARD A. HOLDEN read a paper on

THE EYE SYMPTOMS OF HYSTERIA, NEURASTHENIA AND THE TRAUMATIC NEUROSES.

He cited a number of cases to show the variety of symptoms met with in these cases, some of them simulating the signs of grave ocular disease, such as atrophy of the optic nerve. There were often found functional disturbances of the retina, pain, paresthesia, lachrymation, photophobia and fine tremor of the lids when lightly closed. After reading, the field of vision might be very limited or double. There might be a ptosis of one or both upper lids, but it was easily distinguishable from paralytic ptosis. The pupils were often nearly normal in size and reaction. The ocular muscular spasm might give rise to diplopia. In a case of traumatic hysteria with functional dimness of vision there was uni-ocular diplopia. The acuteness of vision was usually normal, but the patient sometimes made out the distant letters with difficulty. A patient might state that he was unable to read small type, yet when a plain glass, or almost any other kind, was given him he would read it with facility. There might be apparent blindness in one or both eyes. Anomalies of the visual field were most common in hysteria and neurasthenia. In some instances these were to be regarded as evidence of fatigue of the retina, and in others as psychical in origin; while in still others both causes no doubt participated.

Only rarely was there a central defect in the field. The size of the field varied from day to day. The forms of the color fields were often so bizarre that they did not resemble any known lesion. It should not be supposed that these functional disturbances were met with only in young women. They occurred also in strong men; and in conclusion Dr. Holden related a case of pure hysteria, presenting very serious eye symptoms, in one of the mounted police force of the city. The trouble resulted from a fall from his horse, and when last seen, fourteen months after the accident, the man was in perfect health. The only sign that was left of his eye trouble was a slight trembling of the lids.

THE RELIEF OF EYE-STRAIN AND FUNCTIONAL NERVOUS DISTURBANCE.

DR. JOHN E. WEEKS said that observations regarding the relief of eye-strain and the functional nervous diseases might be made along two lines. One, which is perhaps the more extensive, is that of the results that follow the more or less complete relief of eye-strain by the correction of errors of refraction and by the correction of errors of the muscles. The other is the observation of mental disturbances which have occurred as a result of eyestrain, due to *mal-correction* of errors of refraction and to *mal-correction* of actual or supposed errors of the muscles.

The mental disturbances produced by eye-strain are chiefly those that relate to inability to perform mental work, such as conducting business affairs and performing duties which require the use of the eyes. It not infrequently happens that patients complain of loss of memory and inability to concentrate their ideas along any particular line. The sensory functional nervous disturbances that are produced by eye-strain, or, at least, that are remedied by the relief of eye-strain are headache, affecting the whole or any part of the cranium, vertigo in some cases, transient hemianopsia and other defects in the visual field. The motor functional nervous disturbances that may be caused by eye-strain are unilateral facial spasm and spasm of the *orbicularis palpebrarum*, total or partial, clonic or tonic in nature, usually affecting one eye alone, but sometimes both eyes. The motor nervous disturbances that may be alleviated in some cases by the relief of eye-strain are epilepsy and possibly chorea.

Reports of cases occurring in private practice illustrating the results of the correction of eye-strain as affecting the various conditions were referred to, and in conclusion Dr. Weeks stated that his experience had taught him that many cases of inability to perform work requiring the use of the eyes, many cases of headache and some cases of vertigo and of unilateral facial spasm can be completely and permanently relieved by correcting errors of refraction and errors of the muscles; that true migraine can be favorably influenced, but not entirely cured; that the attacks due to epilepsy can often be rendered less frequent by the relief of eye-strain, and that true chorea is influenced but little.

Recent Literature.

The Nutrition of the Infant. By RALPH VINCENT, M.D. Member of the Royal College of Physicians, Physician to the Infants' Hospital, Late Senior Resident Medical Officer, Queen Charlotte's Lying-in Hospital. New York: William Wood & Co. 1904.

In this little book of about three hundred pages Vincent takes up in detail both the natural and substitute feeding of infants and then considers the bacteriology and chemistry of digestion, disorders of the digestive tract and also those of nutrition. He gives a fairly complete resumé of our present knowledge regarding infant feeding. He is a most thorough believer in breast feeding and, if this is not possible, in modified cow's milk as the substitute. He is a strong advocate of laboratory feeding and is evidently one of the leaders in the introduction of the method of percentage feeding into England. This book should do much to raise the standard of infant feeding in that country and to place it on a more rational basis. We agree most heartily with almost all of the author's views on those subjects, but cannot help feeling that in order to emphasize some of his points he has made

many of his statements on mooted points stronger than the facts justify. We notice a mistake in the year in which the first Walker-Gordon Laboratory was estaolished in Boston, 1901, instead of 1891, and regret that we do not possess the Milk Commission with which he credits us. The chapters on gastric and intestinal disorder and inanition, malnutrition and marasmus are not up to the standard of the rest of the book. Those on rachitis and scorbutus are good.

A Text-Book on the Practice of Medicine. Designed for the Use of Students. By James Magoffin French, M.D., Lecturer on the Theory and Practice of Medicine, Medical College of Ohio; Attending Physician, St. Mary's Hospital; Consulting Physician, St. Francis Hospital for Incurables, Cincinnati. Illustrated. New York: William Wood & Co. 1903.

Dr. French has written a textbook on the practice of medicine, containing 780 pages, which he designs for the use of students, a term which no doubt may be made to include the practitioner as well as the undergraduate, and which is to be preferred to the usual double appeal to the student and the practitioner. Although this volume is somewhat less extensive than many of the recognized textbooks on the practice of medicine, it goes very far beyond an elementary treatise, and discusses concisely, but at considerable length, the important diseases included under the general heading of internal medicine.

In the preface the author remarks that "personal experience has been kept in the background, and the pleasant diversion of case reports has been entirely omitted." This omission is not altogether to be commended. Personal experience is always valuable, and we know of no better way to impress the outlines of disease on the student's mind than by a brief report of actual cases. We are inclined to think that description of disease should in the future give place more and more to an account of the actual occurrences. Conservatism in this matter, however, is still supreme, and narration of cases finds small place in the modern textbook.

The volume is illustrated both by text cuts and by a considerable number of well-executed full-page plates. In the section on the nervous system there is an unfortunate omission of diagrams and cuts, although in no other subject is a graphic representation of processes of disease more useful and more essential to an understanding of the conditions. If economy of space is desired, no better method can be employed than the substitution of diagrams for descriptions in this department. Following the main body of the book a concise chapter is added on clinical methods of examination which should prove useful and practical. The book gives ample evidence of thoroughness in preparation, and no doubt will take its place with the others as a useful guide for students, young or old.

On Syphonage and Hydraulic Pressure in the Large Intestine. By Ralph Winnington Leftwich, M.D., Late Assistant Physician to the East London Children's Hospital. New York: William Wood & Co. 1903.

This entertaining little book of eighty pages calls attention to the similarity of the larger intestine to a siphon, and explains many physiological and pathological phenomena from this standpoint. Emphasis is also laid upon the hydraulic principles which are exemplified in the arrangement of the ileum, cecum and colon. Syphonage and hydraulic pressure offset the large intestine's feeble peristalsis and are rendered effective by the tonic contraction of the longitudinal bands of the large bowel which hold it rigid. Erect position favors syphonage, as experience teaches.

The discussion of constipation, typhoid fever and appendicitis in the latter part of the volume is not particularly instructive.

A Short Practice of Gynæcology. By Henry Jellett, B.A., M.D., B.Ch., B.A.O. (Dublin University), F.R.C.P.I., L.M., Ex-Assistant Master, Rotunda Hospital; Externe Examiner in Midwifery and Gynecology, Royal University of Ireland; Examiner in Midwifery, Royal College of Physicians, Ireland; late University Examiner in Midwifery and Gynecology, Dublin University. Second edition, revised and enlarged, with 223 illustrations. London: J. & A. Churchill. 1903.

This is a book of 406 pages, well printed and illustrated but poorly bound. The author has used good judgment in handling his material, and, with a few exceptions, has included little useless matter and has brought into prominence the important topics. His plan of placing at the beginning of each section the Greek and Latin derivatives from which the different diseases and operations take their names is to be commended as making clearer the meaning of the terms.

The author leaves out extra-uterine pregnancy on the ground that this affection belongs to the domain of obstetrics; this is to be regretted.

The chapters on cancer uteri and diseases of the ovaries, also those on diseases of the pelvic peritoneum and uterine ligaments, are to be especially commended for clearness and conciseness. The figures on the different sorts of genital atresia (pages 217 and 218) are original and give a good idea of the conditions, but it is a question whether it is wise to leave out the customary account of the embryological development.

The portion of the book devoted to gynecological operations is in the main up to date and clear; the aseptic technique, however, does not reach the high standard we in America are accustomed to find in our textbooks. There is no doubt but that this book will prove popular among students and practitioners.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, APRIL 7, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

AN EXPLOSIVE OUTBREAK OF TYPHOID FEVER.

ABOUT five miles before reaching Hamburg the River Elbe divides into two arms, the Northern and Southern Elbe, which reunite below the city, enclosing thus the very considerable island of Wilhelmsberg, some ten square miles in area, of which a plan and a description are given by Bachmann and Rattein in a recent article (*Gesundheits Ingenieur*, p. 12, 1903). A peculiar feature of this island is the extent to which it is traversed in all directions by shallow watercourses, filled with abundant marsh vegetation. The rural population inhabiting this area are for the most part housed under very insanitary conditions, which are herein described. Among the 20,000 inhabitants, diarrhea and typhoid fever are usually prevalent every year during the summer months, but in July, 1902, in the Reiherstieg district, a violent outbreak of typhoid fever, which involved 44 families living in two double blocks of dwellings, made its appearance and occasioned in all 61 cases of illness, of which an account is given. The water-supply was at first regarded as free from suspicion, as the water for all the 44 dwellings was drawn from one tube-well of good construction, some fifty feet in depth, but the water was found on examination by the Hygienic Institution of Göttingen to be infected. It is shown that, owing to the imperfect construction of the joint of a pump by means of which the water was drawn from this tube-well, it had become possible for a leakage to take place of very filthy water from a drain which ran close by, and by this means the water had become so polluted that no less than 480,000 germs per cubic centimeter were found in the pump-shaft. After thorough disinfection the numbers sank to very insignificant proportions, and indicated that the water of the well was in itself of good quality. It was not possible to demonstrate, by actual cultivation-tests, the presence of the typhoid-fever bacillus, but the condition of the water before and after discovery of the defective joint left no doubt that the outbreak was attributable to this cause.

THE DISINFECTION OF DWELLINGS.

IN a recent paper by Kister & Mathes[1] upon the Disinfection of Dwellings, attention is directed to the increasing use of formalin, which, whether employed as vapor or spray, is gradually taking a very prominent place among the disinfectants available for use in dwelling-houses. In those cases in which it becomes necessary to undertake a very searching and complete disinfection, the use of a fluid medium, with which all exposed surfaces can be saturated, and which can be forced into all chinks and crevices, is greatly to be preferred, and hence, in addition to treatment with vapor or solution of formic aldehyde, some mechanical process of scouring with hard brushes, or rubbing down with bread, is resorted to. In the case of floors and painted surfaces, the employment of abundant scrubbing with soft soap and dilute carbolic acid is also needful. As a valuable aid to internal disinfection, the authors explain the construction and use of the portable apparatus invented by Mr. Zorn, and they give the results of certain practical tests carried out in two of the rooms of the Hygienic Institute of Hamburg, one of which was treated in the ordinary way, and one of which was disinfected by means of the above apparatus. The test-substances employed were in each case as follows: Staphylococcus pyogenes aureus, Bacterium coli, Bacillus diphtheriæ, tuberculous sputum, and spores of highly resistant potato-bacillus. The rooms were of nearly equal size, and while the one dealt with on the old system needed the work of three men for two hours and thirty-five minutes, the disinfection of the other room by means of the new apparatus took the same staff only twenty-five minutes, and involved the use of a smaller quantity of carbolic acid solution. By means of diagrams, the mode of employing the spray appa-

[1] Gesundheits-Ingenieur, March 10, 1903.

ratus is explained, and the results of the process in each room are set forth in tables. In the former case 87.5% of the germs were destroyed, and in the latter 88.2%, but the saving in time was very considerable. In neither instance was the disinfection perfect, and some later experiments herein described gave very similar results.

PULLMAN CARS AND MONEY, ROOTS OF EVIL?

It is rumored, and we sincerely trust with authority, that the manufacturers of Pullman cars are awakening to the fact that ornateness of decoration is no longer desirable. Apparently, this change of heart has come about through a regard for the health of the passengers, rather than through merely esthetic considerations. However this may be, the reform will be welcome from every point of view. Plain severity is to take the place of the overdone ornamentation with which we are all familiar, and there can be no question that both the comfort and the health of passengers will be subserved thereby. It has long been a source of wonder to us why, in the crowded space of the ordinary car, every effort should be made to make the space seem still smaller by meretricious ornamentation, unnecessary, and therefore in bad taste.

It has been a somewhat gradual process for the public to recognize the possible dangers lurking in those situations where dust is allowed to collect in large quantities. When such convictions have finally been reached, it is the usual experience that the reformers go to extremes in their attempts to remedy the evil. While recognizing fully the possibility of danger in the ornate decorations of the Pullman car, we are inclined to think that the risk has been exaggerated.

The complete education of the public in sanitary matters is proverbially difficult. On the one hand there is the possibility of minimizing dangers, and on the other the almost equally disastrous tendency of finding danger where none exists. Our experience with tuberculosis in the last few years has been an example of just this difficulty. It has been eminently desirable to impress upon the public the danger of contagion; on the other hand the public evidently has taken the matter with undue seriousness, leading in certain states to restrictive laws which neither can nor should be enforced, and to conditions of fear which certainly do not conduce to the public health. The same may in a general way be said of bacteria of other varieties. If all that was said of these hidden dangers were true, our peace of mind would be wholly at an end. Fortunately, common sense, aided by increasing scientific knowledge, ultimately saves the day.

Commenting on the dangers supposed to exist in dirty money, the *Medical Press* makes the following pertinent remarks:

> It is really time that some check were put upon the scaremongers who daily and hourly face the public with some fresh disaster arising from the invisible evil germs that lurk in every corner of the earth, civilized or savage. Kissing, hand-shaking, hair-cutting, the consumption of unboiled water, oysters or milk, the reading of library books, all, in short, that makes life tolerable, is sternly forbidden by the anti-bacterial maniac, on the ground that the man in the street may by abstinence avoid the evil day. It would be easy to show, however, that the scaremonger, in reality the mildest of Fleet Street journalists, directs his appalling onslaught merely on popular points. Were he consistent, his range of possible microbial infection is so wide that to avoid the malevolent germs man would be no longer able to eat, drink, walk, sleep, smoke, swim, or come into contact with any object in earth, air, sky, or sea. The latest fad is that money should be disinfected. It must be at once admitted that coin in the course of circulation becomes charged with many micro-organisms, good, bad, and indifferent. Now and then it may doubtless convey the infection of disease, more especially if the owner be incautious enough to introduce it into his or her mouth. In the vast majority of cases it is harmless, and a large proportion of the population of the United Kingdom would willingly run the risks of prolonged and continuous contact with any amount of coin of the realm. If coin is to be disinfected, so should door-handles, hand-rails, omnibuses, railway-carriages, penholders, pencils in post-offices, postage stamps and a countless host of things that might act as public distributors of germs. There is more to be said for the disinfection of paper money, but even that seems to be a mere "counsel of perfection." Meanwhile, there are plenty of real microbial dangers apart from the bogus scares of the bacteria-mongers.

On the esthetic side no doubt clean money is wholly desirable, and any means tending to its wider circulation should undoubtedly be encouraged. The same is true of the ornamentation of the sleeping car. It is, therefore, desirable that physicians in general should impress upon the public, so far as may be, the desirability of care in all matters relating to personal or public hygiene, but it is also imperatively necessary that they should not magnify into positive dangers what simply are inconveniences, discomforts and esthetic annoyances.

SOMETHING ABOUT SHOES.

WHILE the primary object of a medical society is to stimulate interest in medical matters among its members, societies of influence can command the attention of a larger audience than that limited to their members. If deliberate consideration of selected subjects is arranged by influential medical organizations and carefully reported upon by competent critics, such reports cannot fail to have weight in the community.

Some of the work of the Boston Society for Medical Improvement, one of the oldest medical societies in the country, may illustrate this fact. The reports and meetings organized by the Society to discuss medical education, the evil effect of street dust, the health of school girls, smallpox and vaccination, the pathology of smallpox, blood pressure and surgical shock have excited much more than local interest, and have been quoted and referred to extensively.

The subjects of scoliosis, of tuberculosis and of antiseptic details have been recently carefully considered. At the next meeting of the Society (announced in another part of the JOURNAL) the subject of "Shoe Deformities and Shoes" is to be presented. If all the members of the profession who have suffered and are suffering, or who are about to suffer from the ills due to faulty shoes attend the meeting, which is to be an open one, one to which all physicians are invited,— there will be no lack of a sympathetic audience to stimulate the speakers and to absorb information which may be of service to many people.

MEDICAL NOTES.

PATHOLOGICAL EXHIBIT AT THE ST. LOUIS FAIR. — Under the general direction of the American Medical Association a pathological exhibit will be provided for the St. Louis Fair, covering the fields of pathology and bacteriology.

ENDOWMENT FOR MEDICAL EDUCATION. — It is announced that Sir Donald Currie has given £100,000 to University College of London, available on its incorporation with the University of London. A new building will be erected on land which has been procured, but the exact way in which the gift will be expended has not yet been determined upon.

MEASLES IN PHILADELPHIA. — It is reported that there are upwards of 3000 cases of measles under treatment at the present time in Philadelphia, and that during a recent week seventeen children died from the disease. Attention is called to the fact that the disease this winter has been more serious in its results than scarlet fever, due in a measure to the popular impression that it is a trifling affection.

BULLETINS OF THE UNIVERSITY OF CALIFORNIA. — It is announced that bulletins of pathology are to be issued from the medical department of the University of California under the auspices of the pathological department. It is a matter of regret that original work of merit should continue to be published in special bulletins of small circulation. Excellent as such periodicals may be in themselves, their multiplication, for obvious reasons, is at the present time wholly inadvisable.

MEDICAL RESEARCH LABORATORY IN PARIS. — A new Medical Research Laboratory was opened in Paris on March 21, with comparatively small ceremony, Prof. Charles Richet acting in the capacity of spokesman for the Faculty of Medicine. The laboratory is built within the line of the old fortifications of Paris, and is intended especially for animal experimentation. Every care has been taken that animals may be kept under the best hygienic conditions. The laboratory is to be under the direction of the Faculty of Medicine, the city giving the ground and the Medical Faculty paying the cost of building and equipment. A considerable amount of money was also given by other persons interested.

CHICAGO WATER SUPPLY. — According to the *Bulletin of the Chicago Health Department* the city water is still bad, all stations showing the presence of serious contamination during the last three days of the week. Nearly every sample shows the presence of colon bacilli and an excessive number of other bacteria. This condition is becoming progressively worse, and may be expected to continue for some weeks. The supply from the Chicago Avenue and the C. H. Harrison cribs has been contaminated for more than a week; that from the other stations has been "safe" only one day each.

The number of positive reactions in the Widal test for typhoid fever is double that of last week, showing that typhoid fever is on the increase, as was forecast in the Bulletin of March 5. This, of course, will continue, especially among those who drink the contaminated hydrant water. All water at the present should be sterilized by boiling.

MEDICAL AND DENTAL PROFESSIONS UNITE ON QUESTIONS OF LEGISLATION. — According to the *Medical News* the Chicago Medical Society

and the organized dental profession agree that all questions of legislation and larger public policy relating to medical and dental affairs shall be referred to a committee, to be known as the Committee on Public Relations. This Committee is to consist of ten members, five from each profession. It shall have a chairman and a secretary. Any questions of public policy or public relation affecting either the medical or dental profession, or of legislation affecting directly or indirectly either of them, can be referred to this Committee. It will be the duty of the Committee to carefully consider these questions. It will have the power to recommend either specific action or general attitude to the societies from which the members come as delegates. There shall be an annual meeting of the Committee at which organization shall be effected and continued. Other than this the meetings shall be special, and can be called by the President or by any two members. The officers shall be elected for one year. The method of election of the delegates and the length of their service shall be regulated by the societies which they represent.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon April 6, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 56, scarlatina 19, typhoid fever 2, measles 197, smallpox 0.

A Home for the Aged. — It is announced that through the will of Mrs. Julie H. Nevins, whose husband was formerly of Methuen, Mass., a home for the aged is to be built and sustained at an expenditure of one million dollars. No definite plans have as yet been made as to the site of the proposed building, or whether it will be established within the city limits or in the country. It is to be designed for the accommodation of one hundred persons.

Censors' Examination, Suffolk District Medical Society. — The censors of the Suffolk District Medical Society, officiating for the Society at large, will meet to examine candidates for admission to the Massachusetts Medical Society, at 8, The Fenway, on Thursday, May 12, 1904, at 2 P.M. Candidates should make personal application to the Secretary, and present their medical diplomas, at least three days before the examination. For further particulars, apply from 2 to 3 P.M., to L. R. G. Crandon, M.D., Secretary, 366 Commonwealth Avenue.

Massachusetts Emergency and Hygiene Association. — At the annual meeting of this association, recently held in Boston, Dr. James J. Minot, the president, spoke favorably of the training of women attendants at the Vincent Memorial Hospital, and stated that their services are greatly sought. Dr. Minot was re-elected president; Dr. H. P. Walcott and others, vice-presidents, and Dr. R. G. Loring, treasurer.

NEW YORK.

Dispensary Building of Mount Sinai Hospital. — The children of the late Mayer Lehman, who for nineteen years was one of the board of directors of the Mount Sinai Hospital, have contributed $93,000 for the new Dispensary Building of that institution, which is to be dedicated in perpetuity in memory of Mr. Lehman.

Bequests to Hospitals. — By the will of Maximilian Schaefer, a wealthy New York brewer who died recently, $12,000 is bequeathed to charities, $7,500 of that amount being left to the German Hospital and Dispensary. Mrs. John E. Parsons has contributed the sum of $1,000 towards the permanent endowment of the New York Eye and Ear Infirmary.

A Heavy Pair. — Mrs. Chauncey Morlan, the lesser half of probably the heaviest married couple in the world, died at Huber's Museum, New York, on March 30. At the time of her death she is said to have weighed about 420 pounds, but her husband states that when she was married to him eleven years ago, at the age of twenty, her weight was 582, and that she retained this weight for over ten years. Her height was six feet, one inch. Morlan's own weight he gives at 748 pounds.

Improvement of Raymond Street Jail. — In consequence of its bad sanitary condition, President Darlington of the Health Department recently ordered the old Raymond Street Jail in Brooklyn to be vacated, and the sheriff of Kings County was consequently put to his wits' end to know what to do with the prisoners under his charge. Sufficient influence has now, however, been brought to bear upon the Board of Estimate and Apportionment to secure an appropriation of $20,000, and it is stated that for that sum the jail can be placed in excellent repair.

Public Comfort Pavilion. — In the new De Witt Clinton Park, on the bank of the Hudson between 52d and 54th streets, there is to be

erected the largest, handsomest and most expensive public comfort pavilion in the city. In it there will be baths for both sexes, in addition to the usual equipment of other public comfort stations, and the estimated cost is $50,000. The facade, 132 feet long, will be typically Italian, with a colonnade similar in construction to a pergola, 206 feet in length, which is to be erected directly opposite to it.

DEATHS IN FEBRUARY. — The bulletin of the State Department of Health for the month of February shows that there were 12,749 deaths in the state during the month, an average of about 440 per day. No previous February mortality has ever equalled this, which exceeds by almost 2,000 deaths the average for the month during the past five years. Pneumonia was the chief cause of the increase. An epidemic of influenza has also prevailed during the last three months. An outbreak of typhoid fever dedeloped in Watertown, Jefferson County, and has continued through February and March. Up to the present time about 600 cases have occurred, with 48 deaths. Smallpox, the bulletin states, exists in forty-seven municipalities in the state.

Miscellany.

CIRCULAR OF THE IMPERIAL BOARD OF HEALTH OF GERMANY UPON TUBERCULOSIS.

THE Imperial Health Board has issued a valuable circular for popular distribution, the topics treated being:

(1) What is tuberculosis? In this portion it is stated that 100,000 persons die in Germany from this cause in each year, and one-third of all the deaths at the wage-earning period of life (fifteen to sixty years) are from the same cause.
(2) In what manner does one become infected?
   (*a*) By breathing in the bacillus arising from dried sputum, or by the minute moist drops thrown from the mouth while coughing or speaking.
   (*b*) By the food.
   (*c*) By wounds or abrasions of the skin or mucous membrane (enumerating many of the modes in which this method of infection may occur).
(3) How may one avoid infection?
(4) Advice to those who are specially exposed to infection.
(5) Advice to the sick.

(The cost of this excellent circular is 25 marks per 1,000, less than one cent each.)

THE WATER SUPPLY OF PARIS.

ALTHOUGH some of the newspapers have fallen into the trap laid by the nomenclature often used in France and more generally in Germany, and have announced that an outbreak of typhus fever has occurred in Paris, the fact is, as mentioned by our correspondent early this month, that the outbreak is one of typhoid fever. It began apparently during the third week of February, and the latest returns show that the number of cases under treatment is steadily increasing. The occurrence has given rise to a lively attack by some of the Parisian journals on the body responsible for the administration of the water supply of Paris; one of the newspapers has announced its intention to placard the infected districts with a notice advising the inhabitants to boil all drinking water. On the same day the Municipal Council adopted a unanimous resolution blaming those responsible for administrating the water supply for not notifying the people of the risk they ran. This had been preceded by an announcement from the Prefect of the Seine to the effect that the recent torrential rains "had modified the régime of the water," and recommending all inhabitants of Paris to boil all water used for drinking. Bacteriological examination of the water collected in certain areas is stated to have shown that it contains bacilli which, though not enteric, are of a suspicious character. — *British Medical Journal.*

GLYKON: THE REINCARNATE GOD ASKLEPIOS.

IN the Bartlett Collection of bronze statuettes at the Boston Museum of Fine Arts is one which has considerable interest for the followers of Æsculapius. It is thus commented on in the last bulletin of the Museum:

The small serpent with semi-human head is an object of much greater interest than would at first appear. It represents Glykon, the reincarnate god Asklepios, whose worship established about 150 A.D., flourished for a century or more throughout Asia Minor and even reached Rome. The story of the origin and spread of the cult is told with much entertaining detail in Lucian's "Alexander, or the False Prophet."

This Alexander was a native of Abonouteichos, a Paphlagonian town on the southern shore of the Black Sea. Of great natural gifts, he was the apt pupil of a certain sorcerer-physician who had learned the magic art from the notorious Apollonios of Tyana. After the death of his master, Alexander found himself a partner with whom he wandered for a long period in Asia and Europe, practicing the profession of magician. Finally, at Pella in Macedonia, they bought a large tame serpent for a few obols, and, to make gainful use of his acquisition, hit upon the scheme of establishing an oracle in Alexander's native town. Accordingly they buried and later caused to be discovered, in the very ancient temple of Apollo in Chalcedon (on the Propontis opposite Byzantium), bronze tablets foretelling that Asklepios was about to return to earth and take up his abode in Abonouteichos. The citizens of that place, moved by the honor thus done them, forth-

with set about building a temple for the god, while Alexander presented himself as his divinely appointed priest. On a certain morning, fantastically apparelled, he led the people to the site of the new temple, went singing and praying down into the water that had collected in the excavation, and drew thence an egg. This broken, a small snake issued forth and twined itself about his finger. Thus was Asklepios reborn and prophecy fulfilled in the eyes of the amazed, adoring multitude. (The egg had been deposited in the mud the preceding night by the crafty priest. It was a goose's egg, with the snake substituted for its contents and the aperture closed with wax.)

A day or two later the people were admitted to a dimly lighted chamber where their priest, gorgeously attired, sat with his serpent-god's body twined about his neck and its tail reaching the floor in front of him (to such a size had it miraculously lengthened) and — greater wonder — its face, peering through the prophet's beard, seemed almost human. The body belonged to the tame snake bought at a bargain in Pella; the head the people saw was an affair of linen, cleverly fashioned and painted in some degree of human likeness, with jaws and fangs worked by means of horse-hair.

When at length the temple had been completed, the new Asklepios, as prophet and physician, gave counsel or information on any matter laid before him for a fee or one drachm and two obols (a shilling). Questions coming in sealed scrolls — with the fee — were returned, answered, with seals unbroken. (Alexander was an adept at duplicating seals, or removing and replacing them undamaged). Responses were in verse, and often ambiguous or unintelligible, in accordance with oracular tradition. The annual income from fees alone was some 70,000 to 80,000 drachms, beside that from the many gifts prompted by hope or gratitude or fear. For a great price, too, it was vouchsafed wealthy and powerful patrons to hear Glykon's response from his own mouth. The well-trained snake would sit coiled up with his head erect, as we see him in the statuette, and wearing his linen mask, which had been fitted with a tube (made of cranes' windpipes, says Lucian), into which a concealed attendant would recite the verse the astonished inquirer heard issuing from the serpent's mouth. Such an "autophonous" oracle sent a general of Marcus Aurelius to overwhelming defeat at the hands of the Parthians. The victory another "autophone" had promised if the Romans should cast a pair of lions into the Danube was won by the enemy. (This episode of the lions is commemorated on the column of Marcus Aurelius at Rome.)

In spite of conspicuous ill guessing and of some exposures of his trickery, Alexander continued successful to the end, partly owing to the protection of the greatest of his dupes, Rutilianus, a powerful senator who became his son-in-law, and whose influence augmented his prestige and assured him against the interference of Rome. The prophet even secured a change of the name of his city from Abonouteichos (Wall of Abonos) to the aristocratic Ionopolis (City of the Ionians).

The cast beside the statuette is from one of the earliest coins issued under the new title, a bronze of Lucius Verus (161 to 169 A.D.), with that emperor's bust and name on the obverse, and on the reverse Glykon with his name and that of the Ionopolitans. Coins of Ionopolis continue to show the effigy of the god at least until 252 A.D.

In the course of his account of this most successful ancient religious imposture, Lucian remarks that innumerable portraits were made of Glykon — paintings and images of silver and bronze. This little figure is apparently the first of these images to be discovered. It shows, incidentally, how well the art of bronze casting was still practiced as late as the latter half of the second century A.D.

Correspondence.

THE GRAPHOPHONE IN THERAPEUTICS.

March, 1904.

Mr. Editor: In Japan during the summer of 1899, a friend of mine and I hired a small island situate in the bay of Sagami, about a dozen miles south of Kamakura and a hundred and fifty yards from the mainland, upon which was a small fishing village called Sajima. The island was of about two and a half acres in extent, sacred to Teujin, the god of caligraphy, and therefore known as Teujinshima. Upon it was a single house large enough for us and our entourage, together with a shrine devoted to the memory and worship of Teujin. The whole outfit was the property of the Imperial household and came into our temporary possession in a very complicated, roundabout and Japanese fashion, the details of which are too numerous to mention. A common friend of ours came to visit us on the island. He had just returned from Formosa and was broken down from a combination of dysentery, malarial fever and rheumatism which had confined him to hospital for six months. He had been very ill and came to us in hopes that the quiet and isolation of our insular paradise might benefit him. He did not improve, but gradually grew feebler and finally was obliged to take to his bed, as we say, which in Japan means that he did not rise from the floor. With this increasing weakness there developed a constipation upon which neither Cockles pills nor Hunyadi Janos water had any effect. After a week's delay in having a movement of the bowels, my friend and I held what is known in the practice of medicine as a consultation. We decided that the case demanded the administration of an enema. We commanded and carefully supervised the concoction of an injection composed of hot water, glycerine and soapsuds, a pailful. After the injection fluid had been compounded and pronounced good, we made the discovery that although we had plenty of ammunition we had no gun. There was no syringe on the island, not even a Royal P., and none nearer than Tokyo, a distance of some sixty miles. We had a small bamboo which we fashioned into an excellent anal pipe but nothing more. It was suggested that we each blow successive mouthfuls of the injection into the rectum. This idea was rejected as being more likely to produce nausea in us than defecation on the part of the patient. There was a graphophone in the house with which we used to amuse the Japanese kids who swam over every day from the mainlaind to visit us. We were both struck with the fact that the india-rubber tubes of this machine which serve to conduct its vociferations to the ear would also convey fluid. With the help of bamboo, twine and surgical adhesive plaster we spliced the tubes together and attaching the aforesaid bamboo nozzle to one end and the tin trumpet of the graphophone to the other we had an injection apparatus of novel construction but of rare efficacy as its use proved. As the crow flies the distance between the trumpet and the nozzle was a matter of about four feet. The intricate tortuosity of the tubes, however, rendered the distance traversed by the injection one of some yards. The practical results of the use of this acoustic enema were two-fold. Upon the patient the effect was all that could be desired. Upon the graphophone, however, the effect was prejudicial in the extreme. The sounds which issued from it after its prostitution were so fecal and unfit for ears polite that we were obliged to destroy the instrument. I venture to say that this is the first and probably the only instance of the application of the graphophone as an aid to therapeutics.

Shinto.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 26, 1904.

CITIES.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 4,221; under five years of age, 1,083; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 910; acute lung diseases 978, consumption 462, scarlet fever 43, whooping cough 13, cerebrospinal meningitis 20, smallpox 9, erysipelas 20, puerperal fever 15, measles 50, typhoid fever 51, diarrheal diseases 124, diphtheria and croup 81.

From whooping-cough, New York 6, Philadelphia 1, Baltimore 1, Pittsburg 3, Boston 1, Cambridge, 1. From smallpox, Philadelphia 8, Lowell 1. From cerebrospinal meningitis, New York 13, Pittsburg 1, Providence 2, and Boston, Worcester, North Adams and Gardner, 1 each. From erysipelas, New York 9, Chicago 3, Philadelphia 4, Baltimore 1, Boston 3. From measles, New York 29, Chicago 1, Philadelphia 16, Boston 2, Lowell 1, Brockton 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending March 12, the death-rate was 19.0. Deaths reported, 5,577; acute diseases of the respiratory organs (London) 235, whooping cough 169, diphtheria 65, measles 148, smallpox 6, scarlet fever 31.

The death-rate ranged from 6.9 in Tottenham to 25.8 in Preston; London 20.1, West Ham 18.1, Brighton 23.5, Southampton 13.9, Plymouth 21.5, Bristol 17.6, Birmingham 22.0, Leicester 14.0, Nottingham 21.6, Liverpool 21.9, Bolton 16.3, Manchester 23.0, Bradford 16.6, Leeds 17.6, Hull 16.2, Cardiff, 18.6, Rhondda 17.5, Merthyr Tydfil 21.5, Norwich 23.9, Handsworth 15.7.

METEOROLOGICAL RECORD.

For the week ending March 26, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

DELAYED PUBLICATION. — The strike, among printers and pressmen, is now over. And it is hoped to issue the JOURNAL on time from April 14th.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.— The regular meeting of the Society will be held in Sprague Hall, Medical Library Building, on Monday, April 11, 1904, at 8.15 P. M. Dr. Edward H. Bradford will present a paper entitled "Shoe Deformities and Shoes." The paper will be illustrated by many lantern slides. Drs. Lovett, Brackett, Goldthwait and Dane will take part in the discussion. All interested are invited to attend.

ARTHUR K. STONE, M. D., Secretary.
543 Boylston St., Boston.

THE NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — A regular meeting of the Society will be held at Hotel Nottingham, Boston, Mass., on Thursday, April 21, 1904, at 7.30 P. M. The meeting will be in charge of the Section on Obstetrics, Dr. Mary F. Hobart, Chairman. Paper, "Three cases of Eclampsia with Accouchement Force," by Dr. Hobart. "Modern methods of Diagnosis and Treatment of Puerperal Septicæmia," by Drs. Marion Nute and Annie Lee Hamilton.

MARION NUTE, M.D., Secretary *pro tem.*
32 Mill St., Dorchester.

RECENT DEATHS.

JOHN METCALFE POLK, M.D., of New York, a young physician of great promise and the son of Prof. William, M. Polk, Dean of the medical department of Cornell University, died from pneumonia on March 29, in the twenty-ninth year of his age. He was born in New York City and was graduated from Yale in 1896 and from the Cornell Medical College in 1899.

STEPHEN P. TRUEX, M.D., of Brooklyn, N. Y., died on March 31, at the age of forty-eight years. He was a sufferer from cardiac disease and had lately had a severe attack of influenza. While performing an operation at the Bushwick Central Hospital he was suddenly taken ill, and died in a few minutes. Dr. Truex was born in Owego, N. Y., and was graduated from the Long Island College Hospital in 1891. At the time of his death he was attending gynecologist to the Bushwick Central Hospital, Brooklyn, and lecturer on obstetrics and gynecology at the New York Post-Graduate Medical School and Hospital.

GEORGE H. HAMMOND, M.D., of Freeport, Long Island, N. Y., died on March 29, from pleuro-pneumonia, aged fifty-eight years. For some years he had been a visiting surgeon at the Nassau Hospital, Mineola, Long Island. A son of his, Dr. Frank B. Hammond, is practicing in Brazil, South America.

PELEG WADSWORTH, M.D., M. M. S. S., died in Malden, April 2, 1904, aged sixty-nine years.

BOOKS AND PAMPHLETS RECEIVED.

BILATERAL FACIAL ATROPHY, WITH REPORT OF A CASE AND ITS TREATMENT BY THE SUBCUTANEOUS INJECTION OF PARAFFIN.*

BY BENJAMIN T. BURLEY, M.D., WORCESTER, MASS.

THE rarity of this affection, the interest in its etiology and its recent cosmetic treatment, furnish my excuse for presenting this paper.

In 1825 Parry [1] described among some cases of hemiplegia the first instance to appear in literature of unilateral facial atrophy. From that time up to 1898 Beer [12] had collected 142 cases where the atrophy was unilateral and six cases where the atrophy was bilateral. Since then, I have found previously omitted or subsequently reported 70 cases of unilateral and four (including following case) of bilateral facial atrophy.

The disease has been successively termed "proso-dys morphia" (Bergson, 1837); "trophoneurosis" (Romberg, 1846); "l'aplasie lamineuse progressive" (Lande, 1870); and "progressive facial hemiatrophy" (Eulenberg, 1875). The latter term is still usually employed, but is obviously misleading, not only because the affection is at times bilateral but also because it is common for the process to run its course within a comparatively short time and then to remain at rest. Mœbius advances the term "Circumscribed facial atrophy" to which the same exceptions cannot be taken. Even the simpler "facial atrophy," designating the special case as unilateral or bilateral would seem to be sufficient, especially as we still lack a pathological diagnosis. Before discussing the questions of etiology and treatment, I wish to present the following case:

Miss B., now twenty-three years old and single, was born normally of supposedly healthy parents. Her mother, however, died two months later of nephritis. Her father is living and well. She had no brothers or sisters. No history of chronic disease in any of the family could be elicited. She had measles and pertussis in early childhood and had frequent sore throats, once or twice with formation of a peritonsillar abscess, until almost ten years old. At eight she had her first attack of pneumonia, which ran a fairly severe course, but she made a good recovery and was well until eleven years of age (Fig. 1), when she was again a victim of pneumonia. From this attack she seemed to make a normal recovery and got about again. Her friends, however, noticed that her face instead of regaining its fulness became progressively thinner and her cheeks more sunken. Alarmed at her condition, her family and her physician withdrew her from school, kept her out of doors, and plied her with tonics, cod liver oil and prepared foods. This sort of treatment was kept up for a year and a half without apparent effect upon her face, which was now strikingly atrophic, apparently about equal on both sides, and this had happened so far as she remembered without any subjective symptoms. Pain, paresthesia and any consciousness of fibrillary twitching were absent. The rest of her body seemed to have developed normally in this period. As

* Read before the Boston Society of Psychiatry and Neurology, March 17, 1904.

FIG. 1.—Age 11, before onset of Atrophy.

she felt quite herself and was undoubtedly strong, even athletic, she continued her course at school until it was finished, except for a period when she was sixteen years old. At this time she is said to have had pneumonia again with a good recovery, no cough persisting. At sixteen years she first menstruated, but has done so regularly and normally since.

Her fourth and last attack of pneumonia was at twenty-one, and again after being very ill, she recovered fully. The last two attacks apparently had no effect whatever on the condition of her face. In spite of various and persistent treatment by electricity,

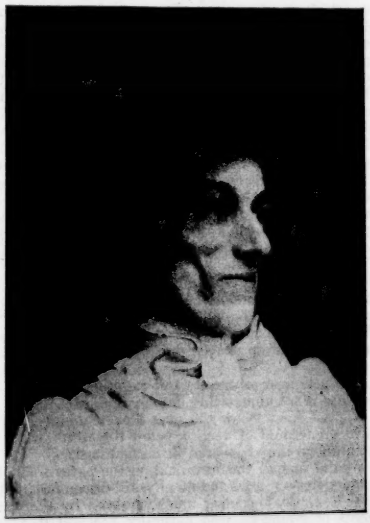

FIG. 2.—Patient just before treatment, December, 1903.

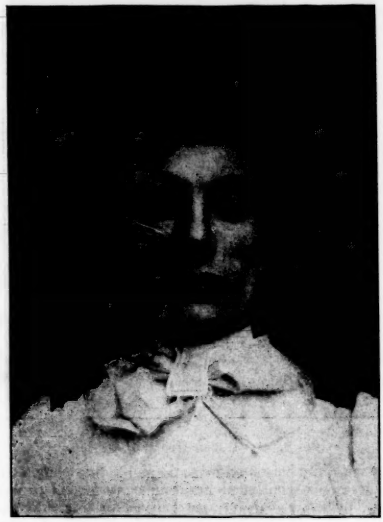

FIG. 3.—Same as Fig. 2. Age 23.

massage, etc., there has been no appreciable change since she was thirteen.

The physical examination of the patient when I first saw her in November, 1903, was as follows: In general appearance, emaciated as to face. Height, 5 ft., 5 in. Weight, 130 lbs. Evidently not of nervous temperament. No stigmata of deviation found. Speech clear. No tremor of any muscles. Movements of eyes normal. No nystagmus. Pupils equal and react normally to light and distance. The skin over entire face is pale and much thinned. The subcutaneous tissues from the orbits to the chin and back to the ears are apparently entirely wanting, the play of the muscle bundles of the delicate facial muscles being plainly visible. The absence of the fat globus leaves also a marked depression in each cheek. The act of laughing causes a marked wrinkling about the mouth. The heart and arteries are normal, as is the pulsation in both carotids. Good resonance over lungs with no rales heard. Abdomen shows nothing abnormal. Quadriceps and achilles tendon reflexes are both present and normal. The superficial reflexes are normal. The muscular irritability to mechanical stimuli is slightly increased, especially in the sterno-cleido mastoid muscle. Sensibility to touch, pain and temperature was normal both for the face and other parts. The electrical excitability of the facial muscles was a little increased (probably due to lack of intervening tissue).

The action of sebaceous and sudoriferous glands of the face is not appreciably impaired.

Viewed from below the eyes looked unduly prominent on account of wasting below the orbits; whereas from above they appeared in normal position.

At the time of this examination the patient had no subjective symptoms and no physical discomfort. She was, however, becoming much annoyed by the comments of strangers, who naturally assumed that she had phthisis or some other destructive disease.

After observing the patient for two months, it was decided to employ paraffin subcutaneously to replace the lost tissue. At the first sitting 1½ c.c. of paraffin of melting point, 109.5 degrees, was injected below each malar process. Aside from a slight prickling sensation coming on occasionally for the next day or two, which was readily relieved by alcohol bathed over the areas, there was no discomfort. The subsequent swelling was slight and disappeared in twenty-four hours. Similar treatments were carried out at intervals of a week, the process of filling beneath the skin being extended outward and downward, both sides symmetrically. At the third sitting 2 c.c. were injected between the buccinator and masseter muscles on each side to replace the fat globus. In all, nine treatments were given, the last three largely to make the surface uniform. To accomplish this, small injections were made at various points. The result at the end of this time is so satisfactory that no further treatment is likely to be necessary, at least for some months. In place of the atrophied subcutaneous tissue, the patient now has a temporary mechanical substitute, namely, an inert, light but firm substance which gradually is expected to give way to new tissue formation. The natural movements of the face are surprisingly little impaired and the patient has ceased to complain of the feeling of stiffness in her cheeks. In fact, Miss B.'s satisfaction in her present over her former condition is enough to itself advocate similar treatment for other cases of this rare disease.

FIG. 4.—After paraffine injection. Before last treatment, February, 1904.

The variety of symptoms in cases of facial atrophy is well shown in the classification of Fromhold-Treu.[10] In 1893 he collected the

cases and divided them into six groups. He included in group (A) 52 typical cases involving one half of the face; in group (B) 19 cases of atrophy of certain areas of the face; in group (C) 24 cases that were in some way complicated by other symptoms or diseases; in group (D) three congenital cases; in group (E) six cases of bilateral atrophy; and in group (F) eleven cases in which the hemiatrophy was not wholly confined to the face. In spite of this variable symptom-complex there are one or two symptoms that are common to all cases.

Mœbius says, "atrophy of the skin is the only constant symptom." It is probable that he means by this all the lower layers and the fat overlying the muscles, for I have failed to find any case where atrophy of the immediately subcutaneous tisues was not either stated or implied. Atrophy of the skin and lack of underlying and supporting tissue is then characteristic. The skin undergoes a varying amount of degenerative change, usually becoming thin and pale, often discolored and pigmented.

The structure of the sebacious glands and hair is next to go and very rarely that of the sweat glands. The degeneration lacks completeness, however, for tactile sense is practically never absent in a pure case and rarely diminished. Beer found a difference in temperature over the atrophic area in 12 out of 20 cases. In 3 an increase; in 9 a decrease. A seeming high percentage of change but often slight in character.

The muscles usually escape atrophy and are prompt in their action. Their electrical excitability to both faradic and galvanic currents is normal or slightly increased. Sachs [13] reported a case showing muscular twitching, but this is extremely rare.

Atrophy of the cartilages, especially of the nose, also of the bones of the face, may occur and give rise to considerable deformity. These occurring in children are to be distinguished from congenital deformities. A fairly common accompanying symptom especially in areas supplied by the fifth nerve is neuralgia. Apparent involvement of the sympathetic is occasionally mentioned and is accompanied usually by dilated pupil, vaso-motor disturbance on that side, increased tear secretion, and cervical, as well as facial atrophy. More unusual symptoms are atrophy of one half of the tongue, and involvement of the organs of special sense. Taste was diminished in four cases. The ears were eight times affected, twice of traumatic origin. The eyes are often affected in some way or other, though aside from their retraction on account of loss of fat from the orbit their disturbance is not characteristic. There have been reported cases of narrowed field of vision, limited motility, abnormal fundi and inflammations of the whole eye. Occasionally the atrophy affects other localities on the same side. Cerebral symptoms with headache, vertigo, epilepsy and insanity have been reported in about 15% of the cases. It is not to be forgotten that even during the progress of the trouble it is usual for the patient to appear well and strong, and when the course of the disease is once interrupted the cosmetic defect becomes the chief factor.

Immediately one starts to consider the etiology of this condition he is struck with the apparently important influence of sex and age. It is characteristically a disease of childhood to which girls are more susceptible. Beer found the ratio of 57 males to 89 females, and found that over 75% of cases were under twenty-one years of age. Among 78 reliable cases the total of instances following trauma was 24%, accompanying nerve lesion 22%, showing lack of development 6.4%; accompanying skin lesion 3.8%, and presumably following infection 45%. Moreover during the first twenty years, when most of the cases occur, about 50% follow infection, while but 15% follow trauma.

Heredity seems to be without influence in etiology: Seeligmueller alone reporting a case where an aunt had some facial atrophy. More remote hereditary tendencies as to neuralgia and migraine have been reported.

The variability of anatomical location of the atrophy; the lack of definite physiological data, such as the demonstration of special trophic fibers; and the scarcity of evidence from pathological findings still leaves us groping for some general etiological factor. The accumulated evidence can, however, enable us to view the subject with greater advantage than had some of the earlier writers. Bergson [2] in 1837 offered the first theory of the disease in which he bespoke the involvement of the nerves supplying the blood vessels. Later Stilling [3] in connection with his work on spinal irritation, produced a case and a theory that the "diminished reflexion of the sensitive vascular nerves upon the corresponding vaso-motor nerves" was the cause of the atrophy. In 1846, however, Romberg [4] gave the disease more prominence by accurate description and classified it as a tropho-neurosis. This classification was given the confirmatory touch by Samuel [5] in 1860, when he published his interesting work on the trophic nerves. Observers since that time, influenced no doubt by the particular characteristics of the case at hand, have changed, disputed, or credited this theory, and the discussion as to etiology has been held open to each new writer. Lande [14] for instance, had a case in which there seemed to be little change except the loss of fat and connective tissue, and he thereupon advanced the theory of primary local affection of this tissue. Baerwinkel [6] and others placed the seat of the disease in the gasserian ganglion; others have called attention to the involvement of the seventh nerve also. Much interesting material has been written on the part which the cervical sympathetic fibers have to play in this disease, from the time of Seeligmueller, [7] the champion of the theory of the paralysis of the sympathetic, and Brunner, [8] the champion of the "permanent state of irritation of the sympathetic," down to the recent work of Barrel. [9]

The monograph of Barrel prompted by the

theory advanced almost simultaneously by Bouveyon of Lyons and Jacquet of Paris may have sufficient bearing upon the foregoing case to warrant further notice. The writer first explains the position of the inferior cervical gangloin of the sympathetic as being more thoracic than cervical, lying as it does just in front of the articulation of the first rib with its vertebral body. It, moreover, is often found fused with the first dorsal ganglion. Its bed is just over the summit of the parietal pleura in a triangular cavity, with the vertebro-pleural ligament below, the costo-pleural ligament and the small scalenus muscle outside. This relation to the pleura and lung figures significantly in the published cases. Quotations are made from physiological experiments on animals. Among others, Floresco[15] in 1899 concluded that after double section of the sympathetic "the skin, the muscular system, the central nervous system, the eye and probably the osseous system, undergo an arrest of development." Barrel then goes on to report six cases, in three of which there was cervico-facial atrophy of one side. This obviously could not be explained by a lesion of the fifth nerve alone. Further, in one of these cases the upper part of thorax and arm were involved, a condition which called attention to the sympathetic as the only communicating system for the nerves supplying these areas. In these three cases there was marked pulmonary tuberculosis, and autopsy on each case revealed the fact that the inferior cervical ganglion on the affected side had become involved in a pachy-pleuritis or cellulitis extending from the pleura. This deposit became fibrous, could hardly be removed and had evidently destroyed the function of the ganglion. In two of these cases either vasomotor, secretory or pupillary disturbance was also present, but in one case there was only the facio-cervical hemiatrophy.

Mendel's[16] much quoted case, autopsied seven years after it had been described by Virchow, showed an interstitial neuritis of the branches of the fifth nerve with degeneration of the fibers. Some of the upper root fibers as well as some cells of the locus ceruleus also showed atrophy. He conjectured from this that the upper root of the fifth nerve contained trophic fibers. Homen[17] has added an important contribution to the anatomical and pathological data. His patient in the course of a few weeks developed an hemiatrophy of the face and tongue accompanied by anesthesia of the region and paralysis of the oculomotor nerves. At autopsy a tumor of the dura was found pressing on the gasserian ganglion, the branches of the trigeminus and partially, the oculomotor nerves. Microscopic examination of the cranial nerves showed the phenomena of degeneration to be very marked in all the branches of the fifth and less marked in the third, fourth, sixth and eighth nerves. In the reported cases following trauma which affect usually some branch or branches of the fifth nerve, it is common, as in cases reported by Bechtereff,[18] Romberg, Banham[19] and others, to get, beside the atrophic disturbance, pain and a diminution of sensibility in the area supplied by the nerve, — probably the attributes of a greater or less degree of neuritis and nerve degeneration. In most of these cases where atrophy persists on top of an interstitial neuritis of the trigeminal Nothnagel admits a lesion of the superior cervical sympathetic ganglion through which pass the vasomotor fibers of the facial region. Nothnagel in this is inclined to overlook the possibility of a lesion of the inferior cervical producing a similar trophic change. Yet Seeligmueller's two cases of injury give some evidence to this effect. Case (1) was a child that had its clavicle and scapular broken in delivery. Not only was there paralysis, motor and sensory, of the right arm, but the right side of the face atrophied and the right pupil dilated. Later, remarkable improvement took place as to paralysis, but the eye and face remained unchanged. Case (2) was a lieutenant, who was struck in the neck just above the left clavicle by a bullet. The bullet made its exit at the fourth dorsal vertebra behind, crossing the path of the inferior cervical ganglion. Paralysis of the left arm occurred at once and considerable suppuration followed. The case was not seen again until nine months later when as in the former case there was found marked atrophy in the corresponding side of the face with pupillary paralysis and some vasomotor disturbance, while the brachial paralysis was fast improving.

From this evidence then and that furnished by the cases reported by Barrel; from the anatomical relation of contiguity if not of anastomosis of the sympathetic fibers with the cranial and cervical nerves, especially at the gasserian ganglion (Vulpian[20]); and from the fact that no other system of nerves is adequate to explain many of the cases of atrophy, it is natural to turn to the sympathetic system as the probable etiological factor. The argument of some writers that the absence of dilated pupil and visible vasomotor change rules out involvement of the sympathetic is hardly conclusive when we recall that these may be only special functions of the sympathetic, and that the fibers to produce them arise from certain regions of the cord. (Langley.[21])

The influence of sensory stimuli in atrophic conditions is a subject of some interest, but from clinical evidence is not of great importance. The fact, however, that "after severance of the afferent roots, the motor nerve cells of their spinal origin soon present recognizable structural change" (Warrington[22]), may prove to be significant. In fact, Dercum[23] believing the disease to be due to a "radical perversion of the afferent stimulus," recommended early resection of the various branches of the fifth nerve.

Weir Mitchell[29] in 1885 published a remarkable case of a girl twelve years old who since the age of six had shown a lack of fat tissue above the waist, the hips and legs remaining normal. He attempted to account for such a condition only on the probabilty of a separate center for

fat nutrition. On account of the accompanying analgesia in his case, he was inclined to place the center in some portion of the posterior segment of the cord.

The diagnosis of facial atrophy can usually be made at once when it is unilateral. The lack of underlying fat and the degenerated skin of one side form a contrast to the well side which can hardly be mistaken for anything but a congenital deformity. When the case is bilateral, however, a diagnosis may only be arrived at after a careful review of the history and after finding an atrophy practically confined to the face which resists all therapeutic treatment. The above reported case is one in point. Miss B. since her pulmonary infection twelve years before had developed facial atrophy. For a long time it was not remarked that the rest of her body was not similarly involved, and in the meantime she was suspected to have phthisis or other chronic disease, and received treatment accordingly. Later, treatment by electricity, massage and oily inductions was more directly applied to the face but without avail. The face still apparently belonged to a woman of twice her years. These facts occurring in an otherwise plump and athletic girl are sufficient for a diagnosis. The resemblance of this case to the second bilateral one published by Mœbius is striking.

As to the etiology in my case I can only point to one or two possibilities. It seems clear that her trouble followed a pulmonary infection, and whether this infection displayed some selective action on the nerves and tissues of the face; or whether, following the suggestion of Barrel, we might not suppose a sufficient involvement of the inferior cervical ganglia in the pleuritis to interfere with their function and cause the loss of their normal influence upon the distributing nerves to the face, will have to be left an open question.

The prognosis in this condition, once the diagnosis is made, is always uniform. The atrophy progresses, usually within a year or two of its beginning, to a certain point; and there the process ends with no danger to life and often without discomfort. It is typically, however, unaffected by treatment toward the restoration of normal tissue.

As to treatment Mœbius says, "Es gibt bisher keine Behandlung;" and this is still true as far as most mechanical and therapeutic measures are concerned. It is natural in every case, however, to give a thorough course of massage and electricity at the same time that the patient is receiving tonics and a fattening diet; and any appreciable result from these measures means an error in diagnosis. Up to 1901 this was the most that could be offered to a patient. At that time, following the idea of Gersuny[24] of injecting vaseline in different parts of the body to replace lost tissue, Luxenburger[25] treated two women from Klaussner's clinic in Munich by the subcutaneous infection of prepared vaseline. These were ooth cases of facial hemiatrophy occurring in girls nineteen years of age, and each had been of about three years' duration. After some months treatment by galvanization without improvement, case 1 was in the course of three weeks given fourteen injections of vaseline in different areas covering the greater part of the left half of the face. Case 2 in whom the atrophy was confined to the lower half of the face and jaw had the contour corrected by only four injections. No mishap occurred in either case and there were no disagreeable subjective symptoms. When seen one and a half months later there had been a slight shrinking of the tissue about the "vaseline depots" which were themselves harder.

Eckstein[26] last year, presented before the Berlin Medical Society another case in which unlike Luxenburger he injected a large quantity of paraffin at one sitting. The patient, a woman of fifty-four years, had had a marked atrophy of the left cheek for forty-four years. Fifteen to 20 cm. of paraffin of 56–58° C. melting point was injected at one time and the patient was discharged the next morning. After six days she returned, the face showing a slight swelling and redness of the part, but no further symptoms. No further report of the case was made.

I find also that, in the report of the Royal Society of Physicians in Vienna for Nov. 6, 1902, Schlesinger presented a similar case whose deformity had been corrected by Gersuny in six sittings with paraffin injection. More recently Moszkowicz[30] and Mauclaire[31] have carried out similar treatment in their cases. I have seen the report of no case of facial atrophy in this country treated in this manner.

The principal use of subcutaneously injected paraffin has been in the treatment of deformities of the nose, and in this manner hundreds of cases have been treated. The results show almost uniform success with careful technique and the operation is seldom attended with marked discomfort or dangerous mishap. Embolism has, however, occurred a few times as in a case reported by Pfannenstiel[27] in which a large amount was used around the rectum and the patient allowed to return home at once. The melting point of the paraffin was not reported which might probably explain the cause.

Paraffin is a hydrocarbon obtained from petroleum by distillation with a melting point varying from about 120° to 160° F. Experience has taught that the most practicable material for use has a melting point around 110°; for, if the melting point be high, injection is difficult on account of rapid cooling and the high temperature is more apt to lead to necrosis; if, however, it is near the body temperature the substance tends to spread and will not support the parts. It is common to add some oily substance to the paraffin to produce a certain melting point. The preference is for a stout all-metal syringe with fixed screw-head so that the paraffin may be forced out gradually by rotating the piston.

The consistency of the paraffin when injected should be soft and pliable so that it comes out like a white thread or comedo. With this precaution that the paraffin be not injected in

liquid form, with strict aseptic technique and with care not to inject enough in one area to cause undue tension of the tissues and consequent disturbance in the circulation, the operation is apparently without danger.

A general anesthetic is not necessary and many do not use a local one on account of the annoyance of the slight local edema. A sensitive patient, however, should have the benefit of cocaine or eucaine locally where the pliability of the tissues will not interfere with the moulding.

The discussion as to what becomes of the injected paraffin is one of great interest. Valuable histological work has been done, but as yet the closing seal of time cannot be put upon the experiments. Mozkowicz found no paraffin in the lymph vessels neighboring the injected area, and finding the paraffin globules surrounded by connective tissue cells, he concluded the paraffin was not absorbed but became encysted. Mauclaire arrives at a similar conclusion, but calls attention to giant cells which appear at the borders of the vacuoles where the connective tisue has penetrated the paraffin. The significance of the cells is not yet determined.

Morton [28] has published some interesting microphotographs of the paraffin in situ in the tissues at intervals of one, two, three and four months after injection. At the end of the first month the globules of paraffin were surrounded by a capsule of embryonic tissue. This tissue was increased at two months and new blood vessels were permeating it. At three months there was marked increase of new tissue, connective, fibrous and embryonic, with a decrease in the amount of paraffin. By the end of the fourth month the space where the paraffin was deposited was entirely filled with embryonic tissue. This the writer says, "shows conclusively that the paraffin soon disappears, whether it undergoes some chemic change or is carried away through the lymphatic system by the leucocytes remains to be settled."

Finally, I wish to express my indebtedness to Dr. James J. Putnam for his valuable counsel; and to Dr. W. G. Curtis for sending me the case and efficiently cooperating in its treatment.

The following cases of facial atrophy make, in addition to those collected by Beer (1898), a total to January, 1904, of 212 unilateral and 10 bilateral cases:

A MANY-PHASED CASE OF CHOREA.*

BY HORACE E. MARION, M.D., BOSTON.

Mrs. ———, age thirty-seven, died of corrosive-sublimate poisoning at 7 A.M. July 27, 1902. A victim of chorea from childhood, as will be seen later, she gradually became worse. Symptoms of dementia and melancholia, with suicidal tendencies, gradually developed. For a year or more previous to her death she had a trained nurse in constant attendance. On the afternoon of July 26, with the cunning peculiar to this class, she eluded the nurse and swallowed several corrosive tablets which were supposed to be put away beyond the reach of everybody except the nurse.

The immediate effect of the poison was to inhibit the vaso-motor nerves, almost arresting the heart's action, causing the extremities and body to become icy cold, and exciting vomiting and purging. Nothing that was done for her stayed for a moment the fatal termination. Yet for more than twelve hours physicians, nurses and husband worked constantly to relieve what in all reason ought to have been terrible suffering. She never made a single murmur nor expressed the slightest regret for what she had, by her own confession, done.

Family History. — Grandmother and two grand-aunts on her father's side suffered from chorea from childhood. Her father and his three sisters were victims of the same malady, — the father but slightly, the aunts much more severely, one becoming insane and one for many years bedridden and unable to feed herself.

Personal History. — As a child, intellectual and refined, suffering only from chorea in a mild form. Married at twenty-five; giving birth to six children in eleven years — two girls and four boys. The second (a girl) and the third (a boy) died in infancy — one of entero-colitis, the other of marasmus, both preventable diseases. The fatal termination was no doubt due largely to the increasing infirmity of the mother, who even at this time began to show evidence of beginning dementia. All the subsequent children were cared for by a nurse or an attendant. She had measles and whooping-cough after marriage. Other than this she had no illness, save her confinement, until she was pregnant with her fifth child. Early in this pregnancy she began to suffer from parenchymatous nephritis. The urine contained, most of the time, a large trace of albumen, normal blood, hyaline and granular casts. The last of April, 1898, she was seized with pneumonia, which extended to both lungs, making her desperately sick. During her convalescence she had otitis media, extending to the mastoid cells. Undoubtedly the same micro-organism was in evidence, though its presence was not demonstrated by the microscope.

Mastoid operation was performed on June 2 by Dr. Leland, and she was confined June 12. Her confinement and convalescence thereafter were uneventful. During the attack of pneumonia the chorea was much aggravated, she having practically no control of her muscles. Her chorea and mental conditions were such that she spent March and June, 1900, at the Adams Nervine Asylum. At this time she complained mostly of persistent headache, which, however, never prevented her from sleeping.

In April, 1901, she spent two weeks at the McLean Hospital for the same reason. Symptoms of melancholia became more and more pronounced. Her experience at the hospital made a strong impression upon her, and she constantly alluded to the helpless and hopeless condition of many she saw there. About this time she became interested in the Swedenborgian faith. Spent much of her time reading a book entitled "Our Eternal Homes," which alludes pleasantly and beautifully to the hereafter. So unmistakable became her suicidal tendencies that for more than a year a trained nurse was kept constantly with her.

In December, 1900, to her great delight, no doubt by reason of her feeble mental condition, and to her husband's horror, it was certain that she was pregnant with her sixth child. Her husband was much exercised as to the probable condition and fate of the offspring, and strongly pleaded that abortion might be produced. As his anxiety was certainly not without reason, I called to my assistance Dr. J. J. Putnam, who had been familiar with the case for a long time. After careful consideration, weighing the pros and cons, we were agreed that we had no right to assume that the product of this conception would prove a mental derelict and declined to countenance any interference. Gestation was uneventful, as was her confinement on Sept. 4, 1901.

In February, 1901, I removed an adeno-fibroma of the nipple which had been gradually growing since her first child and which was now very troublesome. The specimen was shown to this Society at the time, on account of its rarity.

Ever after the birth of her child until her death, as already stated, she was under most constant observation, both day and night. Chorea was always present. She complained bitterly of headache, which nothing seemed to relieve, although many nostrums and various "treatments," such as Christian Science, electro mesmerism, etc., were tried, only to be soon thrown aside. Dementia became more marked and melancholia more pronounced, until death closed the scene.

Autopsy, Nov. 9, 1903, by T. Leary, M.D. — Body of a woman about forty years of age; well developed; fairly well nourished. Body warm; no rigor.

Peritoneal cavity: fluid somewhat increased, otherwise normal.

Pleurae. — Few adhesions about apices and backs. Lungs moderately pigmented; present several nodules of superficial, lax consolidation of a deep red color,

* Read before the Obstetrical Society of Boston, December 15, 1903.

which are most abundant over back. These foci vary in size from a pin-head ecchymosis to that of a half-walnut. On section are dark red and contain free blood.

Pericardium normal.

Heart. — Of normal size and appearance; valves and cavities normal.

Esophagus. — Posterior surface shows several small elongated superficial erosions whose wedges are bordered by a zone of opaque white coagulated epithelium. These erosions are limited in great part to the lower portion just above cardiac orifice.

Stomach. — Organ somewhat contracted and heavy. Surface congested. Walls tremendously thickened. On laying stomach open summits of rugæ are uniformly discolored a brilliant red, and here and there the intervening sulci show round patches of reddened mucosa. Smaller punctuate ecchymoses are scattered irregularly throughout remaining mucosa. Walls vary in thickness from .4 to 1.4 cm., the greatest thickening being present beneath the rugæ.

Beginning of duodenum shows a continuation of discolored patches for 2 cm. beyond pyloric orifice. Rest of small intestine normal. In cecum and again in lower portion of sigmoid, and in rectum, black masses of pigment are found overlying and intimately attached to mucosa, which, however, shows little or no congestion.

Liver is large, injected; edges slightly rounded; on section drips some free blood; cut surface is grayish-red; opaque; markings indistinct.

Spleen. — Of normal size; capsule tense; consistency slightly decreased. On section Malpighian bodies indefinite; trabeculæ distinct; pulp slightly increased.

Kidneys. — Slightly enlarged; soft; capsule peels smoothly; surface injected and moist. On section cortex increased in thickness; vessels injected; surface opaque; pyramids injected; markings indistinct.

Genitalia. — Uterus of normal size. Left ovary replaced by a thin-walled oval cyst 3 x 1.5 cm., which is filled with clear serum. Right ovary contains a partially organized corpus with gelatinous contents 1 cm. in diameter, a serous cyst 1 cm. in diameter and several corpora fibrosa. Tubes normal.

Microscopic Examination. — Stomach: Thickening of stomach-wall is limited in great part to submucosa and sub-peritoneal connective tissue. Mucosa is completely necrotic along summits of rugæ and filled with free blood. The necrosis becomes more superficial as one approaches the sulci; but everywhere, even in what appeared grossly to be normal mucosa, the superficial cells of gland layer are very granular or necrotic. Surface is covered with a thick layer of mucus, which over rugæ is coagulated and admixed with blood. The loose areolar tissue of submucosa is widely distended with an exudate, largely serous, but more or less hemorrhagic near mucosa. Immediately about the vessels of submucosa and in muscle layers polynuclear leucocytes are abundant. Lymphatics enormously dilated.

Liver: Capillaries dilated and filled with blood, trabeculæ of liver cells standing out with unusual distinctness. Liver cells are very granular and may contain an occasional small droplet of fat.

Spleen: Marked degree of acute congestion; otherwise normal.

Kidney: Glomeruli injected; glomerular vessels show no marked changes. Proximal convoluted tubules stand out distinctly from surrounding structures, taking a heavy eosin stain. High power shows cells lining convoluted tubules to be swollen, granular, complete filling tubules and in large part necrotic. In many tubules the epithelium is completely disorganized and converted into a granular mass without nuclei. The epithelium lining Henle's loops is somewhat swollen and granular. The distal convoluted tubules are less markedly affected and the straight and collecting tubules are normal. There is nowhere evidence of the presence of lime salts in the renal tubules.

Sections of lung through consolidated portions show air spaces, including terminal bronchi, filled with recent blood. Hemorrhages appear to be capillary in origin, arising from vessels of alveolar wall. Outside of foci which were visible in gross, small capillary hemorrhages are evident here and there throughout sections. No thrombi present in vessels.

Brain: Turned over to physicians from McLean Asylum for examination.

Anatomical Diagnosis. — (Corrosive sublimate poisoning.) Acute hemorrhagic esophagitis, gastritis and duodenitis. Capillary hemorrhages into lungs, producing sub-pleural ecchymoses. Acute congestion with granular and fatty (?) degeneration of liver. Acute congestion of spleen. Acute degenerative nephritis with necrosis. Cyst of ovary.

MICROSCOPICAL STUDY OF THE BRAIN OF MRS. ——— BY DR. AUGUST HOCH.

A careful study was made of sections from both paracentral lobules, from two regions of the first frontal convolution on either side, from both first temporal convolutions and from the region of the calcarine fissure on either side. Also from both anterior central convolutions. These pieces were hardened in alcohol and stained by means of Nissl's methylene blue.

It should at once be stated that there are no striking differences seen in sections from these various regions. They all present the same alterations, which may be summarized as follows:

The general architecture of the cortex is nowhere appreciably disturbed, so that any appreciable loss of nerve cells or of the intervening gray substance cannot be demonstrated.

The nerve cells are everywhere markedly altered. They are shrunken, their nuclei rather homogeneous, the cell body often presents a honeycomb appearance. While these alterations resemble in many ways that form of cell change which Nissl has described as the "chronic cell change," it is, to my mind, very unlikely that in such a case we would have such extensive and at the same time so marked changes in nerve cells without any corresponding disorder in the general architecture and without adequate changes in the glia. As a matter of fact, it has been found that a very similar appearance is seen in the cortices of many individuals who die from ordinary somatic diseases, more especially those which lead to a general stasis, and we have been able to show experimentally that this appearance is produced by the action of the alcohol on a tissue, the fluid contents of which is probably somewhat increased. I regard these nerve cell alterations, therefore, as artefacts. The glia nuclei in the lower layers of the cortex are not infrequently found to be somewhat increased, but the nuclei are not otherwise altered. They present no active stages, and the cell bodies are not abnormal except for the fact that many of them contain more pigment (bright yellow) than they would normally. The significance of this pigment is not clear to me, but the increase of the nuclei is evidently of little moment, as it may frequently be seen in cortices of individuals who die from various somatic diseases.

The blood vessels often presented somewhat crumbly looking walls and not infrequently pigment in their endothelium. The spaces around the vessels were normal and presented in no way accumulations of cells. In the vessels were seen an unusual and certainly abnormal number of polymorphonuclear leucocytes.

In a word, the changes found are of very slight importance.

There are no gross changes.

It may be thought far afield to report this case before an obstetrical society. It certainly has food for thought in many departments of medicine. The general practitioner may truly feel that his field is yet broad and that it still remains for the family physician to decide when and what specialist to call.

The obstetrician conducting a physiological process through pathological quagmires to a happy termination must feel that his calling is something more than a blind following of textbooks.

To the neurologist and alienist this case opens up a broad vista in the ultimate nerve-cell process in the neurons of the brain, of which we hope to learn much in the future from those qualified to teach.

But the great question of all, it seems to me, is sociological, — the transmissability of certain brain defects, thus bringing us face to face with that ever broadening question of marriage and the part the medical adviser should play in preventing unions the fruit of which tend to the lowering of the scale of intelligence in the coming generation. Under this head, also, is presented the question of terminating gestation.

In this particular case the future of these offsprings is yet to be demonstrated. The two older are certainly neurotic. The two younger show nothing as yet. The youngest, born when the mother was furthest advanced in her mental infirmity, is extremely bright and attractive.

A CASE OF HUNTINGTON'S CHOREA: ITS SOCIAL ASPECTS.*

BY J. J. PUTNAM, M.D., BOSTON.

I first saw this interesting patient on Feb. 16, 1897, and give such extracts from my notes as may be useful in supplementing Dr. Marion's description.

As regards the family history, besides the repeated cases, five at least in number, which showed themselves in the two previous generations, it is to be noted that of the patient's three children who were living at the time of my examination, one was eccentric to the point of real deficiency and another excitable and otherwise neuropathic.

As for the patient herself, although she had been accounted as fairly well in childhood, yet she began even then to suffer from the nondescript headaches of neurasthenic type which followed her through life, noticeable, as she said, "any time that she stopped to think of them." Even before her marriage she began to exhibit the choreiform movements which formed one of the characteristic features of her case, although when I saw her first she was thirty-one years old, of soft and pleasing face and gentle manner, and her movements were not so obtrusive that they would have been recognized at once, by a casual observer, as abnormal; they seemed rather a sort of caricature of a somewhat affected and coquettish manner. One could easily imagine, after talking with her, what a singular charm she might easily have exerted upon an unwary lover, half a dozen years before. Her speech had a lisping quality and was somewhat spasmodic and drawling. Frequently she would conclude sentences with a prolonged ye—s, accompanied with a slight half laugh, interjected without cause. Her husband said that one of her predecessors in illness had spoken with the same mannerism.

These facts are of obvious importance, because in view of the problem which faces the community, How people should marry so as to avoid the danger of increasing the number of cerebral degenerates, it must be borne distinctly in mind that youthful neurotics are often very attractive, especially to suitors who are themselves neurotic. In such cases it can only be through a wider knowledge of early signs of disease and a recognition of the significance of family tendencies, on the part of both physicians and the laity, that this danger can be averted.

It is not to be doubted, as regards the diagnosis, that this case deserves to be ranked as an example of the affection known as Huntington's chorea. This is a well marked disorder, imminently hereditary, fatally progressive, beginning usually in later adolescence or middle life, and associated regularly with a mental enfeeblement which goes on slowly but surely, although not always to a dementia of high degree.

This deterioration has marks of its own which are fairly characteristic. At first, the mental disorder seems often rather a sort of absent-mindedness or lack of power of concentration than a true dementia. Later, the real defect becomes more prominent, but yet in spite of the gradual decline in power, and the approach of an ever-increasing apathy, attacks of excitement or depression may intervene. And so, in this instance, the first signs of weakness were a lack of initiative, of power of taking responsibility, but associated with a real willingness to help, as a child helps, and, at the same time, with a somewhat childlike appearance of light-heartedness. As time progressed the ineffectiveness became greater, and unreasonableness and lack of insight (as for example with regard to the propriety of having children) became more marked; until finally there came on the serious mental state which eventually led to suicide.

When, in the midst of this career, this unfortunate lady became pregnant for the sixth time, her husband, a man of high character and intelligence, was naturally overcome with horror at the outcome of his own indiscretion.

Dr. Marion, who had long been his friend as well as his physician, was asked if abortion was not justifiable, but decided that it was not, and in this view I entirely concurred. Fortunately, we were able to add that there was no certainty that the husband's fears would be realized, and a fair chance that the child might turn out strong and well, as has so far proved to be the case.

I should have doubted whether there was anything more to be said on the point of the justification of performing abortion, were it not that, a short time ago, having chanced to ask two friends, one a surgeon and the other a physician, both on the staff of the Massachusetts General Hospital, if they could refer me to any literature

* Read as part of the Discussion of Dr. H. E. Marion's paper before the Obstetrical Society of Boston, Dec. 15, 1903.

with relation to the matter, they both said no, but each one added that, not long since, he had been approached by a physician of eminence and reputation who wished to have an abortion done; in one case because the prospective mother was neurotic and should not be expected to care for another child; in the other because the father was a drunkard and had deserted his wife and family. It is well known that ideas of this sort are prevalent amongst the laity, but it was a slight surprise to me that they were as common in the profession as these confidences would indicate. In fact, it is hardly to be doubted that the practice of abortion, even where offspring is obviously very undesirable, is not only a crime before the law, but, historically, a survival of the practice, formerly universal in various countries, of exposing unwelcome children to perish after birth. Possibly, indeed, an advanced civilization may revive this custom as a means of improving a racial or national stock, but a satisfactory proposal looking to this end is not yet in sight. The nearest approach to this of which I know is the scheme brought forward recently by Dr. McKim of New York, according to which the state should put to death such degenerates as come under its authority. Neither of these plans has, as yet, become sufficiently popular to meet with legislative favor, and I do not believe in the right of physicians to take the law into their hands. They may, perhaps, refrain from retarding, by minutes or hours, an obviously approaching and inevitable death, but further than this their privilege does not extend, if indeed so far.

Is it justifiable to recognize the right to life of the so-called "viable" child in utero, and to deny such right to the living being that has not yet made its presence felt? I do not think so, nor does there seem to be any justification for that common distinction, though it is one which is recognized by the laws, I believe, for certain circumstances and in certain states of the Union. An interesting report, bearing on this point, was read before the State Board of Health of Michigan some years ago, in which the frequency of abortion, the present state of the public sentiment, and the barbarous and unreasonable conditions of the then existing statutes was pointed out, and a change urgently demanded.

Can the physician aid in other ways to remedy this unfortunate state of things? Obviously, yes; in the first place by calling urgent attention to the inexorable laws of heredity; next, by standing ready to consult with their patients as to the conditions under which it is right to prevent conception and as to proper means of accomplishing this end.

Is it right that marriage should be entered on with the distinct intention that no children should follow? Under most circumstances, and especially where pride or selfishness cause this custom to prevail, I think we should all say emphatically no. Yet, there are cases, some of which occur to each hearer's mind at once, where no such categorical negative is justified.

As regards means of prevention, it should be clearly understood, I think, that total abstinence is not injurious to the health, or only in the rarest cases. Whether this is the only justifiable means is another matter, and one about which the physician is bound to keep himself liberal, wise, and sympathetic, in the face of the exacting instincts and deeply rooted habits which at times make abstinence well-nigh impossible; though on the other hand it often seems far more difficult than it actually is.

As to the former matter, namely, the laws of heredity, a number of important and interesting questions suggest themselves, with regard to which the opinions of scientific men are by no means uniform.

The importance of unfavorable heredity may be considered, both with relation to the individuals concerned and their immediate families and friends, and also with relation to the community. Here, again, I will begin with the second point.

One often hears it said, and the argument is dwelt upon at great length in the book by Dr. McKim to which I have already referred, entitled, "Heredity and Human Progress," that the civilized races are in great danger of degenerating and being swamped, in consequence of the increasing tide of neurotic and defective citizens forming the outcome of marriages that ought never to have taken place. It is pointed out that insanity increases faster than the population, and neuroses of a lesser grade but belonging to the neuropathic family and therefore in a certain sense an equal menace to society, even faster than insanity, strictly speaking.

In this state of affairs the author just referred to sees no escape from general decay, except in a drastic extinction of the sources of evil, and his therapeutic recommendation is nothing less than that the state should follow the example set by some of the humane societies that care for delinquent cats and dogs, and put to death such persons as come into their hands, who, in their opinion, ought not to become the mothers and fathers of future voters. Analogous remedies have been proposed by others, and extraordinary as such schemes sound, they would, I believe, find many defenders in the community.

If the writer's premises were correct, perhaps we might feel bound to listen more attentively to his proposal, but I for one believe that they are incorrect.

Various reasons have been suggested which indicate that the increase in insanity and the neuroses is more apparent than real. Even if that is not the case, there are very cogent scientific grounds for thinking that the racial stock is not injured to anything like the extent that individual deterioration would suggest; that, in other words, the deleterious effects of such influences as the strain of the present fast mode of living, and the exposure to so many causes of domestic poisoning, especially alcohol, serious as they are for the health and happiness of individuals, are nevertheless to be classed as ac-

quired traits and as such not to be transmitted by inheritance. In the world's history there have been races of heavy drinkers, but no signs of increasing deterioration of racial stock due to that cause. On the other hand, strange as it may appear, it is, fortunately, said to be true that in these races drunkenness has regularly led to temperance, through the influence of natural selection. The germ cells vary constantly, but in obedience to causes which are wholly unknown, and they are not greatly affected, if this opinion is correct, by the diseases, the bad habits, or even the age of the possessors. The evidence is considerable that the children of the aged are as vigorous as those of the young, and that a child conceived during a period of manifest insanity is not more likely to become insane than a child of the same parents conceived before or after this period, and pregnancy is not more dangerous during a period of insanity than it would have been before. Each person must, if he is wise, estimate in advance the good and ill fortunes which are in store for himself and his children, by looking at the past and especially the immediate past, of the house with which he is about to ally himself. It is, probably, not necessary or possible to go back very far, and from that point of view it may be mentioned that even the attempt made by the breeders of cattle to improve their stock through selection have their limitations, and that their beneficial effects cannot be indefinitely extended either in time or in amount. According to Galton's law, the child derives, in general, about one-half from his father and mother, one quarter from his grandparents, one eighth from his great-grandparents, and so on, and while all sorts of surprises must be looked for and may give rise to well-grounded fears and hopes, yet they are hardly to be reckoned with in calculating the actual chances.

Marriages where either party is burdened with an inheritance like that of the subject of this paper ought, of course, never to occur. Neither ought epileptics or insane persons to marry. On the other hand, where it is a question of the milder neuroses and psychoses, or where the severer ones have shown themselves only in preceding generations, more latitude may be allowed. The thing which should decide us, looking upon the matter as we now do, as outsiders and advisers, should be the answer to the question, What gains are to be expected from a given union to offset its dangers? Putting the matter in a somewhat brutal way, one might ask, For what do we breed? Surely not for health and physical qualities alone, or even for health and strength exclusively.

I believe that we have a right to breed for genius, including under that term any quality, such as great common sense, or a fine unselfishness, which makes strongly for the public welfare, even if liable to be associated with a certain amount of bodily and nervous weakness.

I do not believe that genius is a psychosis, and although it may be true that in some cases its existence side by side with the psychoses is more than a coincidence, yet I think that even here its existence may count for infinitely more good than would be necessary to counterbalance the harm done by these psychoses themselves.

A NEW TREATMENT FOR MORPHINE ADDICTION.

BY WILLIAM S. BIRGE, M.D., PROVINCETOWN, MASS.

PROBABLY there has been no subject within the domain of medicine that has baffled the skill of the physician, so far as satisfactory results are concerned, and has likewise taxed the fortitude, endurance, and I might well say every particle of manhood, from a physical, mental and moral standpoint, of the unfortunate patient, as the treatment of morphine and other drug addictions.

The treatment of morphine addiction by the gradual reduction method means a period of weeks of the most agonizing form of slow torture that lies within the power of man to inflict upon his fellow; while upon the other hand the sudden withdrawal of so powerful a narcotic has always associated with it, aside from the very unpleasant nervous and mental manifestations, the danger of sudden collapse.

In perusing the medical literature on the subject of morphine addiction any fair minded physician cannot help but feel that the progress made in this particular line of work has been almost *nil*, and that the treatment of to-day, as conducted in the best known institutions throughout the country, remains much the same as it was a quarter of a century ago.

When one considers the many relapses that have followed the treatment of these unfortunates, he is almost led to feel that there is more truth than poetry in the statement that I have often heard advocated by physicians, men of brilliant minds and good standing in their profession, "Once an habitué of morphine, always one."

That the statement is overdrawn there is no doubt, but there is no question, in following up the so-called cures, that at least fifty per cent do relapse, and that, even after, sometimes, two or three attempts have been made, upon the part of the patient, to throw off the chains that have bound him so securely. In these cases the relapses occur most often where the patient has been practically free from the use of the drug for a longer or shorter period.

During an experience of several years in conducting a small sanitorium for nervous invalids I have refused to consider the acceptance of these cases, feeling that the best known methods of treatment thus far have been so far from satisfactory that I could not conscientiously undertake it.

During the past summer my attention was called to a new method of treatment that was being used, it was claimed, with remarkable success, at a private institution in one of the Southern states. Before entering into any direct cor-

respondence I made inquiries and ascertained, from some of the foremost physicians in that section, that the treatment was all that it was represented to be, and that several private institutions and one public hospital in the city had investigated the method, and had adopted it in the treatment of their own cases. I then entered into direct correspondence with the superintendent and physician in charge of the institution that claimed the discovery of this new method. I was cordially invited to visit the sanitorium and investigate fully the method of treatment, remedies used, etc. Later on, in the fall, I took advantage of the opportunity that presented itself, and spent over three weeks in daily observation of the patients under treatment, and I must say that the most skeptical could not fail to be convinced of its efficacy in such cases.

One of the most remarkable things connected with the treatment was the fact that the length of time of the addiction, or the amount of the drug used, whether two grains or fifty, made no difference with the success of the treatment, the antidotal and eliminative effects being equally efficacious, and the time required for treatment no longer.

It seems like an improbable statement to make, but it is a fact, nevertheless, and I saw it exemplified in numerous cases, that when the system of the patient is put in proper condition by a few days' (three to five) preparatory treatment, seventy-two hours suffices for the taking away entirely of the drug, and its complete elimination from the system, and this, too, without shock to the system, and without suffering or discomfort.

Among the cases that I saw treated were four physicians. We will all acknowledge, from experience, that physicians generally make bad patients, and all of these men acknowledged that they felt no pain or discomfort, and one of them returned to his home and practice the third day after treatment, making just one week from the day that he entered the institution until he left it, as he said, " A well man." He was taking twenty grains of morphine, and five grains of cocaine daily.

In none of the cases was there nausea or vomiting, and in none any persistent diarrhea. The food was taken at regular intervals, and a fair amount of sleep enjoyed every night.

The method of treatment is as follows:

A careful physical examination is first made of the patient. The quantity of drug used is still continued until time for active, or seventy-two hour treatment, begins, but if patient is using alcoholic stimulants of any kind they are discontinued or left off as soon as possible. The active treatment should not begin until three days after patient has entirely discontinued the use of alcoholics. A dose of 10 gr. of calomel is given at bed time, followed in the morning by a full dose of epsom salts. This should start up the secretions freely, and completely unload the bowels. If this has not been done satisfactorily give 5 gr. of calomel the second night, following as before by the dose of salts in the morning. In addition to the above a Turkish bath should be taken at least every second day during the preparatory treatment. When the time for the active treatment comes the usual dose of morphine is taken up to noon of that day when it is dropped for good and all. At two o'clock 5 drops of a specially prepared solution of mandragorin is given hypodermically, together with one-eighth of a grain of pilocarpin. This dose is repeated every two hours. If the symptoms of abstinence manifest themselves from lack of the morphine, the dose of the mandragorin may be increased until comfort ensues, even if 15, or sometimes even 20 drops of the solution are taken. The dose of pilocarpin remains the same until the patient is brought into a profuse perspiration, and then sufficient quantity should be given to keep the skin in a continual moisture. Usually as long as the patient perspires freely he is perfectly comfortable. As I have said before, any symptoms of abstinence that may arise can be relieved by the mandragorin. The pulse which was stimulated and quick before beginning the treatment usually becomes slower, but soft, full and regular. The above treatment is continued during the seventy-two hours with the exception of the morning dose at four o'clock which is omitted, that is, there is no medicine given between the hours of two and six in the morning. The patient is usually quiet and sleeping at this time and it is not needed. At the beginning of the second day's treatment, or before, if there is any weakness of the heart's action, a dose of one twentieth of a grain of strychnia nitrate and one eighth of a grain of sparteine is added to the hypodermic solution and given every two or four hours during the remainder of the treatment. If, as occasionally happens, the patient becomes extremely restless during the treatment a hypodermic of one-half grain of codeine, or one quarter of morphine may be given. This will at once quiet all restlessness and can do no harm, for the secretions are so active that it would be worked out of the system in a few hours. At the end of forty-eight hours the antidotal and eliminative effect of the remedies are usually complete, and there is not a vestige of morphine left in the system. This is plainly demonstrated by the fact that a dose of one eighth or one quarter grain of morphine would produce the same effect as it did before the addiction had been formed.

During the treatment light food should be given at regular intervals. It is always taken and well assimilated, the patient even craving a larger amount of nourishment than it is well for him to take for fear of overloading the stomach and causing indigestion.

After the completion of the active treatment the patient should take the hot and cold shower bath, but not enter the hot air or vapor bath cabinet. The strychnia nitrate and sparteine should be given hypodermically for three or four days afterwards, and a good nerve tonic and

sedative given for several weeks. An excellent preparation in the form of an elixir was given the patients I saw under treatment. It was composed of:

℞ Lactucarium, elix.; celery, elix.; hops, elix.; gentian, f. e.; wild cherry, f. e.; quassia, f. e.; sparteine, sulph.; ammonia mur.; hydrastis, mur.; strophanthus, tinct.; brew; mandragora offi.; ext. Signa: One teaspoonful in fourth glass of water before meals and on retiring.

In giving the mandragorin it will be found that a blonde is more susceptible to its effects than a brunette. This is common with all mydriatics, in consequence of which it is well to begin the treatment with the smallest dose mentioned, viz.: 5 drops. If the bowels should be too loose after treatment, which is not common, they are generally easily controlled by bismuth subgallate.

If after treatment the patient complains of a nervous feeling of unrest, or fidgets, one of the best remedies at our command is an occasional dose of cicutin (alk.) one-sixtieth of a grain given hypodermically.

The number of cases I saw treated during the three weeks of my stay was eleven. Of this number all went through the treatment without any suffering or discomfort to speak of. There was no shock to the nervous system, and the day following the period of active treatment they were all able to get up, dress themselves, and walk about the grounds. Some of the cases that were complete physical wrecks on entering the institution remained for a few weeks to regain their strength, others remained but a few days and returned to their homes, and resumed their occupation. Out of 50 cases that had received treatment and left the institution from three to five months previous there had been but four relapses. This certainly is a good showing, and I doubt if there is any other method of treatment that can produce like results.

There is no question but that mandragora is the only remedy thus far discovered that will completely antidote morphine, and eliminate it from the system without shock, pain or discomfort.

Mandragora officinalis is not a new remedy, but rather a very old one, and was supposed by the ancients to possess magical virtues, and this superstition is still cherished in some parts of Europe regarding its use. It seems to be isomeric with atropin, but is not converted into it by alkalies. "The sulphate and the hydrochloride or crystalline are deliquescent. A second alkaloid in much smaller amount was also extracted, of which the gold and platinum double chloride were formed. Both alkaloids had a mydriatic action."

The *United States Dispensary*, fifteenth edition, 1888, says "Mandragora is unknown as a remedy in the United States." "It was also used by the ancients as an anesthetic agent before surgical operations."

The therapeutic action and the physiological effects of mandragora are somewhat similar to that of morphine when combined with atropin, but without the unpleasant effect of that combination of drugs. Mandragora will not diminish the appetite, disturb the stomach, or constipate.

Mandragora is also a vigorous aphrodisiac, quickly restoring the weakened sexual powers of the morphine habitué; this action of the drug is so marked that its effect may be observed even though the use of morphine be still continued.

Mandragora is the nearest thing to a specific we have in the treatment of dipsomania, and almost any case of delirium tremens may be aborted by the proper administration of this remedy.

In giving this paper to the medical profession I do so not from a desire to exploit any particular remedy or method of treatment, but from a sense of duty that I owe my brother practitioners, and a desire to help suffering humanity.

That there is a gentle cure for the morphine and other drug addictions without shock to the system, suffering, or even marked discomfort is an established fact.

That this method of treatment need not extend over a long period but, under ordinary circumstances, may be accomplished in from one to three weeks is also proven.

That no bad results have ever followed this method of treatment or deaths resulted therefrom is shown by the statistics kept in the treatment of over one thousand cases in the past three years at the Homestead Sanitarium in Memphis.

My own observation and experience show that the treatment of any case of drug addiction should be in a hospital or sanitorium.

That any physician treating a drug patient during the period of active treatment should see that patient personally every two hours, and always be within easy call. This is imperative, not from any danger to the patient in the method of treatment, but that the action of the medicines may be closely observed, and the dosage increased or diminished according to the condition and comfort of the patient. If, for instance, the patient should begin to experience any discomfort, he should be relieved at once by an increase of the mandragorin; if this should not be done he would, of course, get into an exceedingly nervous condition, lose faith in the treatment and retard his own recovery. To gain the confidence of the profession in this method of treatment it should be open to the fullest investigation of any reputable physicians, allowing them, if they so desire, to be present during the entire period of active treatment of any patients they might choose to bring for treatment.

Clinical Department.

CONCERNING GERMAN MEASLES.

BY CHARLES W. TOWNSEND, M.D., BOSTON.

I HAVE been seeing lately a number of cases — some twenty-five or more, — of a mild eruptive disease which I have called Rötheln or German

measles. Having previously been somewhat skeptical as to the separate existence of this disease, and having expressed this skepticism in the study [1] of a mild epidemic of measles occurring in 1889, my reasons for a change of view are here noted. I am especially moved to state these reasons, for I find that some of my confreres in Boston are still skeptical of the separate existence of this disease.

The cases I refer to are characterized by a macular measles-like rash, suddenly appearing over the whole body, mostly in children, occasionally in adults, with little or no accompanying symptoms. Only in exceptional instances are there any prodromal symptoms, slight malaise for a few hours. The rash is the first thing to attract attention. In a very small minority there is slight conjunctival redness, while cough and other catarrhal symptoms are practically absent. The temperature is either normal, or slightly elevated to 99° F., rarely as high as 100° F. With a very pronounced rash, I have several times found the temperature 98.6°. In one case I took the temperature five times during the whole period of the rash, which lasted twenty-four hours, and found the highest point reached was 98.8°. The rash in this case was profuse. The child felt perfectly well through it all. The rash generally disappears in forty-eight hours, and I have known it to last only five or six hours. A rash lasting only one day is common. While the rash resembles that of measles very closely, it sometimes assumes in places, especially on the face, a diffuse erythematous character, causing us some anxiety on the score of scarlet fever. I have seen a rash that was at first macular, become diffuse over a considerable part of the body. These cases are undoubtedly at times mistaken for scarlet fever. In all doubtful cases, where the macular character of the eruption is not clear, it is better to err on the safe side and call them scarlet fever. In five cases I have seen some swelling of the face, especially about the eyes, coincident with the diffuse erythema there, the body at the same time being covered with the measles-like eruption.

Swelling of the glands in the neck and a very slight sore throat occurred in a few, both being symptoms which may occur in measles. The tongue never suggests scarlet fever in its appearance.

The description I have given differs from the description of true measles as little as the mild cases of scarlet fever with their transitory rash and absence of symptoms differ from severe cases of scarlet fever. Cases of measles exactly resembling the German measles are found in epidemics of true measles. In other words, as I said in 1890, "The symptomatology of Rötheln is not distinct from that of measles." There are several reasons, however, which lead me to think that there is a distinct disease, which is called German measles or Rötheln.

In an epidemic where there are cases of mild measles we find many, generally the majority, where the cases are characteristic, or even severe. In none of the cases I have reported, have I found characteristic cases of measles to be communicated by them. All the cases where the exposure has been from these cases are of the same very mild type.

A second and most important fact is that German measles attacks those who have had measles before and those who have not, and it is not any more severe among those who have not had measles. It is true that second attacks of true measles undoubtedly do occur, but it is hard to believe that second attacks may be so common, that, as is the case now, previous attacks afford no protection at all from this eruptive disease.

A third argument, and one of considerable force, is that the stage of incubation is generally longer in German measles than in measles, it being ten to fourteen days in measles and generally twelve to twenty-one days in German measles.

In nine of my cases where I have been able to compute this stage, I have found it as follows: Thirteen days, 2 cases; fifteen days, 1 case; seventeen days, 2 cases; nineteen days, 2 cases; twenty days, 1 case; twenty-one days, 1 case.

Another fact is pertinent, namely, that there are more adults attacked, than in epidemics of true measles. Why? Adults rarely have measles, being protected by previous cases in their youth. Adults more frequently have German measles not having had in this vicinity at least as much exposure to that disease in their youth, although they are certainly much less susceptible than children.

A final point is that the contagiousness of German measles while marked is not so extreme as is that of true measles. It is rare for other children in a family to escape if one comes down with measles, while such immunity in one or more members is not uncommon in German measles.

[1] An epidemic of measles with remarks on Rötheln. Arch. of Pediatrics Vol. VII p. 269 April, 1890.

Medical Progress.

PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D., BOSTON.

(Concluded from No. 14, page 380.)

DANGERS OF DISINFECTION BY MEANS OF CORROSIVE SUBLIMATE.

BERTARELLI [25] gives an account of the opinions which, at various times since Guttmann and Merke first called attention to the subject, have been expressed with respect to the possible dangers to health that might arise from the metallic mercury due to the decomposition of corrosive sublimate (mercuric chloride) when employed in solution for the purposes of disinfection. Among others, the views of Esmarch, Morner and Sjoqwist are cited and the observations of Krupin and Bordoni-Uffreduzzi on the health of members of the

[25] Zeitschrift fur Hygiene, Vol. xlii, 1903, p. 553.

staff engaged in the work of disinfection, where corrosive sublimate was in use, are discussed. In the presence of some conflict of opinions, the author has undertaken, in the course of 1900 and 1901, a series of investigations into this subject at Turin, where an excellent opportunity was afforded for the enquiry, as it has been the practice to employ for many years past a very concentrated solution of the mercurial salt (ten per mille) for disinfecting purposes. His experiments included both persons who inhabited the disinfected dwellings and those who were habitually engaged in the work of disinfection. The urine and the excreta were systematically collected and tested, and small special chambers of wood and cement were constructed for observations upon animals. The walls of these chambers were frequently well washed with the solution, and live mice were then placed in them with such arrangements for feeding as to avoid all possibilities of direct contact of the food with the walls and floors. A full account is given of the methods of testing and of the extent and duration of the experiments. The author likewise examined the air-currents passing through chambers in which the corrosive sublimate had previously been used as spray, but in no case was it possible to demonstrate the faintest traces of sublimate in the water employed for washing the air. As the general result of his investigations, he states that this substance may be employed with the utmost confidence for disinfection, and that, with proper precautions, such as are always enjoined, even the officials, who are constantly engaged in the work, run no risks of mercurial poisoning.

Water Supply and Sewerage.

Bacterium coli as an indicator of fecal pollution. (Petruschky and Pusch.)

Weissenfels published in the year 1900 the results of his investigations,[27] which cast doubts upon the practical value of the coli-test, since this bacterium was found to be present in all samples of water. The authors controvert this opinion and state, as the result of very numerous experiments, that the ubiquity of bacterium coli can certainly not be established. In the case of a pure spring water, it was sometimes not possible to cultivate it from quantities even of three-quarters of a litre. In highly polluted waters, as, for instance, in river water, it was always present, and its relative abundance furnishes a good test of the degree of the impurity. The fluctuations in the extent of coli-pollution in surface waters were so great that the variations in a series of samples were more than a million-fold, and it was possible to establish four ascending degrees in a scale of impurity, which were each ten times that of the lower one. No increase took place in the coli-contents of slightly impure water, even when kept for a long time, if stored in the ice-chamber, and therefore samples sent up in the winter-time can safely be dealt with, notwithstanding the interval that may have elapsed since they were procured. The methods of conducting so-called titration-tests for the bacterium coli are described, and the results of numerous experiments conducted by Dr. Pusch are set forth in a series of tables.

[27] Zeitschrift fur Hygiene, Vol. xliii, 1903, p. 304.

Sewage purification by means of intermittent irrigation.

Oesten[28] states the problem of the purification of town sewage as a twofold one — first, the removal of the fouled water in such a way as to avoid all objections from the sanitary point of view, and, secondly, the extraction from it of the valuable manurial constituents in such a form as to be most serviceable for the production of new organisms; while a third condition may be added, namely, that this should be done with the smallest expense and on the least possible extent of ground. The author states that the modern tendency is at all hazards to satisfy this third set of conditions. The long-established practice of agricultural irrigation is being pushed into the background, though the results obtained thereby are in the main satisfactory. That system is, from the present aspect, too costly, both in regard to area, management and working expenses. Owing to this fact efforts are continually being made to obtain equally good results at a less outlay. This has led in the past to the introduction of the various precipitation processes, none of which, however, fully satisfy the conditions, and more recently to the adoption of the so-called biological or oxidation processes; but these last, while they fulfil the first of the requirements, are conspicuously inefficient as respects the recovery of the manurial ingredients. The author discusses the main principles on which the biological treatment of sewage is founded, and shows that a highly porous mass must be filled and emptied alternately with air and sewage water. By reference to diagrams, the best method of obtaining parallel results by means of a system of intermittent irrigation on a restricted area is described. In order to carry out the plan efficiently, arrangements must be made for giving rest to certain plots for a long period (not less than a year), during which time the land must be used for agriculture. Reference is further made to the possibility of utilizing the effluent or subsoil drainage-water, which, although clear and colorless, has still a certain proportion of organic matters and salts in solution. This water may be stored up in ponds for breeding fish, and the effluent will speedily become available for this purpose, owing to the luxuriant vegetation and the abundant supply of minute animalculæ which it is capable of producing.

The existence of nitrites in drinking-water.

Dienert[29] does not regard the presence of nitrites in water as necessarily a proof of serious contamination. As the results of observations and analyses of different waters he concludes:

[28] Gesundheits-Ingenieur, May 31, 1903, p. 242.
[29] Rev. d'Hygiene, April, 1903, p. 301.

(1) That nitrites may be found in the subsoil independently of any contamination. (2) That contamination of water is not always accompanied by the formation of nitrites. (3) Certain precautions are necessary in examining for nitrites in water, since if the temperature of the air is raised during the transportation of the sample, nitrites may be found which did not exist in the water when it was collected. (4) According to the conclusions of Spiegel, any opinion as to the quality of a sample of water should be made independently of knowledge as to the existence of nitrites.

SUPERVISION OF WATER SUPPLIES AND TYPHOID FEVER.

Fuller[30] furnishes the following suggestive figures showing the death-rate from typhoid fever in the principal cities of two populous states. In one of these states careful supervision of public water supplies is exercised under legal authority, by the State Board of Health, and in the other, no such supervision exists.

Deaths per 100,000 *inhabitants from typhoid fever in certain cities for the years* 1898–99 and 1900.

MASSACHUSETTS		PENNSYLVANIA	
Boston	30	Pittsburg	108
New Bedford	30	Alleghany	86
Springfield	26	Johnstown	83
Lawrence	25	York	83
Taunton	25	Chester	64
Brockton	24	Lancaster	59
Chelsea	24	Philadelphia	54
Salem	23	Mackiesport	53
Fitchburg	21	Reading	50
Lowell	21	Allentown	49
Lynn	20	Harrisburg	41
Newton	20	Altoona	33
Cambridge	18	Wilkesbarre	29
Worcester	18	Erie	28
Fall River	15	Scranton	23

(The mean death rate of the whole state of Massachusetts from typhoid fever in the five-year period, 1896–1900, was only 24 per 100,000, and the highest rate in any one of its thirty-three cities in that period, was only 39 per 100,000, and this in one of the smallest cities.)

ENGLISH SANITARY LEGISLATION OF 1903.

The Parliamentary Session of 1903 was not very fruitful in the enactment of laws for the protection of the public health and safety. The only acts of general importance of this character were the Motor Car Act (3 Edward 7, chap. 36) which provides protection against reckless driving of automobiles, and for their registration and the licensing of drivers of such vehicles, the Housing of the Working Classes Act (3 Edward 7, chap. 39) which facilitates the adoption of the existing acts by local authorities, and makes it possible to close any house, which in the opinion of the Council is "not reasonably capable of being made fit for human habitation" or "is in such a state that its occupation should be immediately discontinued." The Employment of Children Act (3 Edward 7, chap. 45) provides for all children, or for boys and girls separately, and with respect to occupations:

(*a*) The age below which employment is illegal.

(*b*) The hours between which employment is illegal.

(*c*) The number of daily and weekly hours beyond which employment is illegal.

It also prohibits absolutely, or permits under conditions, employment of children in certain occupations.

It provides that local authorities may prohibit or regulate street trading by persons under sixteen years of age. With reference to prospective legislation, according to the *Sanitary Record Diary* for 1904, it appears probable that the General Public Health Act will be taken in hand at the present session of Parliament, and that the questions of death certification and of vaccination may come in for a share of discussion. The Conscientious Objections (Vaccination) Act expires Dec. 31, 1904, the time having been extended one year at the last session. River pollution, and the regulation of the trade in the cultivation of oysters also are likely to be taken up in consequence of recommendations which have been made regarding them.

A UNIFORM STANDARD FOR BOARDS OF HEALTH.

The *Journal of the American Medical Association*[36] calls attention to the need of uniformity among the local boards of health throughout the United States, in regard to the matter of reporting infectious diseases, isolation and subsequent disinfection.

Inquiry of the health authorities of the principal cities shows wide diversities of opinion and practice as to what diseases should be considered notifiable, and also as to what measures should be taken to prevent their spread. Philadelphia, for example, insists on the reporting of chickenpox, since many cases of smallpox are thus detected. Baltimore, Salt Lake City and St. Louis are the only large cities which require the reporting of both measles and whooping cough.

A difference also exists as to what diseases should require the use of placards.

In Salt Lake City isolation is applied to a greater number of diseases than in any other city.

In one city "the work of the health department in disinfecting with formaldehyde has been exceedingly successful," while another city reports 'all forms of formaldehyde disinfection as a delusion and a snare."

It is exceedingly desirable that the work of local health authorities should be made more uniform, and that these diversities in practice should be brought to the attention of the National sanitary association for discussion and action.

VITAL STATISTICS.

VITAL STATISTICS OF ITALY IN 1901.

Bodio[31] reports the following for the year 1901, for an estimated population in that year of 32,574,563. Marriage rate 7.21 per 1,000 (persons married 14.42 per 1,000). Birth rate, 32.47. Death rate, 21.95.

[30] Journal of Mass. Assoc. of Boards of Health. Vol. 14, 1904, p. 12.

[36] Editorial, Feb. 6, 1904.

[31] Movimento della popolazione nell' anno, 1901. Roma, 1903.

Comparing the three years 1882–84 with the three years 1899–1901, the marriage rate had declined from an average of 8.05 per 1,000 in the former period to 7.24 in the latter. The birth rate from 37.80 to 33.11, and the death rate from 27.36 to 22.54. The birth rate exceeded the death rate in the former period by 38%, and in the latter by 47%, thus showing an improvement in the natural increase of the population. Illegitimate births had diminished from 7.5% of all births in 1882 to 5.8% in 1901. About one third of this class of births had been legitimized by subsequent marriage of the parents or by royal decree during the last three years. The statistics of causes of death show a marked decrease in nearly all of the infectious diseases in the past fifteen years. The deaths from small-pox had declined from 549 per million inhabitants in 1887, to 104 per million in 1901. Measles from 803 per million to 171 in the same time. Scarlet fever, from 494 to 36; typhoid fever, from 939 to 361; diphtheria, from 952 to 167; whooping cough, from 376 to 212; malarial fevers, from 710 to 416; erysipelas, from 178 to 79; malignant pustule, from 24 to 10; pellagra, from 125 to 94; dysentery, from 212 to 2; puerperal fever, from 85 to 31.

In very few countries do the figures show such marked changes in so short a period.

There was an increase in the deaths from cancer from 427 deaths per million to 526; phthisis, from 1,074 to 1,112; pneumonia, 2,154 to 2,288; kidney diseases, 255 to 376, and suicide, 49 to 62 per million.

SUICIDES IN AMERICAN CITIES.

Hoffman [32] gives the figures of the suicides in fifty American cities with a population of fourteen and one-half millions. The years in question were the ten years 1892–1901, and the single year, 1902. The cities having the highest rate in the ten years were: St. Louis, with 25.7 per 100,000 population; Hoboken, N. J., 24.6 per 100,000; Chicago, 23.4; Oakland, Cal., 22.5; New York City, 21.2, and Milwaukee, 20.1; Cincinnati, 18.5; Newark, N. J., 17.9; Brooklyn, N. Y., 16.2; Boston, 15.9; New Orleans, 15.5. Of the fifteen cities having the lowest rate eleven were Massachusetts cities as follows: Worcester, 9.0; Lawrence, 8.8; Chelsea, 8.4; Fitchburg, 8.2; Cambridge, 8.2; Lynn, 6.6; Holyoke, 6.2; Somerville, 5.8; New Bedford, 4.6; Newton, 2.7, and Fall River, 2.7; the suicide rate for these fifty cities had increased from 12.0 per 100,000 population in 1890, to 17.3 in 1897 and 1898, and then decreased slightly to 17.0 in 1902.

By nationalities the rate was lowest among the Irish, 6.1; among native Americans, 6.8; Germans, 19.3; French, 22.0.

REDUCTION IN INFANT MORTALITY.

Dr. R. G. Freeman [33] attributes the striking decline in infant mortality to many agencies. The general adoption of pasteurization and sterilization of milk for infant feeding is by far the most important, and applies not only to New York City, but to the whole United States. Other agencies are improved city administration, milk inspection, the Straus Milk Charity, the fresh air work of St. John's Guild, cleaner streets, asphalt pavements, new parks, playgrounds and recreation piers, improved tenements and the use of diphtheria antitoxin.

GENERAL DEATH-RATES PER THOUSAND LIVING IN DIFFERENT COUNTRIES.

Twenty-five years' average (1876–1900) and in 1901. [34]

	England and Wales.	Scotland.	Ireland.	Denmark.	Norway.	Sweden.	Austria.	Hungary.	Switzerland.	Germany.	Holland.	Belgium.	France.	Spain.	Italy.
Average in 25 years, (1876-1900) ..	16.9	19.2	18.2	18.3	16.6	17.0	28.6	32.3	20.6	24.2	20.3	20.1	21.9	30.3	26.5
1901	19.1	17.9	17.8	15.8	14.9	16.0	24.2	25.4	18.0	20.7	17.2	17.1	20.1	27.6	22.0

The highest death rate in any year was 37.4 per thousand in Hungary in 1878, and the lowest was 14.9 in Norway in 1901.

DEATH-RATES PER MILLION LIVING FROM DIFFERENT INFECTIOUS DISEASES AND FROM CANCER.

In England and London in 1901, and in Germany and in Berlin, Paris, Hamburg, and Munich in 1900.

DISEASES.	1901. England.	1901. London.	1900. Germany.	1900. Berlin.	1901. Paris.	1900. Hamburg.	1900. Munich.
Smallpox	10	5	9	0	105	0	0

[32] The Spectator, Aug. 27, 1903. [33] Medical News, New York, Sept. 5, 1903. [34] Registrar General's Report, England.

The figures for cerebrospinal meningitis are not given in the returns of Paris, Munich, and Hamburg, and those of puerperal fever are not given in the Paris returns, hence the absence of figures for these diseases in the foregoing table does not imply the absence of the diseases in the places named.

PHYSICIANS, DENTISTS AND APOTHECARIES IN GERMANY.

Dr. Wehmer[35] gives the following figures for the year 1901:

Population of Germany in 1901: 34,463,377.

Number of physicians: 16,500, or 479 per million inhabitants.

Number of dentists: 1,024, or 29 per million inhabitants.

Number of apothecaries: 3,178, or 92 per million inhabitants.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOM STORER, M.D., SECRETARY.

MEETING of Dec. 15, 1903, the President, DR. J. B. SWIFT, in the chair.

DR. H. E. MARION read a paper entitled

A MANY-PHASED CASE OF CHOREA.*

DR. G. H. TUTTLE: This woman was a patient in the McLean Hospital for two weeks in the spring of 1902, and a diagnosis of Huntington's chorea was made. She represented the fourth generation after the appearance of adult chorea in the family. Her paternal great-grandmother, grandmother, a grandaunt, and three paternal aunts were choreic. Her father, who was described as of a nervous, high-strung temperament, full of energy and apt to be impetuous, was lost at sea at the age of thirty-five, so that this may be no exception to Huntington's statement that if one member of a family escaped, his descendants were ever afterwards free.

The choreic movements began at the age of twenty-eight and had existed about eight years at the time of admission. They appeared first in the face and were for a long time unnoticed by her. Even when they had become general, she appeared to have little appreciation of them. She spoke rather quickly, hurrying as she proceeded and finishing each sentence with a sharp inspiration. This was usually followed by a little laugh, which gave the appearance of a greater degree of dementia than was really present.

In general, it may be said that the choreic movements were entirely arhythmic and were irregular and confined within certain well defined limits. They were not so severe and violent as are sometimes seen in these cases, and she required no special precaution to keep her from injuring herself. They were, to a certain extent, under control of the will.

The movements of the face presented the greatest range, the most frequent being spasm of the *risorius*; at the same time the upper lip was raised. Very frequently she contorted her mouth, pursing up her lips and twisting them to right and left, and with this there was a contraction of the *corrugator supercilii*. At times she blinked. The head occasionally was pulled over to the right. Now and then the neck and upper part of the trunk were the seat of a clonic spasm. The legs would be flexed at the knee and then extended and kicked about irregularly. Occasionally there was a complete turning of the body at the hips, so that she would turn over in bed, pulling the clothes with her. The arms were least involved, though they were occasionally thrown about at random. She thought she had no difficulty in walking, but her gait, to say the least, was irregular and uncertain.

Voluntary movements were not very much interfered with. She could approximate the finger tips with a fair degree of accuracy and could pick up things perfectly well. The tongue was protruded quickly, but was fairly steady. To test her control, the pulse was taken for two minutes, during which time she was practically free from the movements, even her face being at rest most of the time. The nurse reported that when sleeping soundly they ceased entirely, but when partially awake they began again. Her greatest complaint was a severe frontal headache, which she had had for more than two years.

Her mental condition was one of moderate dementia, with marked depression of spirits. She had relinquished her household accounts and duties at least a year before admission because of illness and to avoid mental stress, and it was difficult to judge of her administrative capacity. She presented no exhilaration, no hallucinations or delusions. There was no gross memory defect, but there was a childishness in her conversation and her manner aside from the frequent laugh. She did not comprehend situations and their significance, as was shown at the time of the illness and death of her children. She was careless of exposure in the presence of the physicians and would get up and follow them out on the ward in her night-dress. In general, she showed a decided lack of perception of the fitness of things. She had suffered from the intense headaches for two years, and in a degree she appreciated her position and often told the nurse that if she failed of relief at the hospital, she had better die. She had reason for her depression and her suicide was the logical outcome.

Huntington, in reporting his cases in 1872, called attention to the occurrence of mental symptoms and the tendency to suicide. Others have spoken of irritability, violent outbursts of anger, suspicions, delusions of persecution, and exaggerated ideas: but these are merely incidental to, and symptomatic of, a progressive dementia, and are found also in senile dementia and general paralysis. In the later stages these patients show a marked dementia, with loss of memory and a general loss of intellect. The mental symptoms usually appear years after the onset of the choreic movements, though occasionally they are coincident with them. Unless from suicide or intercurrent disease, death comes from exhaustion in from ten to twenty years.

While the disease bears the name of Huntington, its essential features were given by Waters thirty years before, and to the present time little has been added to his description; that it is hereditary, that it rarely appears before adult life or after forty-five years, that it is incurable, and that it induces dementia.

Few careful autopsies have been reported and there is no uniformity in the findings. There is no doubt that various lesions may cause choreic movements if the process is a diffuse one — and perhaps some so reported are not cases of Huntington's chorea. The autopsies of Dana (1895)[1], Clarke (1897)[2], Collins (1898)[3], and Good (1900)[4] agree substantially that it is a degenerative and not an inflammatory process; that the

chief changes are an atrophy of the cerebral cortex with a degeneration of the ganglion cells, especially marked in the motor areas and in the frontal lobes, with an increase of neuroglia, most conspicuous where the cell degeneration is most marked; and an enlargement of the perivascular spaces, — a parenchymatous degeneration of the cerebral cortex.

Dr. Marion: As to the question when this patient first developed chorea, my impression is that it was even in childhood; that is to say, her peculiarly silly laugh and manner of saying "Yess-ss" with a rising inflection. While the second boy was certainly rather idiotic in appearance, he has improved vastly since some adenoids were removed.

Dr. D. H. Fuller: This patient came under my observation at the Adams Nervine Asylum two years before her death. Her cause for coming was entirely the suffering from her headaches. She told me that these had existed from early childhood without relief from any treatment. While at the hospital these headaches were practically constant. Her choreic movements were very little in evidence. Her hopelessness of ever getting relief from these headaches was the great cause of her depression. With us she was never suicidal. When questioned she would always reply that she was in pain, but at times it was much more severe than at others. Her silly laugh and tendency to make irrelevant remarks were the only symptoms that suggested impairment of her mental powers.

Dr. Edw. Cowles: This is a case of quite unique interest — the only one that has occurred in my personal knowledge. I have little to add to what Dr. Tuttle has said. The question of heredity is of great interest. It seems to me that in psychiatry, with more modern methods of study, less stress is being laid on heredity as an essential cause of insanity. Twenty years ago this was much insisted upon. Even the classification of mental diseases was fundamentally based upon heredity. As the symptom groups are being more carefully studied, we are coming to see that there are not so many forms of mental disease as was once thought, and most of these may occur without a hereditary cause. Heredity has, of course, some value as a predisposing condition, but the necessity of insanity following as a consequence of the neuropathic condition does not seem to be the case, except in a class which are distinctly neuropathic — the paranoias — and these are much less numerous than was supposed a few years ago. Looking at this question from the point of mental hygiene, it can be said that we can offer the hope that patients of neuropathic heredity are susceptible of improvement, and care in bringing them up may avert these troubles. This view is one that should be carefully considered by the profession. I have no doubt that many cases of insanity are induced by the fear of becoming insane. Too much is made of heredity. The laity have come to think of heredity as did the profession twenty years ago, and this is the cause of a great deal of unnecessary suffering.

Dr. J. G. Blake: While the process of lifting up is going on, the profession can do a certain amount of missionary work by discouraging marriage in cases in which there is an inherited tendency to disease by pointing out its dangers. We can create a public sentiment, which in time may produce laws to protect itself against the diseases due to the marriage of persons having diseases liable to be transmitted.

Dr. Edward Reynolds: There is extant a society in which human breeding is regulated by law, or, rather, custom. In a personal communication Lumholtz, the Australian traveler, tells me that the Australian blacks have developed a system to that end. When a boy reaches puberty he is brought before a council of the elders, and if exceptionally healthy and vigorous, he is accepted as a breeder. If, on the contrary, he is in any way deficient, an artificial hypospadias is made with a sharp clam shell, with the result that he cannot procreate. Such a practice cannot but tend to raise the average of the race.

Recent Literature.

A System of Clinical Medicine. Dealing with the Diagnosis, Prognosis, and Treatment of Disease. For Students and Practitioners. By Thomas D. Savill, M.D. (Lond.), Physician to the West End Hospital for Diseases of the Nervous System; Physician to St. John's Hospital for Diseases of the Skin, London; formerly Medical Superintendent of the Paddington Infirmary; Medical Officer of the Paddington Workhouse, etc. Vol. I. Illustrated. London: J. & A. Churchill. Philadelphia: P. Blakiston's Sons & Co. 1903.

The volume before us, which is one of two, is of more than usual interest because it offers a new point of view in the presentation of the general subject of clinical medicine. We have grown accustomed to the ordinary method of textbook writing, consisting essentially in a more or less complete description of individual diseases with relatively slight attention to the underlying principles governing diagnosis. There is a strong tendency in the ordinary textbook to present a series of facts simply, rather than to appeal to the reasoning faculty of the student.

Dr. Savill has departed radically from this conception of textbook-making in the volume before us. Regarding the origin of his plan the author says that after beginning medical practice he at once began to feel the importance for diagnostic purposes of reviewing various diseases which might give rise to a patient's leading symptom or symptoms. This information he failed to find in the ordinary textbook. He therefore kept a record of his cases, derived largely from the rich material, so generally underrated, obtainable in workhouses and infirmaries. With this material he approaches his subject from the standpoint of symptomatology; he follows the sequence ordinarily adopted in the actual examination of a patient.

The first chapter gives a general scheme of examination. The general principles of disease are discussed in the second chapter, and thereafter the various symptoms and signs referable to the several organs and regions of the body are taken up with such other details as the individual subject calls for. He divides each chapter into three unequal parts, the first dealing with the symptoms which may indicate disease, the second with physical signs and methods used in their discovery, and the third, and larger portion of each chapter, to a clinical classification of the disease affecting that region, this followed by descriptions dealing with individual

diseases arranged according to their clinical relationships.

In addition to this general plan the author has introduced two special features, the first being, at the beginning of each chapter, a detailed list of symptoms and their causes; secondly, italicized paragraphs have been used to emphasize the important features of separate diseases, thereby facilitating reference and diagnosis. The author considers that the advantages of his method, thus briefly described, are that clinical medicine is approached from the positive rather than the negative side. It is opposed to the so-called "process of diagnosis by exclusion," since the reader is guided not to the least improbable but to the most probable diagnosis. He is further of the opinion that this plan gives a truer view of nature's facts than one which deals with diseases as so many separate entities, an opinion with which we are in most cordial accord.

The task which the author has set himself in carrying out this somewhat elaborate scheme is clearly far greater than that comprised in the making of an ordinary descriptive textbook. We have not as yet had occasion to put the volume to the actual test of experience, but the principles involved in its construction are certainly in the line of scholarly medical writing and stand in marked contrast to the increasingly stereotyped method of producing books.

This first volume, complete in itself, contains 702 pages, including an elaborate index, is most attractively illustrated, and printed in varying sized types to permit of ease of reference and to promote a general systematic arrangement. The first volume takes up so-called local diseases, or diseases causing local symptoms and acute specific fevers of microbic origin. A glance at the pages indicates the very great amount of work and care for detail which the author has expended in the perfecting of his plan. We welcome this volume, and shall look forward with much anticipation to its successor as a unique departure in textbook writing, and are confident that the theory upon which it is based is one which must appeal to men who prefer to study medical problems from a rational rather than from a purely descriptive standpoint. The illustrations, type and general appearance of the book, which is of convenient size, are all beyond criticism. We hope it may have a wide circulation in this country as well as in England.

The American Year-Book of Medicine and Surgery for 1904. A Yearly Digest of Scientific Progress and Authoritative Opinion in all branches of Medicine and Surgery, drawn from journals, monographs and textbooks of the leading American and foreign authors and investigators. Arranged, with critical editorial comments, by eminent American specialists, under the editorial charge of GEORGE M. GOULD, A.M., M.D. In two volumes. Vol. I, including General Medicine. Octavo, 673 pages. Illustrated. Vol. II, General Surgery. Octavo, 680 pages. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1904.

These two familiar volumes, with the date 1904, appear in identical form with those of several preceding years, namely, in two volumes, one devoted to advances in medicine and the other in surgery. It is of some interest that the volumes this year comprise slightly fewer pages than in 1903, owing, no doubt, not so much to a diminution in work done, as to discreet condensation of the material. There have been several changes on the staff of contributors owing to resignations of certain men previously serving in this capacity, but the new names are quite sufficient guarantee of the continued excellence of the general editorial work.

A certain innovation has this year been made in placing at the head of each chapter a brief summary of the more noteworthy advances and discoveries of the preceding year. This is an excellent plan, and no doubt will be appreciated by readers who find it difficult or impossible to read the various abstracts of the original articles in detail. The books, as usual, are adequately illustrated and printed with such a use of type that ready reference is facilitated. The work of the publishers is excellent, as we have come to expect from them.

Uric Acid as a Factor in the Causation of Disease. A Contribution to the Pathology of High Blood Pressure, Headache, Epilepsy, Nervousness, Mental Diseases, Asthma, Hay Fever, Paroxysmal Hemoglobinuria, Anemia, Bright's Disease, Diabetes, Gout, Rheumatism, Bronchitis and Other Disorders. By ALEXANDER HAIG, M.A., M.D. (Oxon.), F.R.C.P., Physician to the Metropolitan Hospital and the Royal Hospital for Children and Women, etc. Sixth edition. Illustrated. Philadelphia: P. Blakiston's Sons & Co. 1903.

Six editions of this much-discussed book have appeared within twelve years. In the three years which have intervened since the preceding edition Dr. Haig has found occasion to amplify his work on the classification of what he calls uric acid diseases, to rewrite in great measure the chapter on treatment and to discuss some of his investigations with the uric acid filter. The author's attitude remains radical, and might be expressed in his own words as follows: "What eleven years ago in the first edition was little more than possibility or probability is now absolute certainty, a certainty which can be made visible to the untrained and unaided eye in a few moments."

That Dr. Haig is an extremist will be generally acknowledged, and relatively few men in the profession are willing to follow him to his comprehensive conclusions. At the same time it must be acknowledged that the insistence upon the study of uric acid has been profitable and has led to a clearer conception of certain processes of metabolism and disease.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, APRIL 14, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

CO-OPERATIVE MEDICAL WORK.

Whatever our opinions may be regarding specialism in medical practice, it is growing each year clearer that intelligent investigation of medical matters demands the special study often of many investigators. We have before us a very striking example of an excellent type of co-operative medical research in the recently published volume on smallpox, comprising the last number of the *Journal of Medical Research.*

It is not our purpose at this time to comment particularly on the character or results of this elaborate piece of work, but rather to call attention to the fact that, under the general direction of Dr. W. T. Councilman, no less than eight men, including himself, have taken part in the various lines of study which have finally led to the completed work. It is scarcely possible that so broadly constructed an investigation could have been carried on by one man. Each, working in his own field, has added something of interest to the general subject, which in its completion presents a well-rounded discussion of the subject from various points of view. We quote this simply as an illustration of what is unquestionably coming to be the best type of medical work. The individual, no doubt, will always be able to produce results of great value, and in certain detached fields will continue, in the future as in the past, to add to the sum total of knowledge.

Many problems, however, which are particularly agitating medical men at the present time, demand the intellect and resources of many investigators directed toward a common end. If under proper leadership such united effort may be brought to bear on single problems, it cannot be doubted that results of more far-reaching significance will be reached than through the researches of individuals, however gifted they may be. Not only is this type of work desirable in our laboratories, but it may well be extended to the broad, practical clinical fields which absorb the attention of many medical men. The modern hospital, for example, with its elaborate outpatient department, subdivided more and more into sub-departments, is offering as never before a field for intelligent co-operative work. The familiar disease processes which may be seen daily at the various clinics, but about which we are still in extreme ignorance, offer a field for research which should include the laboratory as well as the clinical side.

Each department, be it surgical, neurological or laryngological, or any of the others, approaches the subject of tuberculosis, for example, from its special standpoint, and fails in many cases to recognize the far-reaching interrelationships which exist. The suggestion has been made, which appears eminently feasible, that departments of a hospital should unite toward elucidating certain of the medical problems in such a way that each could bring the data derived from its special point of view, and finally unite the results into a general conception of our present knowledge of the subject in question. Details naturally would have to be worked out in each individual case, but the fundamental principle implied in the word "co-operation" cannot be too strongly insisted upon at this time of diversified specialism. The knowledge of the specialist is invaluable. This must be generally recognized, but the knowledge of all, as never before, must be brought together into one comprehensive whole. Could this plan be carried out systematically in hospitals, as in laboratories, there is no question that much of the disrespect with which specialism is treated in certain quarters would give place to a feeling that out of it has come decided advantage to medical knowledge, looked at from the broadest general point of view.

A similar plan may with very great advantage be used in the conduct of medical meetings, as experience has amply shown. General subjects, which have wide bearings and which may be discussed by men working in different fields, always excite attention and stimulate interest as a more restricted subject could not do.

It has been an interesting evolution to observe the gradual development of the special student,

and it will be no less interesting to establish in the future the necessary relationship of this special student to investigators in collateral fields and so to the general body of men concerned with scientific medicine. We have long been convinced that specialism is but a step toward a very much broader and deeper general attitude than has hitherto been attained. This must ultimately be brought about by the completest possible co-operation.

THE TYPHOID EPIDEMIC AT WATERTOWN, NEW YORK.

IN regard to the epidemic of typhoid fever at Watertown, N. Y., mentioned in the last bulletin of the State Department of Health, an investigation conducted by Dr. George A. Soper, whose work at Ithaca as the representative of the department is well remembered, has established the fact that the primary cause of the outbreak was the polluted condition of the town water supply drawn from Black River, which carries the sewage of some thirty or more villages and of a large number of mills. The spread of the disease was due to the usual methods of secondary infection. Some wells were found to be infected and other agencies were discovered. Dr. Soper at once took vigorous measures to combat the epidemic. The over-crowded hospitals were supplemented by accommodations provided in the new high school building, and a second emergency hospital was established for cases complicated with erysipelas, of which a number had occurred. A bacteriological laboratory was instituted, and it is said to have proved extremely useful. Disinfectants of standard quality were distributed free, with cards of instruction relating to their proper and effective use. A cheap and abundant supply of good spring water was arranged for by private enterprise, and the quality of the water insured by daily analysis. The public records, which previously had been very imperfectly kept, were made complete and valuable, and a system established by which they will remain so in the future. The city was cleaned as never before, and the consequences of years of municipal negligence as fully as possible corrected. As a result of the steps taken the epidemic is now abating. According to the latest reports there are 203 cases of typhoid in the city, of which 88 are in hospital and 115 in dwellings under good oversight. A filter plant is being built which will purify the public water supply; but as the seeds of infection have been sown broadcast, great vigilance exercised through a long period will no doubt be needed to eradicate the disease.

THE INFLUENCE OF TRAMPS IN SPREADING SMALLPOX.

DR. KAYE, medical officer of West Riding, England, (*Journ. of the Sanitary Institute*, January, 1904), presents many instances of the introduction of smallpox, through the medium of tramps. In 1893, out of 63 towns invaded by smallpox, at least 37 owed its first introduction to tramps, and in 1903, out of 138 towns, " 100 definitely attributed the introduction to visitors of the tramp class."

In Sheffield, out of 28 importations of smallpox from November to May, no less than 21 were brought by tramps. In Huddersfield 8 out of 13 invasions were thus attributed, and in Barnley, " all of their 46 cases could be traced back to visitors of the lodging-house class."

" When once a tramp receives infection," says Dr. Kaye, " he rarely comes under official observation until he has been in close contact with numbers of his kind, who, in the meantime, have dispersed in all directions, probably carrying with them the seeds of disease, while they in turn will infect other wanderers before their own progress is checked."

The author advises that direct powers be obtained by sanitary authorities to secure the following ends:

(1) Vaccination or revaccination of any tramp *exposed* to the infection of smallpox.

(2) Disinfection of the person and clothing.

(3) Detention of the present inmates of infected common lodging houses, and refusal of new admissions.

(4) Complete closure of common lodging-houses where necessary.

The first of the foregoing recommendations is defective, in advising the vaccinations of *exposed* tramps only, since it is a very difficult matter to determine who has or has not been exposed to infection; hence it were preferable to vaccinate all tramps without exception.

MEDICAL NOTES.

COMPULSORY VACCINATION IN PENNSYLVANIA. — It is stated that a bill will be offered in the coming Pennsylvania legislature to provide for compulsory vaccination in the state under the jurisdiction of health boards.

College of Physicians of Philadelphia. — It is stated that at a recent special meeting the College of Physicians decided to erect a new building at a cost of approximately $250,000.

University of Pennsylvania, Department of Medicine. — The medical department of the University of Pennsylvania will conduct, as usual, a summer school in medicine. It is announced that the course will begin on the ninth of May and extend over a period of six weeks. In most instances the individual courses will be limited to ten students.

Gift to the Johns Hopkins Medical School. — Mr. John D. Rockefeller has given to the Johns Hopkins Medical School and Hospital $500,000, without conditions, to meet its expenses. It will be remembered that the hospital funds suffered severely on account of the fire which destroyed some of its real estate in Baltimore. A more beneficent gift under the circumstances could hardly have been made.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon April 13, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 50, scarlatina 12, typhoid fever 5, measles 155, smallpox 0.

The Union Label Rampant. — It is stated, and we understand correctly, that at a meeting held last Sunday in Boston the Building Trades Council refused to receive a communication from the Boston Society for the Relief and Control of Tuberculosis because there was no union label on the letter head. The letter was returned to the society unread. It has since transpired that the letter heads of one or more of the unions themselves have no union label. Such behavior as this, especially toward a philanthropic body, striving for and seeking assistance for the regeneration of the community is depressing. It emphasizes President Eliot's plea for a free democracy and illuminates his refusal of the union label.

Report of Cambridge, [Mass.,] Board of Health. — The Cambridge Board of Health in its annual report recommends that a new hospital for cases of diphtheria and scarlet fever, with a ward for the care of measles, be established. It is also recommended that a proper hospital be constructed for treatment of cases of smallpox, and also one for tuberculosis.

In general, the board feels that it is desirable that the various infectious diseases should be treated in proper buildings constructed especially to that end. Dr. Eugene A. Darling of the bacteriological laboratory reports that 75 cultures for the determination of the presence of diphtheria were made from 68 cases, and that sputum from 30 cases of tuberculosis was examined with but 4 positive results. The city laboratory was also called upon to use the Widal reaction in 18 samples of blood.

The Smoke Nuisance. — On April 12 the committee on cities gave a hearing on a bill to provide for the abatement of smoke in Boston and vicinity. Prof. C. H. Benjamin has recently contributed an article to *Science* in which he draws attention to certain fallacies regarding the necessity of smoke. He maintains, as has been done before, that smoke means waste, and that, therefore, an attempt to abate the nuisance should meet rather with the co-operation than the hostility of the factory owners and those burning large amounts of coal. Perfect combustion and the prevention of smoke are equivalent terms. The attainment of perfect combustion, which is another word for complete economy, is the problem. This is possible provided firemen are sufficiently educated to do their work with intelligence. The bill certainly should be passed without difficulty, and should meet with the hearty approval of every class in the community.

NEW YORK.

Memorial Chapel at Lincoln Hospital. — A memorial chapel at the Lincoln Hospital and Home (for negroes), in the borough of the Bronx, was dedicated on Easter Sunday. The chapel is the gift of Miss Anna Van Santvoord, and was erected in memory of her parents, the late Com. and Mrs. Alfred Van Santvoord, at a cost of about $10,000.

Cornelius Williams, Insane. — Cornelius Williams, the negro who last autumn murdered Andrew H. Green, revered as the "Father of the Greater City of New York," without provocation and without motive, has been adjudged insane by a jury in the Court of Special Sessions and committed to the State Hospital for Insane Criminals at Matteawan. Drs. Austin Flint and Carlos F. Macdonald, representing the state, and Manson and Allan MacLean Hamilton, for the defense, all pronounced the man positively insane.

DECISION AGAINST UNIVERSITY OF NEW YORK. — After a legal contest extending over several years the University of New York has finally lost in its endeavor to retain the ownership of the Medical College Laboratory of New York City, which for some time past has been under the control of Cornell University. On April 5 the Court of Appeals at Albany handed down a decision, sustaining that of the courts below, that the university reconvey to the laboratory the property in question.

PASSAGE OF THE ELSBERG BILL. — The Elsberg bill, abolishing the office of coroner in New York City after the termination of the incumbency of the coroners now serving, which recently passed the state senate, was passed by the lower house of the legislature on April 8 by a vote of 80 to 30. As it will doubtless receive the governor's signature, this much needed reform, which has been secured after years of determined opposition, may be regarded as an assured fact. By the provisions of the bill the duties at present performed by coroners are assigned to a board of medical examiners under the jurisdiction of the city department of health.

CONVICTION FOR CRIMINAL ABORTION. — Dr. Edward E. Conrad who, through clever detective work on the part of the agents of the New York County Medical Society, was recently convicted of attempting a criminal abortion was sentenced on April 8 by Recorder Goff to an indeterminate sentence of not more than two years nor less than one year in state's prison. This was the first case of conviction for attempted violation of the law against illegal operations, and in pronouncing sentence the recorder stated that he would be pleased if a certificate of reasonable doubt should be obtained in order that the questions involved might be settled by a higher tribunal. Dr. Conrad will therefore probably be kept in the Tombs prison, where he is now confined, pending his attorney's appeal to the supreme court.

MORTALITY REPORT. — The weekly reports of the health department show that during the month of March the mortality in the city represented an annual death rate of 23.80, as against 22.59 in February and 19.23 in March, 1903. The death rate is therefore exceptionally high, while in March of last year it was exceptionally low for the season. The corrected rate, excluding non-residents and infants under one week old, was 22.76. Among the diseases in which there was an increased mortality were the following: The weekly average of deaths from pneumonia increased from 263.25 in February to 296 in March; of deaths from pulmonary tuberculosis, from 172.25 to 195.6; from influenza, from 24.25 to 28.2; from measles, from 17 to 29; from typhoid fever, from 8 to 9.4; and from cancer, from 49 to 51. The mortality from pneumonia reached its climax in the week ending March 5, when there were 350 deaths from the disease. Since then there has been a gradual decline in the number of deaths, and in the week ending April 2, 250 were reported. Among the diseases in which there was a decreased mortality were the following: The weekly average of deaths from diphtheria and croup declined from 54.75 in February to 40.8 in March; of deaths from scarlet fever, from 27.75 to 26.2; from broncho-pneumonia, from 118.5 to 114; from diarrheal diseases, from 48.5 to 41.6; from diarrheals in children under two years, from 38.5 to 32.4; from Bright's disease and nephritis, from 139.5 to 130. 6; and from organic heart diseases, from 118 to 106.4. During the month there was one death from smallpox.

Miscellany.

DR. WEIR MITCHELL IN A NEW FIELD.

IN the April number of the *Century Magazine* there is begun the publication of an article by Dr. S. Weir Mitchell entitled "The Youth of Washington, Told in the Form of an Autobiography." We have all been charmed with Dr. Mitchell's fiction, and probably this article may be said to border on fiction, though abounding in historical facts. The author imitates Washington's style of writing, necessarily. Without inquiring too closely as to the success of the imitation — a most difficult task — we may say that in the main this first installment of the article has the Washingtonian quaintness, and certainly does not misrepresent the great man. Furthermore it is intensely interesting. It is embellished with an excellent portrait of the author. — *New York Medical Journal.*

RECENT WORK ON THE "N" RAYS.

WHATEVER incredulity may be expressed in England in regard to the so-called "n" rays French *savants*, notably M. Blondlot who first described these emanations and M. Augustin Charpentier, are still freely contributing papers on the subject to the Académie des Sciences. The most recent development is the discovery by M. Blondlot of certain new rays allied to the "n" rays and, like them, emitted by the Nernst lamp.

For these the name " n_1 " rays is suggested and they exhibit the peculiarity that whereas the " n " rays increase the brightness of a suitable feebly luminous surface the " n_1 " rays diminish it. M. Charpentier's investigations have been chiefly directed to the physiological action of rays of both kinds. Having found, as mentioned at page 594 of *The Lancet* of Feb. 27, that the acuity of vision is augmented by the action of the " n " rays, he has tried their effect upon the senses of smell, taste and hearing. The organs of all these senses have their activity stimulated by the rays when these are brought to bear upon the nasal mucous membrane, the tongue, or the ear, respectively, and in addition to this the sense of smell can be affected by bringing a source of the rays opposite a point immediately above the glabella or, better, by placing it upon the top of the head a little in front of the bregma. Whether, as in the cases of sight and smell, the effect of greater intensity of taste and hearing can be produced by the action of the emanations upon the brain through the skull is yet undecided, but the difficulty is probably only that of localising the appropriate centers. On repeating his experiments with the still newer " n_1 " rays M. Charpentier found that, as in the case of the luminous screen, results opposite to those already stated were obtained, there being a general decrease in sensitiveness of the organs concerned. — *The Lancet.*

Correspondence.

AN UNAUTHORIZED LABEL.

NEW YORK, April 11, 1904.

MR. EDITOR: Referring to my letter of Feb. 29, regarding the unauthorized use of my name on the labels of the new anesthetic " Anæsthol " (a fact which had only just then come to my notice) I herewith beg to enclose a joint communication from Messrs. Chas. Cooper & Co. and Lehn & Fink, with the request that you kindly have the same appear under " Correspondence " in the next issue of your esteemed JOURNAL.

I hope you will do me this favor, as it will vindicate me in the eyes of such colleagues as may have seen the label and consider it wrong — as I certainly do — for a reputable physician to have his name used for commercial purposes. The enclosed notice is the outcome of a rather lengthy controversy carried on under legal advice.

Very truly yours,

WILLY MEYER, M.D.

ANÆSTHOL.

NEW YORK, March 29, 1904.

MR. EDITOR: We beg to state that the use of the name of Dr. Willy Meyer of New York upon the label of the new anesthetic " Anæsthol " was introduced without his knowledge, though in entire good faith upon our part.

At his request the label has been changed and, in order to protect the medical profession against unreliable imitations, it will henceforth bear the name of Dr. Weidig, the originator of the new compound.

Deaths reported, 3,960; under five years of age, 1,015; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 894; acute lung diseases 806, consumption 454, scarlet fever 52, whooping cough 14, cerebrospinal meningitis 39, smallpox 7, erysipelas 18, puerperal fever 16, measles 51, typhoid fever 53, diarrheal diseases 102, diphtheria and croup 69.

From whooping-cough, Boston 5, Philadelphia 5, Pittsburg 2, Boston 1, Newburyport 1. From smallpox, Philadelphia 7. From cerebrospinal meningitis, New York 31, Baltimore 2, Boston 1, Worcester 2, Lawrence 1, Newton 1, Chicopee 1. From erysipelas, New York 9, Chicago 4, Philadelphia 2, Boston 3.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending March 19, the death-rate was 19.7. Deaths reported 5,781; acute diseases of the respiratory organs (London) 205, whooping cough 188, diphtheria 53, measles 180, smallpox 5, scarlet fever 37.

The death-rate ranged from 8.3 in Hornsey to 31.0 in Warrington; London 18.8, West Ham 14.5, Brighton 19.0, Southampton 14.4, Plymouth 20.1, Bristol 21.9, Birmingham 24.6, Leicester 22.3, Nottingham 19.9, Liverpool 23.2, Bolton 20.5, Manchester 27.4, Salford 22.3, Bradford 18.1, Leeds 19.3, Hull 16.6, Cardiff, 18.3, Rhondda 23.0, Wigan 27.4, Tottenham 18.0, Preston 22.2.

METEOROLOGICAL RECORD.

For the week ending April 2, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING APRIL 9, 1904.

E. C. TAYLOR, assistant surgeon. Detached from the Naval Museum of Hygiene and Medical School, Washington, D. C., and ordered to the naval hospital, naval station, San Juan, P. R., sailing from New York, N. Y., about April 9.

F. E. CAMPBELL, assistant surgeon. Detached from the Naval Museum of Hygiene and Medical School, Washington, D. C., and ordered to the "Constellation."

J. D. MANCHESTER, assistant surgeon. Ordered to the "Columbia," April 11.

T. N. PEASE, assistant surgeon. Ordered to the "Har tford,' April 14.

J. S. F. REEVES, assistant surgeon. Ordered to the "Minneapolis," April 14.

A. R. WENTWORTH, surgeon. Granted leave for one month from April 5.

L. W. BISHOP, assistant surgeon. Detached from treatment at the naval hospital, Hare Island, Cal. Ordered home and granted sick leave for two months.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED APRIL 7, 1904.

VON EZDORF, R. H., passed assistant surgeon. Detailed as recorder of board of examiners that met at Washington, D. C., April 4, 1904, for the examination of candidates for appointment as assistant surgeon. April 6, 1904.

FOSTER, M. H., passed assistant surgeon. Bureau letter of March 19, granting Passed Assistant Surgeon Foster leave of absence for ten days from March 30, amended so that said leave shall be effective April 29. April 6, 1904.

ANDERSON, J. F., passed assistant surgeon. Relieved from duty as recorder of board of examiners that met at Washington, D. C., April 4, 1904, for the examination of candidates for appointment as assistant surgeon. April 6, 1904.

MCCLINTIC, T. B., assistant surgeon. Relieved from duty in the Hygienic Laboratory, Washington, D. C., and directed to proceed to Tampico, Mexico, for duty in the office of the United States Consul. April 2, 1904.

GLOVER, M. W., assistant surgeon. To proceed to Vancouver, B. C., for special temporary duty. April 3, 1904.

WARREN, B. S., assistant surgeon. Granted leave of absence for six days from April 10. April 5, 1904.

MONCURE, J. A., acting assistant surgeon. Department letter granting Acting Assistant Surgeon Moncure leave of absence for thirty days from April 1, 1904, amended so that said leave shall be effective from April 10. March 31, 1904.

BOARD CONVENED.

Board convened to meet at Stapleton, N. Y., April 4, 1904, for the physical examination of officers of the Revenue Cutter Service. Detail for the board: Passed Assistant Surgeon A. C. Smith, Chairman. Assistant Surgeon T. W. Salmon, Recorder.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the American Climatological Association. For the year 1903. Vol. XIX. Philadelphia.

Die Entstehung der Tuberkulose mit besonderer Berücksichtigung der v. Behringschen Lehre. Von Prof. Cornet. 1904. Reprint.

The International Medical Annual: A Year Book of Treatment and Practitioner's Index. By thirty-two Contributors. Twenty-second year. New York: E. B. Treat & Co. 1904.

Lecture.

INTRODUCTORY LECTURE AT UNIVERSITY BELLEVUE HOSPITAL MEDICAL COLLEGE.

BY BEVERLEY ROBINSON, M.D., NEW YORK,
Clinical Professor of Medicine.

THERE are few greater pleasures, I believe, than to speak to a thoroughly sympathetic audience when one knows something and wishes to tell it. Such is my attitude towards you, young men, who are working in a great career, if properly understood by yourselves and by the public.

I come before you as Clinical Professor of Medicine. I have, therefore, to do with a big subject, well worthy of the highest ambition of the best medical man to excel in. To teach it well, one should have very many great and good qualities; to teach it as it has been taught, and is still being taught by a very limited few, one should be *facile princeps* amongst his fellows.

What are, or rather should be, the relations of clinical medicine to the different specialties and even to general surgery itself? In my judgment, it should, so to speak, embrace or include them all. Not that I mean to say that any one man can familiarize himself theoretically or practically with all that is known of these divers branches. That is simply out of the question and Utopian.

But on the other hand, the honored professor of clinical medicine should be sufficiently familiar with the different special branches to be able to give a final and wise judgment as to what to do or not to do in nearly every case, and in the event of particular interference to say at what point or time an arrest of treatment may properly be advised. This has long been my position and it remains so; only with firmer conviction as to its great usefulness to the public and to the profession.

Later, I am convinced, when real knowledge of medicine and its higher aims is more generally disseminated and recognized, individuals and families will select their practitioner as the sensible ones to-day do their business advisers. First of all on account of high personal character and absolute rectitude above and over all; then education and opportunity will be considered; then brains; then that quality of heart and hand which obliges a man to do right, and in a kindly, sympathetic way, as well as merely to think straight.

The study of clinical medicine is continuous; it never ends. New knowledge comes every day, and this has to be valued and tested, the good wheat to remain and be cultivated, the chaff to be thrown away, gotten rid of, disregarded. Therefore your motto should be with one of my old French masters, "*Le travail, le travail — toujours le travail.*" Besides, from the clinical standpoint, cases always differ. No two patients are ever precisely alike. In a sense there is no such thing as *a disease;* there is invariably a *person* affected with a disease. Thus we see that while the textbook, or the clinic may provide a description of one or many forms of a given complaint, there are other forms not touched upon; at least the program is incomplete during many long years.

Admitting, in general, we may ere very long find all the types, and familiarize ourselves with them, of various phases of a known disease, we would still have differences depending upon the personal equation, *i. e.*, habit, occupation, temperament, environment, etc., which are as variable as the features, the manners, the sympathies, the qualities of mind. Hence we see that supposing our mere diagnosis is correctly made, in so far as the recognition of a particular disease is concerned, yet the differential diagnoses may still be far from complete, and the prognosis and treatment in reality a more important and difficult subject, although often too much ignored, may rarely be exhaustively treated in individual instances.

With each successive year, I come before my class with a keener appreciation of my own limitations of knowledge, and of how little informed I am practically in certain directions; notably in the more advanced work of the microscopist, the chemist and the bacteriologist. In these lines I must turn, and do so gladly and cheerfully, to the younger generation of physicians for help and guidance. I feel fortunately that I am still appreciative and perhaps possessor of anterior knowledge of these subjects sufficient to enable me in many instances to weigh their value and determine their direct importance when applied to the estimate of a particular patient under observation and treatment.

These clinics before the entire class, and in the college building particularly, have their necessary deficiencies and limitations. In the first place, as you know, our cases are ambulent cases. They come to the dispensary, are seen one or more times by my assistant, and if they present points apparently of interest, they are later brought before the class. Frequently I am unable, in the nature of things, except for a short time or at all, to see the patient in advance; consequently, personally know them only imperfectly. I am of course speaking wholly from the medical side. The salient features of the cases, partly by reason of the information given me by my assistant, partly through my own observation before the class, are considered as carefully before you as circumstances and time permit.

On the other hand, there are numerous modifying, ambient conditions affecting each case, to which I can only refer in a few words, or am obliged to pass over in silence because of lack of accurate available knowledge.

Again, I do not believe mere physical examinations in their entirety and minutiæ can be profitably taught to a large class, by the clinical professor. This is work now assigned to section teaching in a great measure, and very properly so. In the sections with a relatively small num-

ber of students, each student has the opportunity to palpate, percuss, and auscultate, in the various disorders of the heart, lungs, or abdominal viscera, which may be seen outside of hospital wards.

Again, in a limited way, affections of eye and ear, throat and nose, genito-urinary organs and nervous system, may be observed, commented upon and treated. Don't delude yourselves and don't remain under false impressions! There is a very great deal that can be learned only in hospital wards, and in following up cases from day to day, noting changes which occur, the onward progress or arrest of disease and the treatment with alterations and modifications, which new conditions and symptoms render constantly imperative.

A word in regard to the teacher himself. Each professor has his personality; each man will teach according to his own methods and appreciations, provided, of course, he is worthy to fill the place to which he is appointed. Of course he will follow more or less closely certain fixed lines of instruction which may remain unchanged for periods of time, but while this is true, his manner of questioning or examining a patient, his mode of thought, his emphasis of special features of the disease, the importance and bearings thereof, and the conclusions theoretical or practical to be deduced therefrom, are all more or less his own. What you may and can profitably learn from one man lecturing on a given subject, you will not learn in quite the same way from another. But that does not mean to say that the instruction is not equally valuable from both.

Again, the attention is riveted in a different way upon different men. Some professors are precise, cold, deliberate; but their profound knowledge of a subject, their accuracy, their poise, their truth, make amends for coldness and it may be almost stolidity. Other men less profound, perhaps, less prone to see and dwell upon minutiæ, less well balanced at all times in forms, expressions and presentation of facts, have a great attraction in their personal teaching. They are warm and enthusiastic, filled with certain aspects of their subject, which they insist upon and illustrate in ways most taking and suggestive. Such men's teaching must be supplemented usually, to be well rounded and perfect, by the knowledge acquired from books and extensive reading at home. But they have their great value. Their enthusiasm, their honest convictions expressed in no uncertain terms, hold the class almost spell-bound for the while, and the lecture room becomes a delight and a longing. The words, the instruction of such men remain; they are rarely or never forgotten, even in after years when the college benches have been long left behind and the whilom listener has grown gray in the service of his fellow men. I take it that just here remains, and ever will, the inestimable something, the intrinsic power and worth of the spoken word over the written statement. Things written and studied in books are soon forgotten and must be studied again and again, to keep the mind awakened and refreshed. Things spoken, despite the old Latin dictum, "*litera scripta manet*," stand out clearly before the mind's eye, and in times of stress and emergency come forth like beacon lights to help, guide or direct. But in order that this may be so the teacher must always teach the truth as he understands it, unwaveringly, unflinchingly, with trust and hopefulness, in the spirit, like to that of the immortal Harvey. Ultimately, such doctrine from such a source will surely prevail; and why? because it rings true to all men all the way along the line.

A word for the general practitioner and the modern, superabundant specialist. All honor to both. But let us look for a moment at their dividing lines. The one perfecting himself in a single limited branch, the other devoted to all; the one working hard, no doubt, but with many spare hours for self, for home, for relaxation: the other the constant servant of the public in time of trouble and sorrow, of fear and panic, the guiding hand to all, when doubts and anxieties and carking care are present. He it is who carries his own and all others' burdens, and does it willingly, cheerfully, bravely, until tired out with age or disease, and even at such times is rarely known to halt or stop completely, in his Christ-like service to men on earth. He ushers them in upon it, when woeful accents of motherhood about to be make most urgent appeals and cries; he folds the hands, gives the last solace and hope, and says the last prayers with the departing spirit and the heart bereaved mourners, around the flickering lamp of life ere it goes out, many, many times, when no other mortal can, no other mortal does, the thrice holy work.

Is this man now appreciated as of old? Does Ian Maclaren's good physician of "The Bonnie Briar Bush" hold his birthright in isolated communities, or large centers of population? I fear, I believe not, except it be in rarest instances. But I also believe firmly his day will return, and none too soon. It will come back when men, true men, become less ambitious and self seeking, when accurate knowledge of medicine and its lofty aims is more widely disseminated; when worth and service have honors awarded them, when mere wealth is not a passport to high position, when greed and ill-gotten gains are no longer tolerated, and finally, when the clergy generally, high and low, preach more by real life and example, and not so much by doctrine and precept.

Here again, don't let me be misunderstood. The general practitioner, the family adviser, may be true and kind, generous, sympathetic, active, considerate of all men even more than of himself; but to be trusted and relied upon, he must have brains, tact, good judgment. And his brains must be instructed brains, brains that have seen a great deal and observed intelligently, carefully, accurately. He must, of course, be enthusiastic in well-doing, but likewise he must have a fund of common sense (that most uncommon thing of all, perhaps), to fill his thoughts and direct his

actions. He must sift and weigh things before he counsels and advises. He must not be backward in endorsing what is proven to be good and valuable; but he must be lukewarm and partially blind to fads, conceits, ill-reasoned measures to promote health, whether they come from the polypharmacy doctor, or the too daring operator, with other men's health, comfort or lives at stake.

The usefulness then of oral lectures from the veteran in medicine proceeds from the fact that he has seen many moons come and go, many ideas and practices vaunted and heralded with loud hosannas, which very soon were little thought of any more, and consequently comes to possess a prudential reserve of capital, which makes him cry a halt when others rush ahead and do, and find out later how silly and misguided they are, not to say something worse of them. While the newer demonstrations belong to the younger generation, as a rule, in microscopy, chemistry, bacteriology, skiagraphy, the older man should insist upon general conditions which govern, should bring many cases, apparently new or distinct, until properly winnowed and garnered, they re-appear under important laws over-ruling all. He it is who should point out special symptoms or the absence thereof in different cases; he it is who should estimate and assign their due importance and value in all that pertains to diagnosis, prognosis and treatment. The rational explanation of many obscure things should come to him to settle and unravel as far as may be, but not see in every defect or change of organ a local trouble to be attended to with prescription or knife, but only an indication. It is not for him to believe that the body of man is a bit of mosaic work from which here and there a piece may be left out or taken away, without injuring the entire aspect and value of the structure. Rather it is for him to show it is feeling, working, active, dynamic substance and force, which must be most carefully considered from every standpoint before the purposes of nature are counteracted, interfered with, or needlessly and harmfully controlled.

Original Articles.

RESECTION OF THE NASAL SEPTUM WITH REPORT OF FIFTEEN CASES.

BY LEON E. WHITE, M.D., BOSTON,

Clinical Assistant at the Massachusetts Charitable Eye and Ear Infirmary and Assistant in Otology at Tufts Medical School.

Having tried practically all methods for correcting nasal obstruction due to deflection of the septum and finding that recovery was slow, the pain and discomfort great, and the results not commensurate with the difficulties undergone by the patient, I commenced, two years ago, to work on a line which is now developed into what is known as "Resection of the Septum."

This operation has been extensively described by Otto T. Freer, M.D., of Chicago in two excellent articles in the *Journal of the American Medical Association*. In addition to the aforesaid writer we are indebted, among others, to Drs. Krieg, Boenninghaus and Ingals for the work they have done to bring it before the medical profession.

As this operation has not yet received the recognition it merits I wish to enumerate some of its many advantages, to refute the objections, and, as my methods differ from those I have seen described, to give a brief outline of my way of procedure, a description of the special instruments devised and a summary of my fifteen cases.

THE ADVANTAGES.

First: There is accuracy, the work being done under the eye of the operator. As every part of the deflected portion can be seen, and then removed, the position of the septum will be uniformly good. In no other operation is there such a certainty as to the result.

Second: Splints do not have to be worn. These at the best are a great nuisance to both operator and patient.

Third: Rapidity of recovery; three or four weeks as against six or eight by other methods.

Fourth: Lack of pain due largely to the absence of traumatism.

Fifth: Short after-treatment.

Sixth: Freedom from sepsis.

Seventh: Free respiration forty-eight hours after the operation.

Eighth: It is available for either bony or cartilaginous deflections.

Ninth: It creates the utmost possible space by not only straightening the septum but by reducing its thickness to that of the two layers of the mucosa.

Tenth: The lumen of the concave side is never lessened.

THE OBJECTIONS.

First: That it is only adapted to a limited number of cases. As I have obtained perfect results in cases where there was practically total stenosis with an involvement of both bony and cartilaginous portions of the septum it would seem as if the objection were groundless. Dr. Freer while inclined to believe, at the time he wrote his first article, which was published in March, 1902, that there might be cases not suitable for this method, says in his article of December, 1903: "Fuller experience with the resection operation for septal deflections has given me confidence that there is no variety of deviation of the septum it cannot remove in a neat and surgical manner without injury to the patient. Even anteroposterior sigmoid deflections, blocking both nares, may be dissected out from the same nostril in one operation, including both bends."

Second: Length and tediousness of the operation for the patient. The one and one-half hours required is possibly a little longer than is used by other methods but as the patient is in

a recumbent posture he bears it remarkably well.

Third: Difficulties of the operation. With the instruments that have been specially devised any skilled operator easily surmounts every obstacle.

Fourth. Hemorrhage. This is easily controlled with adrenalin and a large number of previously prepared cotton sticks. The question of secondary hemorrhage is no greater, if as great, as in the other septum operations.

Even though the operation does require greater skill and patience on the part of the operator, is he not highly compensated by the perfection of the result and by the comfort and speedy recovery of his patient?

THE OPERATION.

After removing the vibrissæ and cleansing the convex side of the nose it is packed with corrosive cotton pledgets saturated with a 4% solution of cocaine, fresh and recently sterilized. This is allowed to remain about one-half hour; the instruments are meanwhile carefully sterilized, and a large number of cotton applications made ready for quickly removing the little blood that may obscure the operative field. Just before commencing the operation two or three cocaine pledgets are put on the concave side that it may become anesthetic by the time the operation has reached far enough to require it. The pledgets are now removed from the convex side and the surface wiped over with a 1-5000 solution of sterilized adrenalin. This, by the way, should be used sparingly, or not at all, on the concave mucosa as it tends to lessen its vitality and thus to predispose to a local necrosis.

A vertical incision is now made, just anterior to the deflection and extending from a point as high up, or higher than its top, to a point just above the floor of the nose. When we have a simple anterior deflection, with no great thickening, this long vertical incision will be all that is required, but when there is marked thickening or when the deflection is extensive, or far back, it is necessary to make a second incision parallel to the floor of the nose, commencing just beyond and below the most prominent part of the deflection and extending forward to meet the base of the vertical incision.

Figs. 1 and 2 show the two knives I have had specially constructed for making these incisions.

No. 1.

No. 2.

In one the blade is placed parallel to the handle while in the other it is at right angle. These blades are so guarded that they will cut to a depth of 1.5 mm. When a deeper cut is needed it can be made by drawing the blade through the incision two or three times. With these knives I have been able to make my incision with perfect ease and safety wherever necessary. The little bleeding that usually follows these incisions being checked, the mucous membrane is then dissected up, together with its perichondrium, over as much of the convex area as possible. For doing this I have devised two instruments which are peculiarly useful. As shown in Figs. 3 and 4 they have large handles with

No. 3.

No. 4.

blades at an angle of 135° thus giving an unobstructed visual field. The width of the blades are respectively 5 and 9 mm. this being the only point in which they differ. The blades are quite thin, have rounded edges, and are just blunt enough to prevent a cutting of the mucosa. With these powerful instruments the cartilage can be freed from its mucosa in an incredibly short time. In those cases where only a vertical incision is required we are now ready to incise the cartilage, but in those cases where an additional horizontal incision has been made, the mucous membrane is dissected off, rolled upward and backward and, when of considerable size, is held at the top of the nose by a small pledget of cotton. Up to this time the patient has been in a sitting posture and I have used for illumination the light of a 50-candlepower electric reflected into the nose by a head mirror. From now on the operation is done with the patient reclining on a high operating table, the head resting on an adjustable section so that it can be raised or lowered as it becomes desirable to illuminate any particular part of the septum. A portable electric light placed beyond the patient's head and a little below the level of the operating table now furnishes the source of light. The next step is to incise the cartilage at the point where the deflection commences. This is done with the guarded knives used for incising the mucosa and shown in Figs. 1 and 2. I have never yet perforated the opposite mucous membrane when using these knives. The smaller of the two dissectors is now inserted through this incision in the cartilage and the concave mucosa pushed away from it over a small area and then this denuded portion is removed by my cutting forceps. With the larger dissector the mucosa is now, with its perichondrium and periosteum, lifted away as far as possible from the deflected

cartilage and bone. I find that it is important to preserve the perichondrium and periosteum as they give added life and strength to the future septum. The work of the dissector should be watched through the opposite naris so as to guard against tearing the mucosa. Great care must be exercised in removing it from the bony base of the deflection where it tends to adhere. As soon as the mucosa is separated from the deflection the concavity disappears. Having now freed the cartilage from its covering over as large an area as is accessible, it is removed piecemeal by cutting forceps which I have had specially designed for this purpose. These as can be seen in Fig. 5 are very powerful; the

No. 5.

handles are 14 cm. long and the distance from the lock to the end of the cutting blades is 7 cm. With them it is possible to remove not only the cartilage but, when necessary, a considerable area of the bone. Occasionally I find it useful to have recourse to Stacke's rongeurs, Gruenwald's forceps, or a long chisel, for the removal of the bony ledge sometimes found along the base of the deflection. A couple of ring curettes, which I have had made with stronger rings and with larger and longer handles than is usual, are also useful for removing small projecting fragments. The major part of the operation is done with my special forceps. As the size of a section removed by the cutting blades is 10 x 5 mm. it is possible to take out a large deflection in a short time, and, as the blades form with the handle an angle of 122°, one has an almost unobstructed visual field, even when working far back in the bony septum. Occasionally two or three bites have to be made at the same section of bone before it can be detached; as it is advisable to thus remove it, rather than to twist it off. The deflection having been removed, the nose is thoroughly cleansed with a warm alkaline solution and the flap replaced. It is generally wise to replace this two or three times, during the later stages of the operation, to make sure that there are no points of the deflection left that might unduly press against it, which would prevent, when healed, a perfectly straight septum.

The next step is to insert sutures, the number dependent, of course, upon the size and position of the flap; as a rule I use two to close the vertical incision and one or two on the horizontal. In some of my cases the second suture on the horizontal flap has been at a depth of 3 cm. For accomplishing this I have found it necessary to have constructed, short, strong, curved needles which can be turned within the nose, and for holding these a special pair of Alligator needle holders. (Figs. 6 and 7.) Some objections have been made to suturing the flap, one writer claiming that it is a difficult procedure and unnecessarily prolongs the operation, while other authorities, notably Krieg and Boenninghaus, go so

No. 6.

No. 7.

far as to advise one to make no attempt to preserve the lining on the concave side, as they maintain that it rolls up and cannot be stitched in place. As with the needles and needle holder mentioned one can insert three sutures without difficulty in about ten minutes, it would seem that these objections have been overcome. The advantages of the sutures are, that they keep the edges of the wound in coaptation so that, over a considerable length, if not over the entire incision, primary union can be obtained; they moreover keep the flap in place when packing the nose and prevent its curling up, which it has a decided tendency to do; in fact, it almost always seems too small for the space we desire to have it fill and I generally find it necessary to do considerable pulling in order to re-adjust it. In some of my early cases, where I did not use sutures, recovery was much slower than in later ones, as there was always a considerable area to be filled in with granulations. In some of these later cases primary union was practically obtained.

The sutures being inserted the nose is wiped out with a 1-3000 bichloride solution, powdered with Aristol and packed with 10 or 12 cylindrical plugs. These are some 5 cm. long by 5 mm. in diameter and are made from corrosive absorbent cotton, saturated with sterilized liquid albolene. To prevent too much strain on the flap, when packing, I protect it by placing the larger of my blunt dissectors against it while inserting the plugs. These are placed one above the other, close to the septum, so as to cover the flap lightly at first; then other plugs are inserted external to these, not much pressure being exerted, until there is built up, as it were, a sort of triangular barricade with the base on the septum and the apex between the middle and inferior turbinates. The last two or three plugs, the ones which form the apex, are packed in tightly so that the pressure thus obtained is evenly distrib-

uted over those forming the base of the triangle, *i. e.*, the ones in contact with the septum.

In my first cases I used iodoform gauze but found that I could not obtain with it such even pressure over the operated area as I desired and that there was considerable pain and hemorrhage accompanying its removal. When it remained in four days it was saturated with a secretion that was anything but aseptic.

In none of my cases have I found it advisable to pack the concave side, although it is recommended by some writers. At the end of twenty-four hours the three or four plugs that form the apex of the triangle are taken out, which at once relieves the patient from the discomfort of the packing without in any way disturbing those plugs lying against the wound. In another twenty-four hours the remainder of the packing is removed and the nose gently syringed, through the posterior nares, with a warm alkaline solution. The nose requires no repacking, but it is wise to have the patient wear in the vestibule for the next forty-eight hours, small pledgets of corrosive absorbent cotton which he changes frequently and removes altogether when he wishes to sleep. These for about a week are worn when the patient is exposed to dust or cold, otherwise they are omitted. The after treatment is such as may be needed to keep the nose healthy and free from crusts which usually last from three to four weeks. When the crusts have ceased to form, and the septum has become smooth, and is entirely free from granulations, the case is considered well. The results in my fifteen cases, and in all other cases I have seen reported, give this operation a much higher value than those other procedures designed to correct nasal stenosis due to a deflection of the septum. It is based on rational ideas, produces a permanent correction of the deformity and is worthy of more general adoption. My first six cases were done under much difficulty as the instruments were not then developed. Familiarity with the needs of the operation led me to design various instruments, which have been modified and changed until the ones described seem to meet all requirements. As my instrumentarium and technic were developed before I became familiar with the literature on the subject it will be found that they differ in many respects, especially in their simplicity, from those described by other writers. It has been my aim to have as few instruments as is consistent with a quick and accurate method of operating. It is very probable that other methods may have advantages over this, but experience has rendered it possible for me to do my last three or four cases with greater facility than ever before, having reduced the time from two to one and one-quarter hours.

THE FIFTEEN CASES.

The patients were all adults, five females and ten males. Six were deflections to the right, 6 to the left, and 3 in both sides or sigmoid. Six cases were purely cartilaginous, 3 bony and 7 both cartilage and bone. Seven had thick bony bases or spurs while the remaining 8 were deflections, with little thickening above the normal, the obstruction being caused by the angularity. In one case there was absence of the cartilage over a small area, the result of a previous attempt by another operator to correct the deformity with a saw. Nine cases were angular deflections, 3 bowed and 3 sigmoid. In 10 the deflection began near the front while in the other 5 it occurred in, or just anterior to, the bony septum. There were 5 cases where the deflection measured anteroposteriorly 4 cm. or more, and in these it was necessary to remove a large area of cartilage together with a considerable area of bone. In the first six cases I had two perforations while in the last nine but one. The first two were due to a lack of proper instruments and happened at the time of the operation, the last one probably came from a sloughing of the mucosa due either to the too free use of adrenalin or to the pressure from the gauze packing. Since I have avoided the use of adrenalin on the concave side and substituted the oil pledgets for the gauze I have had no perforations, *i. e.*, in the last seven cases. The perforations were all of small size and have not caused the least annoyance to the patients. This is because their periphery consists of mucous membrane only so that there is no crusting or bleeding, as there is in those cases where the periphery is cartilaginous. It is annoying to have perforations, but, with the improved instruments and the use of the cylindrical plugs, it should be of only rare occurrence if at all. In none of my cases has there been any secondary hemorrhage. A vertical incision was made in 4 cases while in the remaining 11, horizontal ones, in addition to the vertical, were required. In 2 cases where the perpendicular plate of the ethmoid was in firm contact with the middle turbinate it was possible to free it of its mucosa with the dissectors and then to work the long, biting blades of my forceps around it and to remove the deflected area which measured over 1 cm. in diameter. In two of the angular cases the mucous membrane of the concave side was caught in a very acute angle and, as it was thin, great care had to be exercised to free it without tearing. In these cases there was almost total occlusion of the convex sides and it looked as though there would be altogether too much tissue for the future septums, if they were to be in the median line; the results were absolutely satisfactory as the tissues shrunk sufficiently to cause the septums to be straight. The lumen of the concave side was not lessened in any of my cases. This is in marked contrast to the narrowing that occurs in those operations where the redundant portions of the septum are carried over into the concave sides.

In the first of my three sigmoid cases I removed the anterior bend at one sitting and the posterior bend at another, some six weeks later. This was, however, an unnecessary procedure as I found in my two later cases that it was possible to remove both bends through one side of the nose at the same time.

In an old specific case the anterior end of the vomer for over 1 c.m. was found to be a sequestrum while the vomer adjoining this was very soft and friable to a considerable depth; convalescence however was rapid and uneventful. In none of my cases was there any damage to the nasal profile, while in two of them, where there was a decided twist in the nasal tip, the deformity was greatly lessened.

All writers on this subject are agreed that there is no danger of a depression of the bridge of the nose from the removal of so much of the septum. The septum is not a support for the nose, but

only a division between the nares. It is further claimed that the cartilage is gradually replaced, but I have not been able to verify this assertion. It would, however, be of small consequence either way, as if replaced, it would be deposited between the two mucous membranes which are in the median line and in contact. Fever did not occur in any of my cases nor was there edema or marked swelling. The results in all my cases were most gratifying. The nose after this operation, to the great surprise and delight of the patient, is neither sore nor painful, and practically the only discomfort is that of the packing which obstructs the breathing for two days. It is not necessary to use enough cocaine to cause any heart depression or faintness and my patients have all been able to go home as soon as the operation was completed. It is not unusual for them to express sympathy for the operator as he seems of the two to be the more exhausted. There is so little reaction after the operation that patients do not as a rule need to be confined to their beds. When circumstances make it rather compulsory they are permitted to return to their work the second day after the operation; a week's rest, however, is always advisable. For three or four weeks the operated naris is more or less obstructed by crusts so that respiration is not as good as it will be eventually. It is important that the general condition of the patient should be carefully watched, his hours of rest and recreation inquired into and tonics prescribed if circumstances warrant their use.

In reply to several inquiries as to the use of my instruments in the sub-mucous operation on spurs let me add that they are useful. The knives and dissectors readily free the spur from its mucosa and then with either the long chisel or the forceps shown in Fig. 5 it can be easily removed. The objection to the saw is, that it does not readily take hold of a denuded bony spur and is liable to injure the flaps. Many so called spurs will be found on careful examination to be but the more or less thickened apices of deflections and to obtain good results it is wise to resect these protruding sections.

NOTE. The instruments illustrated in this article are manufactured by Messrs. Codman & Shurtleff, Boston.

SOME CLINICAL OBSERVATIONS ON THE CARE OF SEPTIC WOUNDS.

BY ARTHUR L. CHUTE, M.D., BOSTON.

THERE is a wide diversity of opinion as to the best method of dressing septic wounds. For some years I have taken a particular interest in this subject, and have watched a considerable number of septic wounds under various sorts of treatment with the idea of determining if possible which method gives the best results. My observations have been entirely clinical, and have been directed particularly toward the following points; the desirability of the moist antiseptic dressing as compared with the sterile gauze dressing; the effect of the so-called "antiseptic poultice," and the result of the use of antiseptic irrigating fluids and antiseptic baths on septic wounds. In so far as my observations have gone they have been practically a comparison of the aseptic, with the moist antiseptic treatment of septic wounds.

The chief advantage which most of its advocates claim for the moist antiseptic dressing, when applied to septic wounds, is its supposed bacteriacidal power. Its ease of application, and the slight grade of aseptic skill required, are, I think, seldom, if ever considered as its great advantages.

We know that by the intelligent application of antiseptics we can render an operating field surgically sterile, even though we cannot, as recent investigators teach, render it sterile from a bacteriological standpoint. We also know that in all sorts of recent wounds, we can, by antiseptic irrigation, remove infectious material, or render it inert. Perhaps a natural conclusion is, that if antiseptics can prevent sepsis when applied to recently infected wounds, they must necessarily be of value when applied to wounds already septic.

I feel confident that we have just reason to doubt the accuracy of this conclusion. When a septic process is under way, I believe the application of antiseptics has no parallel to their application in the conditions spoken of above.

In the instance of the healthy skin or of a mucous surface, we have the organisms on the surface, in the loose upper layers, in the glands or their ducts. In the recently infected wound the organisms are lying free and have not yet begun their growth in the tissues. In both cases the antiseptic can reach and destroy, or exert its inhibitory influence upon such organisms as are not removed mechanically. In a septic wound the conditions are wholly different; the organisms which are actually doing the damage are in the tissues, and the application of an antiseptic, particularly one like corrosive sublimate which is precipitated by albuminous substances, has little chance of reaching them.

Several commonly observed clinical phenomena, seem to me to give us reasonable ground for doubting the penetrating power of antiseptics when applied to septic wounds. The wall surrounding a focus of suppuration becomes, as soon as it is opened, an excreting rather than an absorbing surface. This is shown by the decreased absorption of toxins and the consequent fall of temperature, as well as by the tremendous amount of detritus which these wounds often pour out. It is true that we occasionally see absorption of carbolic acid or iodoform from the surface of wounds; these instances are, however, relatively rare. In my observation this absorption has usually occurred, not in septic wounds, but when these substances have been used either in recent aseptic wounds or on granulating surfaces. In both of these conditions there is a much greater power of absorption than in septic wounds which are essentially excreting surfaces,

trying to rid themselves of organisms and inflammatory products. The fact that a mono-infection easily becomes a poly-infection does not necessarily mean that the surface of a septic wound has any considerable power of absorbing chemical substances. Another point against the absorption, or if there is absorption, against the efficacy of antiseptics in these wounds, is the fact that the signs of infection first disappear in the periphery of the red, indurated area surrounding a septic wound. If antiseptics had any considerable influence on this process, we should expect the area nearest the wound would be the first to clear up, as it is most intimately in contact with the antiseptic. A third reason, to me very conclusive, is that in my personal observation, septic wounds treated aseptically clear up quite as soon as when treated antiseptically.

For the above reasons I believe the antiseptic dressing, when applied to septic wounds, fails in the only advantage which in theory it possesses over the aseptic dressing, and that it exerts no appreciable bacteriacidal action.

A dressing for a septic wound should secure three things: it should give protection from infection from without; it should drain the wound well; it should stimulate as far as possible the proliferation of healthy granulations.

As far as the matter of protection goes, neither the moist nor the sterile dressing has any conspicuous advantage over the other. Both are efficient.

When one considers the question of drainage, the septic cavity which is packed with sterile gauze is much more efficiently drained than that treated by a moist dressing. At the very outset the absorbing power of dry gauze is naturally greater than that of moist gauze; even when that part of the dressing which comes in contact with the wound surface is pretty well saturated with discharge, the absorbing power of the dry gauze remains greater, if the dressing contains anything like an adequate amount of it.

The most conspicuous advantage, however, which dry dressings have over moist dressings, when used in septic wounds, is in the rapid production of healthy and vigorous granulations. Under the use of sterile gauze a septic wound rids itself of its infection and becomes practically an aseptic wound quite as quickly as under the moist antiseptic dressing. Not only this, but the granulations are more healthy and vigorous.

The ease and rapidity with which a wound rids itself of sepsis when unhampered by antiseptics often permit of the employment of secondary suture. In large wounds, one may by this means materially shorten the convalescence. The great advantage, however, of secondary suture is not in saving a few days in the convalescence, but in permitting the closer approximation of the fascial planes in large wounds involving the abdominal wall, or in other situations where a weak scar is particularly undesirable. If a septic wound is to be allowed to fill by granulation, this process requires less time under the aseptic dressing due to the increased vigor and power of proliferation which granulations have, when unhampered by chemical irritants.

This more vigorous production of active granulations under the use of sterile gauze seems to depend on several factors: the mechanical stimulation of the gauze, the dryness which a properly applied gauze dressing brings about, and the absence of the depressing effect of antiseptics.

The mild aseptic irritation caused by dry sterile gauze seems to be just sufficient to stimulate a wound to its utmost in the throwing off of inflammatory products and producing of granulations. It is very difficult to tell just how much is due to the stimulative action of the gauze, and just how much is due to the dryness of the wound. Dryness of a wound seems to be a condition which is particularly favorable for the production of healthy granulations. The presence of any amount of discharge makes granulations dull and sluggish, as can be easily demonstrated by covering any healthy granulating surface with some non-absorbent dressing. That the gauze is in itself an active stimulant can be demonstrated by the rapidity with which a small slough will brighten up when gauze pressure is brought to bear upon it. That chemicals depress the vigor of granulations is, I think, shown by the dull, sodden, bluish appearance which bright granulations often show after soaking in an antiseptic solution. If, as we are so often told, the normal salt solution is the only fluid which does no injury to healthy cells, we need hardly wonder that antiseptic solutions harm cells whose vitality has already been lowered by a septic process.

An accurate comparison of the results gotten by these two methods of treatment is very difficult, as it is hard to say that any two septic wounds are identical as regards the question of healing. So far as outward appearances go, wounds may be very similar, but when one attempts to take into consideration the sort of organism, the virulence of the culture, together with the resistance of the patient, the problem is a complicated one, and an accurate comparison becomes a very difficult matter. From watching the course of a considerable number of septic wounds, with this point in view, I am convinced that we are unable to affect, by any application of antiseptics, such pus organisms as are in the tissues; that we must depend entirely on nature to rid the tissues of these organisms, and that the presence of antiseptics on granulations is detrimental to their vigor, and therefore to the rapidity with which a wound becomes healthy. In dealing with septic wounds, we can make the conditions such as are most favorable for the wound to *rid itself* of its infection, but we cannot in any way exert a direct bacteriacidal action on organisms in the tissues.

Some things which are of importance in helping a wound to rid itself of infection are: making it of such shape that it can be properly dressed, which means in a general way having the mouth

wider than the bottom, and avoiding so far as possible anything like a flask-shaped wound; protecting the wound from secondary infection by carrying out any operation aseptically and doing dressings in an aseptic manner; providing suitable drainage so that the granulations are not depressed by the waste products which the wound excretes; using mechanical stimulation to urge the granulations to their greatest reparative effort. My experience has been, that the dry sterile dressing meets these indications better than the moist antiseptic dressing.

By an "antiseptic poultice," I refer to a warm moist dressing, usually wet with a solution of corrosive sublimate or creoline, which is covered with some impermeable material to retain its heat and moisture. This dressing I have found open to the same charge of inefficiency from the bacteriacidal standpoint as the moist dressing, while its debilitating effect on the granulations is greater. Both these objections, however, I think are of minor importance when compared with a real danger which the antiseptic poultice sometimes possesses. This danger consists of a partial masking of the true condition of affairs. In a certain proportion of cases, the use of such a poultice brings about a marked dermatitis, often accompanied by considerable edema. This dermatitis may mask, to a considerable extent, the real progress of the disease. Lymphangitis, if present, is not so noticeable as it would otherwise be. The brawniness due to the dermatitis hides, or makes it more difficult to tell accurately, what is happening deep in the tissues. Pain is occasionally so much lessened by the antiseptic poultice as to give a false sense of security. This is most marked in septic processes in loose tissues. This analgesic action is probably partly due to the action of the heat and moisture, yet when carbolic solution or allied substances are used, a part may be due to the anesthetic properties which carbolic acid shows when applied to the skin. I have seen several instances in which I feel confident that a septic process has been allowed to extend much further than it otherwise would have been allowed to do, had it not been for this masking of conditions, brought about by an antiseptic poultice.

Certain mild infections, which look as though they would go on to suppuration, resolve under the use of the antiseptic poultice. In these instances we are prone to credit the poultice with bringing about resolution. I have seen a number of similar infections disappear under simply a dry dressing, infections which in every way have resembled the processes I was accustomed to see disappear under the use of the antiseptic poultice, and as I supposed, as a result of it. The claim that the heat is of value is untenable, for as ordinarily used the poultice is soon reduced to the temperature of the part, so that the part is no warmer than when covered with a dry dressing. I have been unable to convince myself that the antiseptic poultice expedites the separation of sloughs. As this process of casting off depends on the proliferation of granulations, anything which enfeebles them is more likely to lengthen the process. That it is at times a somewhat more comfortable dressing, I think cannot be denied.

When a septic wound is of a proper shape, and is properly dressed, it should rarely be necessary to irrigate it. The little discharge left after the removal of the dressing can be wiped off with sterile gauze. There may be instances where it is unwise to make the sacrifice of tissue necessary to have a wound of proper shape for gauze drainage. In these instances irrigation may be necessary in order to mechanically remove the collected discharge. The material used should be salt solution. Peroxide of hydrogen is open to a particular criticism to which the other irrigating fluids are not. Beside being no more effective as an antiseptic as regards organisms in the tissues, and beside acting as an irritant to the granulations, its gas-producing power may make it an actual spreader of sepsis, when used in cavities which are not widely open. This is particularly true in loose tissues. I recall especially a case of suppuration in a fat abdominal wall, in which the vigorous use of peroxide greatly prolonged and apparently spread the suppuration.

The objection to the antiseptic bath is that, like the application of antiseptics to wound surface by other means, it does not harm the organisms in the tissues, while it does enfeeble the granulations, thereby lengthening the reparative process. The bath simply cleanses the wound surface; this can be done more quickly in other ways and without depressing the vigor of the granulations.

While I have found dry sterile gauze the best routine dressing for all actively suppurating wounds, there are conditions where other dressings are indicated. The old indolent surface of which the varicose ulcer is a type, is one of these. In these cases the surface is very sluggish and needs a more powerful stimulant than sterile gauze. If one does not curette away the fibrous tissue base, strongly stimulating applications, such as iodoform, balsam of Peru, boracic powder and the like, are undoubtedly preferable to simple dry gauze. The more active antiseptics, however, have the disadvantage of acting more as depressants than as stimulants. When a septic wound has been reduced to a healthy granulating surface, and we are seeking to encourage an epithelial covering, ointments are indicated, as the changing of gauze injures the delicate ingrowths of epithelium.

There are some points in the aseptic care of septic wounds which deserve particular mention. The first object to be sought in a septic wound is to convert it into one which is, clinically speaking, aseptic. To get the quickest result in this respect it is necessary to keep the wound as free as possible from discharge. To do this the dressing should be changed whenever it becomes pretty well saturated. This may mean in large wounds changing the dressing at shorter intervals than daily for a time after operation, and applies to the outer absorbent part of the dressing, not

as a rule to that part lying in contact with the wound surface. McBurney[1] emphasizes the importance of this, as well as the general importance of treating septic wounds aseptically. With most septic wounds daily dressings are sufficiently frequent; in occasional cases a more frequent change is of benefit.

In dressing a wound care must be taken that the gauze is not packed in so firmly as to actually interfere with drainage. On removing the gauze from a wound cavity, it is desirable to make pressure near the margins while one watches to see if any drop of pus appears on the granulations. This is to guard against overlooking any pocket which is not being properly drained. If the wound is not dry on the removal of the dressing, it should be wiped dry before this pressure is made. The use of a head mirror is often of help in inspecting deep cavities such as those left after opening an abscess about an appendix. When there are sloughs to separate, or places where the granulations are gray or flabby, increased pressure should be made at these points, as the dressing is being replaced. When the whole wound surface is bright, the gauze should be packed in loosely, it should, however, come in contact with the whole granulating surface, that the wound may be kept as dry as possible. When a wound is covered with red, healthy granulations the time of healing may be reduced by secondary suture. This is only worth while in relatively large wounds. The simple device of strapping a wound with gauze strips and collodion applied in such a way as to bring the surfaces together, is occasionally sufficient to make them adhere. It always lessens the time required for a wound to fill in. It is probably unnecessary to say that in dressing all septic wounds the general aseptic technique should be carefully followed in order to avoid a poly-infection.

The conclusions which I have drawn from purely clinical observations on a considerable number of septic wounds are as follows: dry sterile gauze dressings are far preferable for the dressing of septic wounds because they, by their greater power of absorption, most efficiently drain the wound, and by their slight mechanical irritation and comparative dryness make the granulations more active and allow us to take full advantage of nature's reparative power, while moist dressings and antiseptic baths and irrigating fluids have a depressing effect on the granulations; moist dressings are, however, indicated when one cannot obtain sterile dressings or cannot depend on the aseptic skill of the persons who are to apply the dressings. "Antiseptic poultices" are not to be preferred to sterile dressings and there is at times a danger in their use; in case irrigating fluids are necessary, when from some unusual reason we are unable to make a wound of such shape that it can be properly dressed, sterile salt solution should be the irrigating fluid used. One should avoid peroxide of hydrogen since in partially closed cavities or loose tissues its gas production may make it a spreader of infection; the use of dry sterile gauze meets the indications in the routine treatment of the great majority of septic wounds better than any other material.

I wish to acknowledge my indebtedness to Dr. J. W. Elliot who was the first to direct my attention to the importance and advantages of asepsis, rather than antisepsis, in the care of septic wounds.

Clinical Department.

REMOVAL OF CALCULUS IN THE URETER BY A NEW METHOD.

BY EDGAR GARCEAU, M.D., BOSTON, MASS.,

Surgeon to the Boston Dispensary and Surgeon to Out-Patients in St. Elizabeth's Hospital, Boston, Mass.

MRS. M. L., thirty-four years old, married, was first seen on July 21, 1903. She had been in the most excruciating agony for a whole week, during which time she had made ineffectual efforts to pass a stone, impacted in the course of the left ureter. As this was not the first attack of the same nature, and as she had seen stones, passed on previous occasions, there was no doubt about the diagnosis at first glance. On examination there was no difficulty in detecting a very large stone situated fully 9 cm. from the entrance of the ureter into the bladder. It could just be reached with the examining finger.

The patient's condition was serious. She had reached the limit of endurance and immediate surgical interference was imperative.

Although the stone was well back in the vagina behind the uterine artery it was thought best to attempt its removal by a vaginal operation because it seemed that it could be more quickly removed in this way. On examining under ether it was seen that removal by a simple incision of the vaginal vault would be fraught with considerable difficulty on account of the distance of the stone from the vaginal outlet; especially if there should be a hemorrhage, which seemed not unlikely to happen as the patient had just been delivered of a child only six weeks before and the parts were in a very congested state and very soft. It occurred to me that if I could push the stone down into the vagina and keep it there while the vagina was being incised, the stone would serve as a guide upon which to cut. I tried to do this by pressing down through the abdominal walls, but it was not satisfactory; the stone slipped. The thought then occurred to me to incise the anterior cul-de-sac, push back the peritoneum between the bladder and the uterus as far as the broad ligament, then evert the broad ligament backwards, with the tip of the finger, catch the stone with the tip of the finger crooked at the last joint, force it down and towards the vaginal outlet, cut upon it with a very small incision, and finally squeeze it out. If there were hemorrhage it could be easily controlled by pressure from above with the finger, and sutures could be passed without trouble. Hemorrhage from vessels of the anterior cul-de-sac was not to be feared as it could be easily controlled.

The operation was performed as planned without the least difficulty. With the Péan retractors, which are used in performing vaginal hysterectomy, the anterior cul-de-sac was quickly opened, the peritoneum pushed back, and the broad ligament everted. The stone was found with ease and was pushed down into the vaginal vault, where it was delivered through a

very small incision. Immediately upon delivery the vaginal incision was closed with silver wire sutures, which took in the walls of the ureter. Some hemorrhage occurred in the anterior cul-de-sac, and as it was not desired to take any more time a few clamps were left on the vessels. A gauze drain was put in. The whole operation took ten minutes, and the stone was delivered in five minutes. The convalescence was not remarkable and there was no fistula. The ureter has remained pervious since the operation for both ureters have been catheterized since. The stone was a very large one and it could not possibly have been passed *per vias naturales*. It weighed in the dry state 7 dg. and it was 1 cm. long and nearly 1 cm. wide at the widest part. It consisted of phosphate of lime.

At the time this operation was done I was not aware that Doyen* had originated an almost similar operation for the removal of stones in the ureter. Doyen's operation, however, differs in a number of essentials. He incises the anterior cul-de-sac, and the ureter is exposed in the cul-de-sac. Then the stone is removed *through the cul-de-sac* itself and *not* through the vaginal wall. The operation terminates by suture of the ureteral walls and a drain is left in the cul-de-sac. Doyen's operation must take a great deal of time on account of the technical difficulties, and a fistula must be more serious in the anterior cul-de-sac than in the vagina, should one result. The advantages of the operation as performed upon my patient are obvious. The technique is simple. Hemorrhage is under perfect control. It is very rapid. I feel certain that very high stones can be pushed down and brought within reach. If fistula results the consequences will not be as serious as they are when the sacral, the rectal, or the Doyen method is employed, and operations for fistula are easier through the vagina than through the other routes mentioned. The ureteral and the vaginal walls can be sutured *en masse* with success. As the ureter in these cases is always dilated, this suturing is less difficult than it appears on first sight. If it leaks subsequently, the leakage will take place between the stitches and no harm will result. Of all the advantages gained, that with reference to time is the most important. These patients are almost always desperately ill, and time is an element sometimes not sufficiently considered.

Medical Progress.

REPORT ON PATHOLOGY.

BY JOSEPH H. PRATT, M.D., BOSTON.

THE PATHOLOGICAL ANATOMY OF PARATYPHOID FEVER.

Wells and Scott[1] report a fatal case of paratyphoid fever. Only four other instances have been recorded in the literature although nearly a hundred cases of the disease have been recognized during the past six years. The chief clinical features in the case studied by the writers was the continued fever which reached 104° on the day of admission to the hospital. The pulse was somewhat accelerated and dicrotic. A few rose spots appeared on the abdomen and the spleen was palpable. Intestinal hemorrhage occurred early in the disease. The patient died during the fifth week of illness. Agglutination tests with the typhoid bacillus were negative. Unfortunately the reaction of the blood with paratyphoid bacilli was not tested. At the autopsy a paratyphoid bacillus was obtained from the spleen and kidney and there can be little, if any, doubt that the case was one of paratyphoid infection. The organism produced a terminal alkalinity in milk and hence belongs in group β of Buxton's classification, although the authors place it in group α.

The spleen weighed 400 gm. and was very soft. The lymphatic apparatus of the intestine was not involved and the mesenteric lymph nodes preserved their normal size. Numerous irregular superficial ulcers were found in the ileum just above the ileo-cecal valve. There was no infiltration around the ulcers and they resembled those of dysentery much more than those of typhoid. Similar ulcers occurred in the case reported by Lucksch. Intestinal lesions were absent in the three other fatal cases.

The absence of proliferation and phagocytosis in the lymph nodules, which Mallory has shown to be the characteristic intestinal changes in typhoid fever, as well as the absence of any involvement of Peyer's patches in paratyphoid fever indicate, as the authors state, that there is some essential if obscure biological difference between the typhoid and paratyphoid bacilli.

The anatomical picture of paratyphoid fever is that of a septicemia associated with splenic enlargement and occasionally with non-specific ulcers in the intestine.

THE GENESIS OF BLOOD PLATES.

The opinion held by many pathologists that blood plates are products of red blood corpuscles is largely based on the observations of Wlassow made in Ziegler's laboratory some years ago. This investigator found that when blood was treated with a solution of mercuric chloride (saturated aqueous solution of mercuric chloride 10 parts, distilled water 50 parts) there were quickly formed from the erythrocytes red bodies with sharp outlines which gradually became transformed into colorless structures resembling blood plates. Other reagents acted similarly on the erythrocytes. Wlassow observed that these bodies like the blood plates were stained with certain aniline basic dyes and he regarded the two as identical and claimed that this experiment showed that the blood plates are not independent cellular elements of the blood but are formed from the erythrocytes.

Sacerdotti[2] states that the bodies described by Wlassow are not blood plates and morphological differences exist between the two struc-

* H. Morris. Surgical Diseases of the Kidney and Ureter. London. 1901, Vol. 11, page 530.

[1] Journal of Infectious Diseases, 1904, i, p. 72.

[2] Anatomischer Anzeiger, xvii, p. 249.

tures, although they appear similar at the first glance. The little knobs on the erythrocytes are never flattened, while the blood plates are flat. The former are homogeneous and frequently tinged with hemoglobin and thereby differ from the blood plates which present a granular appearance and are always colorless. Another difference was shown by treating a microscopical preparation prepared by Wlassow's method with a dilute solution of acetic acid, preferably a 5% solution. The small globular knobs and the red blood corpuscles vanish while the blood plates remain and their granular appearance becomes more distinct.

Sacerdotti performed another experiment. He defibrinated blood, in order to remove all the blood plates and then mixed the blood with sublimate solution. After the small globular bodies were formed acetic acid was added. The erythrocytes and globules disappeared and nothing remained which bore any resemblance to blood plates. If the action of the acetic acid was studied under the microscope it was seen that Wlassow's globules first swelled, gradually paled and finally disappeared. The erythrocytes were more resistant and for a time a crater marked the site of the dissolved knob. With such differences in form and nature existing between Wlassow's bodies and the plates, how can the view be entertained, says the author, that the blood plates are derived from the erythrocytes?

Schneider [3] under Arnold's direction has repeated Sacerdotti's experiments. When a drop of blood is mixed with Wlassow's fluid changes in the erythrocytes occur with great rapidity. At the moment of contact the erythrocytes become smaller and globular. They lose their elasticity entirely and appear completely fixed. A few of the fixed elements appear as bell-shaped bodies with a concavity on one side. The author does not agree with Weidenreich that the normal form of the erythrocytes is bell-shaped. The majority of the erythrocytes appear as spherical structures. A portion of many of the corpuscles is finally granular and colorless or faintly tinted with hemoglobin. The chief mass of the hemoglobin is collected at the other pole of the erythrocyte where the peculiar little knob is attached. This little body is usually spherical. If two are present they are rarely of equal size. They vary from one fifth to one third of the size of the erythrocyte. Most of the bodies contain hemoglobin and are homogeneous. Transitions were seen between these and quite colorless, slightly granular forms. Some were only attached to the erythrocyte by a thread-like connection, but no free bodies were seen, such as Maximow has described. Schneider calls attention to the fact that both Wlassow's bodies and blood plates stain similarly with methyl violet and gentian violet. But he agrees with Sacerdotti that the plates resist the action of dilute acetic acid while the structures formed from the erythrocytes by the mercuric chloride solution are quickly dissolved. Schneider points out that red blood corpuscles have been shown to contain nucleoid material and he asserts that a part of the erythrocyte is not dissolved by the acetic acid but remains as a shadow and concludes from this that Sacerdotti's experiment does not prove that blood plates cannot be formed from the erythrocytes.

On agar preparations, prepared by Deetjen's method and containing 2 to 10% Na Cl, the author states that blood plates are formed in large numbers from the red blood corpuscles and that some resist acetic acid. As the result of his studies he concludes that the blood plates are not independent cells but simply cell derivatives. The great majority of the plates of normal blood according to Schneider arise from the erythrocytes, but some are derived from the leucocytes. Most of the plates possess nuclear substance, which can be demonstrated by certain staining methods and the nuclear substance is the cause of their resistance when brought in contact with dilute acetic acid.

[3] Virchow's Archiv., 1903, clxxiv, p. 294.

AN EXPERIMENTAL STUDY OF THE SO-CALLED FATTY DEGENERATION.

Fischler [4] arrives at the following conclusions based on a study of the fat in kidney infarcts experimentally produced in rabbits.

The appearance of visible fat in cells, as well in the so-called fatty degeneration, as in fatty infiltration is dependent not alone upon a certain condition of the cell, but upon factors outside of the cell.

Some circulation must be maintained although it need not be complete, of the blood, lymph or diffusion stream, or fatty metamorphosis will not occur.

The most essential condition for the appearance of fat is the life of the cell. Dead cells do not undergo fatty metamorphosis. The experiments summarized in this study add nothing to the support of the theory that fat can originate from the cell proteids. Without doubt the presence of fat within the cell can be due to a great variety of conditions.

THE DIAGNOSTIC VALUE OF BLOOD CULTURES.

Hecktoen [5] records a case in which the concurrence of scarlet fever and typhoid fever was observed. The patient was suddenly taken ill with nausea, headache and pain in the limbs. Deglutition became difficult and painful. On the day following the onset a rash developed on the neck and body and spread to the face and extremities. When admitted to the hospital on the fourth day of the disease there was a deep subcuticular flush with raised points. The tongue had the "strawberry" appearance seen in scarlet fever and the tonsils were swollen. A culture from the blood made the next day yielded a pure growth of the typhoid bacillus and the blood gave a positive Grünbaum-Widal reaction. Typical scarlatinal desquamation occurred. The temperature fell to normal about the twenty-first day. The clinical features seem distinctive

[4] Virchow's Archiv., clxx, p. 100.
[5] Medical News, 1903, lxxxiii, p. 580.

of scarlet fever but, as the author admits, absolute evidence as would be furnished by the demonstration of the causative agent is lacking. The occurrence of desquamation is regarded as strongly supporting the diagnosis of scarlet fever. Two cases of typhoid fever associated with early angina and erythema were observed in which there was no exfoliation. In both instances the typhoid bacillus was obtained from the blood during the first week. The author emphasizes the almost constant presence of the typhoid bacillus in the blood in the early stages of the disease and the importance of blood cultures to settle promptly the diagnosis of typhoid fever in such puzzling cases as the ones reported.

OBLITERATION OF THE SUPERIOR VENA CAVA.

Although compression of the superior vena cava is not very uncommon in cases of aortic aneurism and mediastinal tumors, instances of complete obliteration of the vessel with the establishment of collateral circulation are, according to Osler,[6] very rare. In a search of the literature he found only twenty-nine cases of complete obliteration of the superior vena cava.

I. Thrombosis due to disease within the vein, 10 cases. Simple phlebitis seemed to have been the cause of the thrombus formation in 8 of these; one was a propagated thrombus from the periphery (Duchek), and one was due to tuberculous endophlebitis (Banti).

The majority of the cases belonged in the second class.

II. Disease outside of the vein, 19 cases, grouped as follows: (*a*) tuberculosis, 4 cases; (*b*) mediastinitis, 4 cases; (*c*) aneurism, 4 cases; (*d*) syphilis, 3 cases; (*e*) periaortitis, 2 cases; (*f*) carcinoma, 1 case; (*g*) fibroma, 1 case.

Osler divides the cases clinically into two groups. In one group after years of completely effected collateral circulation and good health the symptoms set in acutely. In the other group the symptoms of venous obstruction are constantly present although the individual may enjoy a fair measure of health.

Osler reports an instance of occlusion of the superior vena cava from compression by enlarged mediastinal lymph nodes in Hodgkin's disease and another case in which the diagnosis of fibroid obliteration of the superior vena cava was made during life. The second case presented many interesting and unusual features. When first seen the patient complained of dyspnea and swelling of the neck. There was gradual distention of the superficial thoracic and epigastric veins. The case was regarded during the first year as probably one of intra-thoracic tumor, but the absence of all signs of aneurism and of enlargement of the lymph nodes, the negative result of the x-ray examination, the slow course of the disease, led to the correct diagnosis. Symptoms of phthisis pulmonum developed and tuberele bacilli were found in the sputum. At autopsy the left jugular, both innominate veins, and the upper portion of the superior vena cava were found converted into a dense thick cord. The superior vena cava was patent within the pericardium from the point where it received the dilated azygos vein to the heart. There was tuberculous caries of the last cervical and the two upper thoracic vertebræ. The fibrous tissue about the diseased portion of the spine was continuous with that about the innominate veins.

[6] Bulletin of the Johns Hopkins Hospital, 1903, xiv, p. 169.

THE RELATION OF MYELIN TO FATTY METAMORPHOSIS.

According to Kaiserling and Orgler,[7] myelin drops resemble fat morphologically only. They are stained light gray by osmic acid, never coloring as intensely as fat. With sudan III and scharlach R they assume a red hue. The osmic acid preparations of myelin, unlike fat, are decolorized by xylol, chloroform and oil of bergamot. They differ from fat in being double refractive. In hardened tissues the double refraction of the myelin is lost. These myelin droplets were found in fatty metamorphosis of the cells of intima of arteries, particularly the aorta, in an amyloid kidney, and a great white kidney of chronic Bright's disease, in the epithelial cells of the pulmonary alveoli, in pneumonia and tuberculosis, and in the bronchial secretion, also in the corpus luteum of the ovary and in the cortex of the adrenal and the retrogressive metamorphosis of the thymus gland.

Myelin granules were not found in the heart, in fatty infiltration of the liver, in the normal fat deposits of the body, in colostrum, in functioning mammary glands, or in four cases of fatty metamorphosis of the kidney.

Schmidt and Muller obtained from the myelin drops of the sputum protargon, a highly complex body, but not a fat. By the breaking up of protargon, lecithin and cerebrin are formed.

ORIGIN OF EOSINOPHILIC LEUCOCYTES.

Opie[8] has made an experimental study of the eosinophile cells in the blood and tissues of guinea pigs and the relation of these cells to nutrition. This investigation lends support to Ehrlich's view that the eosinophiles are derived wholly from the bone marrow.

In the mucosa of the intestinal tract and air-passages and in other tissues of the guinea pig occur eosinophilic polymorphonuclear leucocytes identical with those of the blood. In the bone marrow alone mononuclear eosinophiles are found. These undergo mitosis, and transition forms between them and the eosinophiles of the blood can also be demonstrated in the bone-marrow. When the eosinophiles of the blood become increased the number of eosinophilic myelocytes was far greater than normal and proliferation of these cells was more active. The blood vessels of tissues in which accumulation of eosinophiles occurred contained in certain instances a demonstrable increase in the eosinophile leucocytes.

[7] Virchow's Archiv., clxvii, p. 290.
[8] American Journal of the Medical Sciences, 1904, cxxvii, p. 217.

Starvation caused a diminution in the number of eosinophiles in the blood. A temporary loss of weight was accompanied by an increase while a gain in weight led to a decrease of the eosinophiles.

THE PRIMARY ACTION OF THE TUBERCLE BACILLUS.

Baumgarten has maintained that the production of miliary tubercles and diffuse tuberculous tissue is the result of a direct irritation by the tubercle bacillus of the fixed cells of the part. This irritation causes the cells to proliferate.

According to Weigert's well-known theory such an explanation would not be tenable. The cause of the proliferation of the cells should be sought rather in an injury to the tissue which removes the inhibitory force that normally holds in check the power of growth of the cells. Neither Baumgarten nor the other writers have concerned themselves with the existence of such a primary injury.

Wechsberg [9] studied this problem in Weigert's laboratory. Suspensions of tubercle bacilli were injected into the ear veins of rabbits. The animals were killed at different periods ranging from six hours to twelve days and the lungs hardened and sectioned.

At the end of six hours the blood-vessels showed in places a loss of their endothelium as well as a marked destruction of their elastic fibers. Groups of bacilli lay in the lumina of the vessels surrounded by polynuclear leucocytes. After twenty-four hours epithelioid cells were found. The destruction of elastic tissue was the more extensive the longer the duration of the infection.

Wechsberg concludes that the tubercle bacillus destroys the fixed cells and the intercellular tissue by its toxic action. It then injures the new formed cells so that they are unable to produce connective tissue and blood-vessels. The formation of giant cells indicates that the protoplasm of the proliferated cells is only injured in part. Finally the new formed cells become entirely destroyed and the stage of caseation is reached.

Recently an elaborate monograph on the mode of action of the tubercle bacillus has been written by Herxheimer,[10] one of Weigert's assistants. It is, in a sense, a continuation of the study begun by Wechsberg. Tubercle bacilli suspended in fluid were injected into the trachea of rabbits and guinea pigs. The animals were killed at different intervals, from one-half hour to seven weeks after the injection. The staining method, which gave the best results, was a combination of Weigert's elastic tissue stain and anilin-water-methyl-violet. The tubercle bacilli were colored blue and stood out sharply upon the red background.

(1) Stain the sections in lithium carmine several minutes.

(2) Differentiate in 1% hydrochloric acid alcohol several hours.

(3) Stain in Weigert's elastic stain one hour.

(4) Wash rapidly in acid alcohol.

(5) Differentiate quickly in 96% alcohol.

(6) Stain in anilin-methyl-violet several hours in the cold.

(7) Differentiate in acid alcohol and in 96% alcohol.

(8) Dehydrate in absolute alcohol.

(9) Clear in xylol.

(10) Mount in balsam.

In order to remove the violet color from the celloidin, the sections after treating with absolute alcohol were dipped in an alcohol-ether mixture which dissolves away the celloidin.

The bacilli, as soon as they reached the lung, were taken up by epithelial cells lying free in the alveoli and by cells still attached to the alveolar wall. Desquamation of the epithelial cells soon followed the ingestion of the bacilli. At the same time the bacilli exert a destructive influence upon the elastic fibres. A result of the injurious action upon the cells and the intercellular substance is a proliferation of the fixed elements, a growth of epithelium occurs as well as of endothelium and connective tissue cells.

TUBERCULOSIS CONVEYED BY BOOKS.

A careful study has been made by Mitulescu [11] in Koch's Institute in regard to the possibility of the spread of tuberculosis by means of library books. A large number of old, soiled books, chiefly works of fiction, were examined. Of the books which had been in use over two years, one third were infected with tubercle bacilli. The pages were frequently stuck together by filth and the retained moisture prevented the tubercle bacilli drying. On clean paper drying quickly killed them. None of the books in use less than two years harbored tubercle bacilli, and the covers of the infected books were free from these microorganisms. The presence of the tubercle bacilli was determined by inoculating guinea pigs. The pages and covers of the books were thoroughly cleaned with saline solution, the washings centrifugalized and the sediment injected into guinea pigs.

CHRONIC MYOCARDITIS IN CHILDREN.

Acute myocarditis may develop into chronic myocarditis, or the latter condition may develop independently of the acute process. The acute infectious diseases are the most frequent cause of acute myocarditis, and on account of the greater frequency of these diseases in children, acute myocarditis is more common among them than adults. But it is far from common, even among children. In the autopsy records of the Children's Hospital in Vienna during the last ten years are only five cases of acute myocarditis; three followed diphtheria, two occurred after apparently trivial superficial ulcerative processes, in which other signs of sepsis were lacking. Observations at the bedside indicate that acute myocarditis, especially after diphtheria, is not rare, and recovery occurs even from the

[10] Ziegler's Beiträge, 1903, xxxiii, p. 363.
[11] Zeitschrift fur Hygiene, 1903, xliv, p. 397.

severe forms. Under what condition chronic myocarditis is established we do not know, but it is certainly one of the rarer diseases in childhood, and plays a far less important rôle than in the cardiac pathology of adults. This is probably due to the freedom from arterio-sclerosis which so frequently in later life cripples the power of the heart; and chronic alcoholic intoxication, with its resulting injury to the heart, rarely has to be considered.

Two cases are reported by Zuppinger.[12] In the first, signs of acute myocarditis developed during diphtheria, and death occurred from chronic myocarditis six weeks later, with symptoms of cardiac insufficiency. The left ventricle measured 2 cm. in thickness. It was dilated and in the wall were many areas of fibrous tissue. In the second case there was great hypertrophy and dilatation and a mural thrombus was situated at the apex of the right ventricle. At this point the wall contained fibrous tissue, but it was not demonstrable elsewhere. The boy aged ten had an attack of measles four years before and pneumonia one year after the measles.

THE NATURE OF PERNICIOUS ANEMIA.

Bloch[13] has been able to add no experimental evidence in support of the modern theory, so widely held, that pernicious anemia is the result of absorption of toxins from the alimentary tract. Injection of fecal extracts into animals caused only slight anemia. A special toxicity of the urine or blood serum in pernicious anemia could not be demonstrated.

The buccal lesions which Hunter regards as an etiological factor are secondary to necrosis from subcutaneous hemorrhage and hence without significance.

Reports of Societies.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated meeting, March 14, 1904. The President, Thomas E. Satterthwaite, M.D., in the chair.

Dr. Robert Coleman Kemp read a paper entitled

OBSERVATIONS ON DILATATION OF THE STOMACH AND ON GASTROPTOSIS,

which was illustrated by colored diagrams made from forty cases in the Manhattan State Hospitals, Ward's Island. It had unfortunately too often been the habit, he said, to depend on the examination of the stomach contents alone, and to neglect the investigation of the motor functions and the position of the stomach itself. The latter is necessary in order to arrive at a correct prognosis and undertake proper treatment.

Atony of the Stomach. — This must necessarily first occur before dilatation of the stomach is produced. Atonia gastrica may be defined as a loss of tone or contractile power in the muscles of the stomach, so that the organ becomes distended and does not contract about its contents, with a resulting motor insufficiency. While the dilatation of the stomach in gastroptosis is disputed by some, his own observations have shown that dilatation does exist, and with it, necessarily, a varying degree of motor insufficiency.

Dilatation of the Stomach. — Boas has demonstrated that an apparently dilated stomach may really be in a condition of compensatory hypertrophy. It may, therefore, be stated that as long as the functions of the organ are normal, the condition met with cannot be regarded as pathological. In dilatation the lesser curvature maintains in general its relation to the diaphragm, and this is the differential point between dilatation and gastroptosis. A number of forms of acute dilatation have been described. The first is the result of acute inflammation of the gastric mucous membrane. It is uncertain whether it depends on pyloric spasm or paralysis of the gastric muscles, or on both these causes. The second is a post-operative dilatation, following abdominal section especially. It would seem to be due to some shock of the sympathetic system, either from the operation or the anesthetic, or possibly, later, from uremia or sepsis. Among the other types of acute dilatation mentioned were the following: In typhoid fever; during attacks of migraine and just preceding epileptic seizures in certain instances; during the course of pneumonia and other pulmonary diseases; in convulsions in infants and young children from over-loading the stomach; in attacks of pseudo-angina pectoris from indiscretions in diet.

Chronic Dilatation. — Over-feeding and chronic indigestion are undoubtedly causes of dilatation of the stomach in infants and young children. Holt believes intestinal putrefaction exciting convulsions in young children to be an important factor in the production of epilepsy. Dr. Kemp regards acute dilatation of the stomach with convulsions as an equally powerful factor, when frequently repeated, in producing the convulsive habit, and thinks that some cases of epilepsy can certainly be attributed to this cause. Moreover, chronic dilatation of the stomach is itself one of the causes of intestinal putrefaction and disturbance. Among other etiological factors of chronic dilatation are chronic gastritis, atony of the stomach, rapid bolting of food, spasm of the pylorus due to gastric ulcer, and benign and malignant pyloric stenosis. Each case should receive the special treatment called for by the existing condition. Dr. Kemp washes out the stomach often only in cases in which there is chronic gastritis with the production of considerable mucus, or where there is much retained food with fermentation.

Gastroptosis. — If gastroptosis exists, some enteroptosis necessarily accompanies it. The determination of the position of the stomach, in order to secure the best kind of treatment, is of great importance, and trans-illumination of the stomach he considers the ideal method for accurate diagnosis. The treatment consists in the following measures:

(1) The correction of the functional derangement of the stomach by appropriate diet and medication.

(2) Regulation of the bowels.

(3) Mechanical support to increase the intra-abdominal tension, such as (*a*) various silk abdominal supporters; (*b*) bandages (as the Van Valzah-Hayes method); (*c*) Gallant's corset; (*d*) Rose's plaster belt. He had seen some brilliant results from the last named. Recently he had employed for this belt rubber plaster and moleskin. The sweat evaporates through it on account of its loose texture, and it can be worn for quite a long time with practically no irritation.

Cases at the Manhattan State Hospitals, Ward's Island. — The drawings Dr. Kemp presented were made from forty epileptics in these institutions. The anatomical regions were marked out in blue pencil

[12] Archiv. fur Kinderheilkunde, 1903, xxxv, p. 381.
[13] Deutsches Archiv. fur klin. Medizin, lxxvii, nos. 3 and 4.

on the abdomen of each case, and during trans-illumination of the stomach the outlines of the organ were drawn in color. These markings were reproduced in the diagrams shown. Thirty-four of the patients were females. In 16 there was gastroptosis, in 16 dilated stomach, and in 2 the stomach was in normal position. In the 6 males there were 5 dilated stomachs, while in 1 the stomach was in normal position.

Comparative Methods of Locating the Position of the Stomach. — Having stated that the standing posture was in general the most favorable for examinations, he spoke of changes in the position of the stomach due to ingesta. In the books it is stated that the empty stomach lies for the greater part of its extent beneath the ribs on the left side, entending a short distance below them, that when partially full it descends midway between the ensiform process and the umbilicus, and that when full it comes to within a few finger breadths of the umbilicus. All this is true when the subject is in the dorsal position, since the suspensory ligaments of the stomach are relaxed, and as the organ fills up it gradually gravitates downward. In the standing position, however, as can readily be shown, the stomach, even when empty, at once descends to the full length of its suspensory ligaments, and its lower border is as a constant level, or within almost an inch of the same, whether the organ be full or empty.

The Stomach Whistle. — To demonstrate this Dr. Kemp devised a simple instrument known as the "stomach whistle," which consists of a rectal tube of small calibre with a whistle in the end. To it is attached an ordinary aspiration bulb without valves. The tube is inserted, the finger placed over the open end of the bulb, and a single bulb-full of air forced into and aspirated out of the stomach by short and intermittent contractions. This entirely eliminates the possible chance of distending the stomach with air, and the organ remains practically empty. A stethoscope is placed over the abdomen, and the point of greatest intensity of sound is marked by a cross with a colored pencil. The tube is pushed in and out, and various points of sound are marked. The lowest is the lower border of the stomach. If gastro-diaphany is then performed, it will be found that the lower margins absolutely correspond. This is also a further evidence of the accuracy of the latter method.

Various methods of locating the stomach were tried on the same cases and, as a check, trans-illumination was employed as the last procedure in each instance. (1) Inspection was tried many times, but without success. (2) Carbonic acid gas often failed, and it was found impossible to regulate the amount of gas produced by the sodium bicarbonate and tartaric acid. (3) By administering small quantities of these drugs, with the patient standing, it is possible in a certain number of cases to map out approximately the lower margin of the stomach by listening with the stethoscope to the sound of the effervescence. (4) Inflation with air is advised by many authorities. The method may, however, sometimes cause great discomfort. It is liable to overdistend the stomach, and may even be a source of danger. On many occasions what was apparently stomach becoming protuberant on the abdominal wall was shown by trans-illumination to be intestine forced out laterally and forward by the stomach. (5) Simple percussion in various positions. (6) Auscultatory percussion. (7) Reichmann's auscultatory percussion rod. (8) Inflation with water seems to be a fairly good method, as it is easier to differentiate between dulness and tymphanites than between the different forms of tymphanites. (9) Inflation of the intestines with air is inaccurate. If water is employed, it acts as an enema. (10) The ideal method is trans-illumination, originally devised by Einhorn. As an improvement in technique Dr. Kemp has of late employed fluorescent media. By means of these he has found it possible to trans-illuminate the stomachs of fat subjects, which were formerly unsatisfactory, and, in general, the trans-illumination is increased nearly one half. As a matter of scientific exactness Dr. Kemp suggested the infusion of radio-active saline solutions into animals and also their hypodermatic use. The experiments made, however, showed no results from the standpoint of physiological medicine, and at present he felt that such solutions have no therapeutic value whatever.

THE CONSULTANT'S POINT OF VIEW.

DR. WILLIAM H. THOMSON said that on account of the limited time at his disposal, he would confine his remarks to the relations of the stomach to certain auto-infections which seem to be chiefly caused by changes in the tone and motility of the stomach walls, which changes appear to be closely connected with the etiology of some common nervous derangements. In the first place, he thought it might safely be assumed that when a nervous disorder is intermittent in its attacks (the patient being in the intervals quite free from any of its symptoms), the disease is one due not so much to a neurosis as to a toxemia, since it is only toxemias which furnish us with examples of the curious phenomena of intermittency in nervous symptoms. Thus the poison of a uremia kind may be present in the blood for many days before we have the sudden explosion of uremic convulsions, while attacks of gouty asthma develop only now and then, though the blood state which occasions them may have been long present. So he had no doubt that the great majority of the attacks of epilepsy are primarily due to, and are manifestations of, a toxemia. Nervous symptoms dependent upon organic changes in nerve tissue are never intermittent, and while it is true that in some cases of epilepsy there is a persistent source of irritation in the form of an organic intra-cranial change produced by traumatism or by some analogous cause in the form of a localized lesion on the brain surface, yet even here the attacks are intermittent, which could not possibly be the case if the traumatic irritant were the sole and primary cause of the epilepsy. In any affection which is the result of true organic lesion in nervous texture the resultant symptoms never really intermit, however much they may remit in the degree of their manifestation. Therefore, even in traumatic epilepsy something else besides the standing local irritation is required to develop the convulsive paroxysm, and that something is most certainly one of the forms of toxemia.

He had no doubt that toxemia alone suffices to cause most of the attacks in so-called idiopathic epilepsy, and that our progress in the understanding of this most serious disease and its treatment will be chiefly along the lines of the demonstration of blood poisons, their origin and nature, and how best to counteract them. He believed that in time a case of prolonged epilepsy may acquire an organic basis, on the general principle that every nervous function which is not original to the cerebral cortex, but is acquired, has an anatomical basis there after the function has been acquired. Having illustrated this by a reference to the great cortical function of speech, he said that the well known facts in regard to this prove that the brain cortex is peculiarly plastic to repeated excitation of the same kind, so that in time it thereby becomes anatomically organized to subserve certain functions. He did not see, therefore, why we should not infer that every specific cortical function is similarly organized by habit.

Now apply this principle to nervous pathology. In the brain-training period of life, that of childhood, when the cortical centers are being organized by habit to perform specific functions, an abnormal or diseased habit is being contracted by the special and selective operation of some blood-poison on a special cortical area. All nerve-poisons are characterized by their selective properties. There is no one of them which acts on the whole nervous system; even the most widely acting of them affecting only certain nervous functions. Hence it is only consistent with general law that some poison, habitually formed and habitually charging the blood, may in time, by repeatedly acting on the same cortical area, finally cause an anatomically organized area of morbid activity, without the need of postulating any congenital malformation to account for this morbid habit, as has been done by Dr. M. A. Starr. While not denying that congenital malformations may in some instances be the origin of epilepsy, it may be inferred that the great majority of epilepsies are acquired, rather than congenital, and acquired most easily at the time of life when nervous habits of all kinds are most easily acquired, namely, childhood. Hence the extreme practical importance of preventing epileptic attacks from becoming habitual, and, in order to accomplish this, of making every possible effort to discover the exciting causes of the attacks.

No one can doubt that one of the most common of these exciting causes has its origin in auto-infection, especially from the gastro-intestinal tract. Dr. Thomson said his criticism of the current views of the mechanism of an epileptic attack was that it is looked upon as a primary discharge of cortical motor cells. But no motor cell ever discharges itself; it is invariably in response to some afferent excitation, first, that any such discharge can occur. So, the beginning of an epileptic attack is always on the afferent side; and when we seek for causes of undue afferent excitability it is only in toxemias that we find the most conclusive illustrations. Having cited the phenomena observed in tetanus and strychnine poisoning, he said these facts had led him to attach great importance to every means which will enable us to be more precise in our examination of the organs most concerned in causing auto-infection. Gastric atony and dilatation, for example, always imply not only deficiency of muscular power, but also qualitative changes in the normal gastric secretions; and we should never forget that, besides this primary function to cause digestion, all digestive secretions are powerful antiseptics, so that deficiency or perversion of these, of itself, disposes to self-poisoning. He had taught for years, and was criticized for doing so, that the sensory disorder migraine was not due to a neurosis, but to a toxemia; and it was a satisfaction to find now that it too is definitely connected with changes in the stomach walls which our modern methods of exploration enable us definitely to recognize. All measures, therefore, which improve our means of diagnosis he welcomed from the general standpoint of the practitioner, who has to prescribe not only for stomach and intestinal disorders, but for a great variety of derangements in distant organs, such as neurasthenia, melancholia and epilepsy — not to mention various painful affections, from neuralgia to so-called muscular rheumatism, whose origin after all is generally due to perversions in the functions of the great food channels of the body.

GASTRO-DIAPHANY (TRANS-ILLUMINATION OF THE STOMACH).

DR. MAX EINHORN said that in practicing gastro-diaphany it was advisable to have the stomach empty, except for a glassful or two of water. The great advantage of this method is that it affords an opportunity of examining the stomach in the natural state, and not when it is over-filled or is abnormally distended with gas. A great many mistakes have been made in consequence of the over-distention of the organ with gas produced by effervescing mixtures. This method is also attended with some dangers, and a death has been reported from it. By the use of gastro-diaphany the examiners can observe not only the area of the water, but also the outlines of the stomach. It is undoubtedly a good method, but it is rather an elaborate one, requiring a dark room, an electric battery and a special apparatus. It is particularly serviceable for gastroptosis and when tumors are present. When there is a tumor, we can by means of it determine upon which curvature of the stomach the growth is situated. In some instances also we are able to discover the presence of a tumor which is not as yet distinguishable by palpation. Dr. Einhorn, however, did not think gastro-diaphany should replace other methods. For the general practitioner the most servicable method is the production of a splashing sound when the stomach is partly filled with liquid. This, he believes, affords the most accurate means at our disposal of ascertaining the situation of the stomach and also the outlines of the organ. He would, therefore, place it first as a means of diagnosis.

DILATATION OF THE STOMACH

was discussed by DR. GEORGE R. LOCKWOOD, who said: If a stomach in the morning fasting state habitually contains food remains, or if it contains according to our present lights an amount of gastric juice exceeding 100 cc., it may reasonably be assumed that pyloric obstruction exists, no matter what the actual size of the stomach may be. The main thing is that the stomach is unable to properly empty itself — the actual size of the organ has nothing at all to do with it and affords only corroborative evidence. We find large stomachs that are not to be considered "dilated," since they are adequate in a muscular sense and empty themselves as they should. We also find stomachs of normal or diminished size which are muscularly inadequate and do not empty themselves as they should. Such is usually the case with pyloric cancer. They may be regarded clinically as dilated stomachs, although they are not dilated. The term dilatation is therefore an unfortunate one. If we regard the term as synonymous with "pyloric obstruction" or "motor inadequacy" we will not go so far astray.

To determine absolutely the actual size of the stomach we need to locate the lower curvature, the upper curvature, and the overlapping of the stomach area to the right of the median line. The lower curvature can be readily made out in the great majority of cases. The results of gastro-diaphany have to me been most misleading, and I have of late excluded the method from the list of available means for diagnosis and have placed the gastro-diaphane on the same shelf as the sphygmograph — agreeable playthings, to show to students, but not of practical value. Boas' test of passing a stiff tube and palpating it as it lies along the greater curvature is apt to be misleading, as the stiffness of the tube, as used by Boas, is calculated to depress the lower curvature and make it seem lower than it really is. Such a procedure, moreover, is not devoid of danger. To me the most accurate results have been by inflation, combined with palpation and inspection; next in order of value is the area of succussion sounds obtained. With an oblique light

shining back of the recumbent patient, the shadow outline can usually be distinctly seen. If the upper curvature is not observed descending on inspiration, with the respiratory descent of the greater curvature, the diagnosis of an enlarged stomach can be made with reasonable certainty, and gastroptosis excluded. Inflation should regularly be practiced by pumping air into the stomach through a tube, and not by the use of effervescing powders. In cases where such an inflation is inadvisable, a moderate inflation by effervescing powders may be made, and light percussion, preferably by auscultatory stroke percussion, employed. By noting changes in note before and after such inflation, colon tympany need not be mistaken for gastric. The area over which succussion sounds are heard affords very reliable evidence as to the position of the lower curvature. This sign is fairly accurate, provided there be no liquid in the transverse colon. Tapotement in the cecal region will determine this point. The absence of succussion means very little, as tympanitic distention of the stomach with gas may cause the succussion sounds to absolutely disappear. It is not the place here to enter into a discussion of the value of succussion as a sign of atony; it is sufficient to call attention to its usefulness as a test for the location of the lower curvature.

In normal cases the gastric tympany rarely extends beyond 6 cc. to the right of the median line. An extension of this tympanitic area to 8 cc., or more, to the right affords fair presumptive evidence of enlargement. The detection of the upper border of a normally located stomach is almost an impossibility. Consequently the exact vertical dimension can rarely be determined. The estimation of the exact size is further rendered difficult by displacement downward of a dilated stomach, which so frequently occurs, or its assumption of the vertical position. As a further aid to diagnosis I would call attention to the significance of the enteroptotic habit. If the costal angle is less than 90°, if the right kidney be palpable, if the liver and colon are not displaced, the location of the lower curvature of the stomach is of no diagnostic value whatever. The mistakes in diagnosis, to my mind, depend on two errors: (1) In basing a diagnosis on the location of the greater curvature alone, forgetting that it might be a gastroptosis alone, or a displacement co-existent with a dilatation. (2) In making a diagnosis of dilatation from the size of the stomach alone; the sole sign of dilatation that is accurate being the detection of food remains or of contained secretion in a fasting stomach. No diagnosis, therefore, can be made without careful and, if necessary, repeated examination of the gastric contents in the fasting state.

GASTROPTOSIS

was discussed by DR. ACHILLES ROSE. He thought the term "gastroptosis" unfortunate, and preferred "gastroptosia," which, correctly translated, means abdominal ptosis, not necessarily ptosis of the stomach alone. The word "gastroptosia," he said, was a good term, for all writers appeared to agree that there is, as a rule, not one abdominal organ alone descended, although one may be more displaced than the others. Gastroptosia also had the advantage of including the relaxation of the abdominal walls. He explained that a feminine noun which ends in *sis*, *psis* or *xis*, as the second component, remains unchanged when the first component is a preposition, as, for instance, proptosis, periptosis, diagnosis; but if the first component is not a preposition, then in composition the ending is changed into *ia*, as apraxia, eupraxia, hierognosia. The tone, the activity of the abdominal muscles, aids in retaining the abdominal organs in their physiological position. Relaxation of this apparatus forms a factor in gastroptosia, and it is the first factor we have to consider in therapy. Gastroptosia is identical with relaxation, or, what means the same, atonia. Gastroptosia is atonia gastrica. Those who have used the latter term in the sense of motor insufficiency of the stomach have caused much confusion, since atonia gastrica may exist without motor insufficiency. Motor insufficiency is the disproportion between the capacity of the muscular forces of the stomach and the demand on these forces for labor. Such insufficiency may occur under certain circumstances in a healthy stomach, as when the mass of the ingested food is too large, or the nature or condition of the ingesta unsuitable. Atony may cause insufficiency, or, in turn, may be caused by insufficiency; but it may exist without insufficiency when the resistance at the pylorus is subnormal.

Gastroptosia is never present without dilatation. Gastroptosis depends on relaxation, and relaxation of the fibers of muscles means elongation of the fibers; therefore relaxation is, *eo ipso*, dilatation. Of practical importance is the relation between gastroptosia and gastric and nervous symptoms. It is now generally recognized that many cases which were formerly classified as neuroses are instances of gastroptosia with gastric and nervous symptoms. All forms of anomalous gastric secretion may be associated with gastroptosia, and, as the very exact investigations of Dr. Graham Rogers in the Manhattan State Hospital have demonstrated, relief from anomalous secretions and motor insufficiency may promptly ensue after gastroptosia has been relieved.

In the treatment of gastroptosia the principle to be kept in view is relief from relaxation, and, first of all, from abdominal relaxation, by means of mechanical support of the abdominal walls. This can best be given in most instances by strapping in the way that has been suggested by Dr. Rose. Very often strapping alone, without any other treatment, will restore the secretory and motor functions of the stomach to a normal state. He did not mean to say that medical treatment was to be excluded in any case, but without the mechanical support all medical treatment might prove unavailing. Gastroptosia may play a part in diseases of the organs of respiration and circulation. In illustration he quoted a case reported by Dr. Groddeck of Baden Baden, in which an elderly gentleman with organic heart disease, who had for years suffered from attacks of vertigo and unconsciousness, was successfully treated by proper attention to his enormously distended abdomen. The reduction of the size of the belly, although it did not of course cure the diseased myocardium, was followed by cessation of the attacks mentioned. The size, the weight, of the belly having been reduced, the work of the heart was materially relieved, relieved to such an extent that even the imperfect contractions were sufficient to supply the brain with the necessary quantum of blood. Dr. Rose said he could cite just as striking examples from his own practice, or he might refer to a patient he had seen under examination before a medical society. Everyone present studied the auscultatory and percutory signs, but not a single physician took notice of the most remarkable pronounced gastroptosia existing. They all spoke of various remedies to improve the circulation, but not one had an idea of the most important of all the remedies called for in the case, the support of the abdomen. Mangelsdorf found that every attack of migraine was accompanied by acute dilatation of the stomach and that repeated attacks of the disorder led in the course of years to permanent change in the tonicity of the stomach. He also discovered that a relation existed between

epilepsy and gastroptosia. Many observations during the last few years have shown that gastroptosia deserves much greater consideration than has been accorded to it.

THE SURGEON'S POINT OF VIEW.

Dr. George E. Brewer said the cases for operative interference could be divided into three classes: (1) Malignant disease. (2) Benign disease, such as ulcers and, very rarely, tumors. (3) Spasm, when surgical, rather than medical, aid is required; the condition having gone beyond the point when efficient relief can be afforded by medicinal remedies or mechanical support. In gastric ulcer it is universally conceded that one of the most essential requisites of successful treatment is rest, and there can be no question that in many instances a gastro-enterostomy affords an opportunity for the healing of the ulcer better can than be secured in any other way. The spasmodic conditions produced by ulcers can also be promptly remedied by surgery. The operations for the relief of the various forms of benign disease show a very low rate of mortality. In conclusion Dr. Brewer made a suggestion as to the importance of the early recognition and early surgical treatment of dilatation in the "cancer age." We are now, he said, making much earlier diagnoses of carcinoma than formerly. This is largely due to laboratory methods; but even these do not give us the diagnosis in time to do a really radical operation. Whenever, therefore, a person at the cancer age has a sudden onset of digestive trouble, or a sudden increase in such trouble previously existing, suspicion should at once be aroused. An early exploratory incision is attended with a minimum of risk, and if malignant disease is discovered, it can be treated while the affected area is still very limited and glandular involvement has not as yet occurred. Only thus can we get at the disease at a time when it may be thoroughly eradicated, and by the adoption of this plan we are now beginning to show excellent results.

Dr. Sinclair Tousey read a paper on

THE RELATION OF THE X-RAY AND RADIO-ACTIVE SOLUTIONS TO EXAMINATION OF THE STOMACH.

He said he had repeatedly determined the presence of cancer of the stomach by the use of the x-ray alone. At present he is inclined to rely, in stomach work, more upon the fluoroscopic than upon the skiagraphic examination. Sometimes a tumefied anterior wall or pyloric extremity can be quite positively made out with the fluoroscope, and be merely indicated with a reasonable degree of probability by a skiagraph. In other words, a tumor of the stomach is almost transparent to the x-ray, and, being in constant motion during respiration, is better studied directly. Simple dilatation of the stomach and gastroptosis, without the presence of a tumor, would scarcely be capable of demonstration by the x-ray under ordinary circumstances; and it was with a view to the diagnosis of these conditions that his experiments were undertaken. All his work with radium and radio-active solutions, both in the laboratory and in the treatment of patients, has been with radium of 20,000 radio-activity, and the amount used in each instance was 1 dgm. The radio-active solution was prepared by immersing such a quantity of radium enclosed in a hermetically sealed glass tube for four weeks in 16 oz. of normal saline solution contained in a stoppered glass jar. The fluorescent solutions employed are made in accordance with suggestions from Dr. Kemp.

Dr. Tousey then proceeded to enumerate his observations up to the present time. Among them are the following: (17) In human subjects to whom radio-active solution was given subcutaneously or by the mouth no disturbance of any kind was produced. (18 and 19) Radio-active solutions were injected into a cat and a rabbit, in the lumbar region, every day or two for a week, without producing any symptoms. In the case of the cat there was at first a slight looseness of the bowels, which was thought to indicate that the injection was too large and which disappeared after the amount had been produced. (20) A dog weighing about 12 pounds was etherized and radio-active solution injected through the left femoral vein. The right common carotid artery had been opened and connected with a mercurial manometer registering the blood-pressure upon a kymograph. At first 30 cc. was given very rapidly, and the same quantity was added after an interval of five minutes. The only effect noted was a slight rise in blood-pressure when the infusion was begun. (21) A rabbit was killed and the abdomen opened. The contents of the stomach were partially removed and the organ was then filled up with a mixture of radio-active and fluorescent mixtures. The pylorus and cardia were ligated and the abdomen sewed up. When the animal was examined by the x-ray in the dark, with all visible light from the x-ray tube excluded, no fluorescence was visible to the naked eye; but with the fluoroscope the stomachic region seemed very transparent and could be mapped out exactly. An x-ray picture was then taken with the animal prone upon the table, and, as may be seen, it shows the outline of the stomach in a brilliant manner. The stomach was then emptied of all contents, and another picture taken under precisely the same conditions.

The conclusions reached were as follows: (1) Radio-active and fluorescent solutions are innocuous when given by the mouth or subcutaneously.

(2) They do not produce, either singly or in combination, sufficient fluorescence to be of value in the examination of the stomach without the use of some additional light to excite their fluorescence.

(3) They will in some cases be of the very greatest assistance in the x-ray diagnosis of stomach lesions.

(4) They will in some cases be of value in the x-ray treatment of stomach lesions.

Recent Literature.

Anatomy Applied to Medicine and Surgery. By D. E. Mundell, B.A., M.D., Professor of Applied Anatomy, Faculty of Medicine, Queen's University, Surgeon to Kingston General Hospital. Kingston: The British Whig. 1903.

This small volume of 492 pages is designed to place before the student in a practical way knowledge of human anatomy. In addition to descriptions of anatomical relations, there is added where called for certain practical surgical and medical matters pertaining to the various regions of the body. The volume is almost devoid of illustrations, which is always regrettable in the consideration of a science of this character. It shows also signs of hasty preparation and somewhat careless proofreading; a long list of errata is printed, which does not add to one's confidence in the thoroughness of revision of the text. The binding and type are adequate, but not up to the standard of modern book-making.

A Dictionary of Medical Science. Containing a full explanation of the various subjects and terms of Anatomy, Physiology, Medical Chemistry, Pharmacy, Pharmacology, Therapeutics, Medicine, Hygiene, Dietetics, Bacteriology, Pathology, Surgery, Ophthalmology, Otology, Laryngology, Dermatology, Gynecology, Obstetrics, Pediatrics, Medical Jurisprudence, Dentistry, Veterinary Science, etc. By ROBLEY DUNGLISON, M.D., LL.D., late Professor of Institutes of Medicine in the Jefferson Medical College of Philadelphia. New (twenty-third) edition, thoroughly revised, with the pronunciation, accentuation and derivation of the terms, by THOMAS L. STEDMAN, A.M., M.D., member of the New York Academy of Medicine. Imperial octavo volume of 1224 pages, with about 600 illustrations, including 85 full-page plates. Philadelphia and New York: Lea Brothers & Co. 1903.

When a book has reached its twenty-third edition, it seems hardly necessary to speak in its commendation. Of the various medical dictionaries published within the period of the active development of medical science, none has been more progressive than this. When one considers that at the present time about two new terms daily are added to medical terminology, it is apparent that the work of the lexicographer is peculiarly exacting, and that a new edition means not merely a repetition of the preceding one with certain alterations, but a very extensive addition to the subject matter, with the coincident exclusion of words and terms which have become obsolete.

The revision has been undertaken by Dr. Thomas L. Stedman, and certainly shows evidence of most assiduous care. The illustrations are numerous and excellently reproduced. The definitions are full and often explanatory. In general we commend this book, as we have its predecessors, as a complete and satisfactory epitome of medical progress. The volume before us is provided with a thumb-letter index, which, although not essential, facilitates ease of reference. The printing of such a book is peculiarly difficult, but it has been most satisfactorily done by the publishers.

Quiz-Compends. No. 1. A Compend of Human Anatomy. By SAMUEL O. POTTER, M.A., M. D., M. R. C. P. (Lond.), formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco. Seventh Edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

This is one of the best known of the Quiz-Compends, a type of book which apparently is giving place to others of somewhat more inclusive character. As a collection of facts briefly stated, the book is of value. As a means of studying human anatomy it clearly has its shortcomings. This, its seventh edition, requires no special comment on our part.

A Manual of Operative Surgery. By SIR FREDERICK TREVES, Bart., K.C.V.A., C.B., LL.D., F.R.C.S. New edition, revised by the author and JONATHAN HUTCHINSON, Jun., F.R.C.S., Surgeon to the London Hospital, etc. In two volumes. Vol. II. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1904.

Only a few months have elapsed since the appearance of the first volume of this new edition, a review of which was recently published (BOSTON MEDICAL AND SURGICAL JOURNAL, Vol. cxlix, 740, 1903). The volume now under consideration (Vol. II) completes the work. Like its companion volume it is an ornamentally made book. It is an octavo of 824 pages with upwards of 470 illustrations. An index of names and subjects for both volumes is appended. It is classified by "Sections," which describe the surgery of special regions and organs, and are designated as Plastic Surgery (which includes cicatricial contractions, hare-lip, cleft palate, webbed fingers, congenital defects of the bladder and urethra and ruptured perineum); Operations on the Neck; Abdomen (including the female pelvic organs and kidney); Hernia; Bladder; Scrotum and Penis; Rectum; Head and Spine; Thorax; Breast.

The same general characteristics noted in Vol. I are also present in this volume. Anatomical points are given and instruments required enumerated, the steps of the special operation stated and the after-treatment described. The illustrations are numerous and as a rule well chosen. English, American, French and German methods are freely quoted. The advance in special surgery since the publication of the former edition is strikingly evident as one studies this new edition.

Generally speaking the character of the work is excellent, the subject fully treated. The section on the Abdomen is one of the features of the book which attracts attention. That dealing with Genito-Urinary Plastics is interesting and instructive. In Hernia the author's description of the characteristics enabling one to identify the "sac" in a strangulated hernia is an excellent statement of the actual conditions presented to the operating surgeon. It gives practical, accurate facts which will be of some practical assistance in these difficult emergencies, and not time-worn, oft-quoted, glittering generalities.

The book will well repay a careful study.

In regard to the "making" of the book, the type and paper of this volume, as in Vol. I, attract attention and cause favorable criticism. The gilded edge and uncut leaves, however, although they may be considered artistic and a refinement in book making, are by the busy operating surgeon liable to be regarded as inappropriate elaborations of a professional tool. The latter surely is a time-killing feature, and an extra burden to an anxious brain seeking information by the most direct route.

Progressive Medicine. Vol. I. March, 1904. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. 337 pp. Illustrated. Philadelphia and New York: Lea Brothers & Co.

The first number of the sixth volume of this periodical publication appears in somewhat altered form from its predecessors. Hitherto the volumes have been bound in stiff cloth covers. This volume has paper covers, which permits of rebinding to suit the subscriber's particular taste and also reduces the price. This series is one of the best epitomes of medical progress published in the English language. Its frequent publication permits of a somewhat more complete review of medicine and surgery than is possible in those volumes which appear at wider intervals. Surgery of the head, neck and thorax, infectious diseases, diseases of children, laryngology and rhinology and otology are discussed in this volume. These subjects are reviewed in the usual thorough-going fashion which we have come to expect in this periodical.

Clinical Pathology of the Blood. A treatise on the General Principles and Special Applications of Hematology. By JAMES EWING, A.M., M.D. Second Edition. Revised and Enlarged. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1903.

We have already commented favorably upon the first edition of this book (JOURNAL, July 4, 1901, p. 23). The second edition which has recently appeared does not in general differ in appearance from its predecessor. The intervening years have been, however, prolific in work on the general subject of the blood. This work the author has incorporated into the new edition, a task requiring the study of about four hundred new articles or monographs. The plan adopted in the first edition of appending bibliographical lists to the various chapters is followed in this, with the addition of these new articles. We are glad to see a reversion to the scientific method of bibliographical references, which have been so largely omitted from recent textbooks. It is certainly true, as Dr. Ewing implies, that works without bibliography are of relatively little value in the task of discriminating between authorities requiring consultation of original sources, and he has, therefore, adhered to his plan of appending very complete bibliographical lists.

Certain changes have been made in the chapters on technique, the serum test for blood and the subject of crioscopy. The morphology of blood cells, leukemia and the essential features of Ehrlich's immunity theories have been incorporated. Four new plates and other figures have also been added. The book is an excellent one, clearly the work of a scholar, and this being said, it requires no further criticism than we have already given it.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, APRIL 21, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

SPECIALIZED SURGERY.

PROGRESS in surgery, as in other branches of scientific work, apparently depends in great measure upon wide experience along certain definite lines. The field of operative surgery has expanded to such a degree during the last decade that it is no longer possible for any single individual to gain the knowledge which is essential to progress in all branches. In surgery, therefore, as in the whole domain of medicine, we find a greater and greater tendency toward specialism, which unquestionably has its distinct advantages as well as its individual drawbacks. It is of the advantages, however, that we wish to speak.

It is clear to the most casual observer that if any one man is to attain wide surgical experience in the treatment of the diseases of certain organs or structures, he must be given the opportunity to study and operate upon more cases than would in the natural course of events come under his jurisdiction. This is, perhaps, particularly true of two great fields in surgery which are apparently at the present time exciting wide interest among surgeons; namely, surgery of the stomach and surgery of the central nervous system. These at least will serve as examples of the matter to which we wish to call attention.

In the ordinary hospital service, even of our largest institutions, it is not possible that sufficient patients with diseases of the stomach, upon whom operation is desirable, can be collected to demand the careful study of a large number of surgeons. The result is that energy is wasted, that if operations are attempted they are done

rather as a part of a general surgical service than as a special investigation, with the very natural result that less enthusiasm and interest are developed than would be the case were a larger number of patients available. It is, therefore, unfortunate that some arrangement may not be made by which those men who are particularly interested in this or other lines of surgical work may not have a somewhat exclusive privilege as regards certain types of cases. If we are as a community to produce work of originality, it is clearly essential that one man or a group of men particularly interested should devote themselves for a longer or shorter period of time to distinct lines of work, and should be encouraged in every possible way to accomplish results of importance. This can only be done by liberal co-operation, and it may be self-sacrifice.

The other subject which we have used as an example is that of the surgery of the central nervous system. Here again it is manifestly impossible, even in a very large community, that cases sufficient in number should appear at our various hospitals to permit of division of labor consistent with wide personal experience. Unquestionably there are certain men in every community deeply interested in the surgical bearings of the serious and discouraging disorders of the central nervous system capable of palliation or relief by surgical means. It is no less true that at our large hospitals the interest which any one man may have is checked by the fact that he has small opportunity to apply what knowledge he has, or to extend his knowledge of the operative treatment of these conditions. This again is naturally due to the fact that the cases are not concentrated in the hands of one or several deeply interested men, but are scattered throughout the service of many surgeons whose interest is lessened because of the rarity of the disease as it comes into their individual experiences. On the other hand, if it were possible that all cases of cranial or spinal surgery, coming to one of our large hospitals for operation, could be concentrated into the service of a few men, it is clear that an experience would be gained which is now absolutely impossible, and also that the hospital in question might well look for results of significance from the work of the surgeons so placed. That such a plan is possible, and that it may be fraught with advantage, not only to the particular surgeon who undertakes the work, but also to the institution which he represents, is sufficiently evident from recent happenings in other cities. If cerebral surgery is to be done at all, it should be undertaken with the enthusiastic belief that results of positive importance may be attained through devotion to the various technical details involved, and not approached from the pessimistic point of view which is far too current among medical men.

The foregoing remarks naturally apply to all those branches of surgical work in which the number of patients is insufficient to give requisite experience, and particularly that sort of experience which may give origin to new ideas, new methods and a well elaborated technique. Our contention merely is that in all such branches of surgical work opportunity should be given for the greatest possible attainment of useful knowledge, and this we believe may be accomplished only by dividing the cases as they enter our hospitals. We are quite aware of the difficulties involved in any such plan, nor is it in the least our purpose to discuss ways and means. The fact, however, remains that progress lies along some such line as that suggested, and the principle of specialization as applied to certain groups of cases is certainly a prerequisite to original surgical work. It need hardly be said that many of the surgical lesions requiring operation are so frequent that no such division of cases is called for. Of this we are not speaking. Our contention merely is for the profit to be had from grouping unusual cases in the hands of a few men rather than dissipating them in the hands of many.

REPORT OF THE MASSACHUSETTS GENERAL HOSPITAL.

THE ninetieth annual report of the trustees of the Massachusetts General Hospital, a pamphlet containing 256 pages, similar to the many which have preceded it, is before us. The trustees report that no new buildings have been erected either at the McLean Hospital or at the Convalescent Home in Waverley. At the General Hospital in Boston, on the contrary, there has been an unusual activity in construction and in improvements. Among these are a new ward for children, improvements in various of the old wards, a new relief ward, and the fitting out of a room for the installation of a Zander apparatus.

Naturally the most notable addition to the new buildings was that for out-patients which covers 69,600 square feet. In connection with this out-patient department, which so far as our knowledge goes stands unique in hospital construction, there has been opened the Weld ward, given up largely to treatment of diseases of the

skin, but also providing two beds each for the department of neurology and the department of laryngology. Each year in the history of this hospital has been marked by some definite improvement or further facility for the treatment of the sick, but we are inclined to think that the wide-reaching significance of a really worthy building for the treatment of out-patients will be among the most influential factors in the development of the hospital of the many improvements which have preceded it. Prophecies in such matters are possibly fallacious, but it is quite impossible to conceive that this new building can ever fail to be sufficiently commodious for the purposes for which it was designed.

During the year 1903, 5341 patients were treated at the hospital as against 5199 for the previous year, with an average weekly cost per patient of $16.45 as compared with $17.16 for 1902. About 200 more patients were received in the out-patient department than in the preceding year. The average stay of patients in the hospital during the year was nineteen days as against seventeen days in the preceding year. At the McLean Hospital slightly fewer cases were treated in the year under consideration than in the preceding one. The weekly cost of maintenance of patients in this department of the hospital was about $2.00 more than in the preceding year.

During the year 1903 there was a somewhat unusual number of changes in the visiting staff, among the more important of which were the retirement of Dr. Charles B. Porter and the resignation of Drs. James C. White and William L. Richardson. Dr. John T. Bowen was appointed senior physician to out-patients with diseases of the skin in place of Dr. James C. White. Drs. C. L. Scudder and James J. Minot were respectively made visiting surgeon and visiting physician to the hospital. The retirement of Dr. Edward Cowles from the superintendency of the McLean Hospital led to the appointment of Dr. George T. Tuttle as superintendent to fill the vacancy.

The report of the visiting staff is largely given over to a consideration of the advantages to be derived from the new out-patient department. The plan recently inaugurated of employing as paid lecturers for the Training School for Nurses two graduates in medicine has entailed naturally an increased expense to the school, which has been more than justified by the results obtained. Reference is also made to the significant discovery of Dr. J. H. Wright that the disease known as "Aleppo Boil" is due to a protozoön. In the report of the McLean Hospital Training School for Nurses Dr. Edward Cowles' well known pioneer work in instituting adequate nursing for the insane is well commemorated in his own words which we append:

My retirement from the hospital at the end of this year closes my immediate relations with the school, but cannot change my interest in it, nor in those whose names are borne in the long list of its pupils; my memories of their faithfulness and loyalty and the never-failing sense of mutual personal respect and friendly esteem are treasures that cannot be lost. These have another value in the assurances they give of interest, sympathy and good wishes, professionally and personally, among all who have been members of this company of workers and helpers in this great service for the relief of mental illness. It was the support given by the nurses that made possible, in large measure, my own share in this work, and no words of acknowledgment of it can adequately express my grateful appreciation.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, April 20, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 47, scarlatina 21, typhoid fever 9, measles 189, smallpox 0.

A Bequest to the Yale Medical School. — By the will of the late Mrs. Henry Farnam of New Haven, Conn., the Yale Medical School receives a legacy of $54,500, as an addition to its general endowment fund.

Dinner for Professor Ehrlich. — Drs. W. T. Councilman, H. C. Ernst and Theobald Smith gave Professor Paul Ehrlich a dinner on the evening of April 19, among other guests being President Eliot and Professor Richards of Harvard College and Drs. Meltzer and Dunham of New York.

Anthrax in Lynn, Mass. — The recent death of a workman in Lynn from anthrax calls attention to the fact that during the past three or four years there have been in the neighborhood of fifteen cases of the disease in that city, of whom it is said that the great majority died. The matter is certainly deserving of careful investigation and study.

LECTURES ON INTEGRATIVE ACTION OF THE NERVOUS SYSTEM.— Prof. Charles S. Sherrington, M.D., of the University of Liverpool, is to give the Silliman lectures for 1904 at Yale University on the above subject. There will be ten lectures.

LECTURE ON EXPERIMENTAL THERAPEUTICS. — Professor Paul Ehrlich, director of the Institute for Experimental Therapeutics at Frankfort, gave an informal address in German at the Harvard Medical School Wednesday evening, April 20, on "Pharmacology and Experimental Therapeutics."

THE STILLMAN INFIRMARY. — The corporation of Harvard University announces an additional gift of $25,000 from Mr. James Stillman. Mr. Stillman had previously contributed $50,000, and that, with the very recent gift, will make possible the construction of a ward for contagious disease. The new buildings will be erected adjoining the present one on land which was secured sometime ago.

PREVENTION OF BLINDNESS AT BIRTH. — The Massachusetts Association for Promoting the Interests of the Adult Blind has published a leaflet on the prevention of blindness at birth, giving directions for treatment which may be carried out by the laity. The leaflet calls attention to the fact that inflammation of the eyes in new born infants is a contagious disease which must be treated early and vigorously under a doctor's direction, and the statement is made that in England about thirty per cent of pupils in the schools for the blind lost their sight through neglect or wrong treatment of the disease.

NEW YORK.

RESIGNATION OF PROF. W. T. BULL, M.D. — At a meeting of the Board of Trustees of Columbia University held April 11 it was announced that Dr. William T. Bull had tendered his resignation as Professor of Surgery, to take effect June 30, 1904. The resignation was accepted and a resolution was adopted expressing regret at Dr. Bull's retirement. The students, it was stated, would still have the opportunity of attending his clinics at Roosevelt Hospital. Upon the recommendation of the Medical Faculty, Dr. George E. Brewer, Professor of Clinical Surgery, was given a seat in the Faculty of Medicine. Dr. Edward L. Trudeau, of Saranac Lake, N. Y., having resigned as a member of the board of trustees of the university, Dr. T. Matlack Cheesman was elected as his successor.

A TUBERCULOSIS COTTAGE HOSPITAL. — By a gift from Mrs. Andrew Carnegie a tuberculosis cottage hospital is to be established under the auspices of the Speedwell Society for Sick and Convalescent Children. Many of the children cared for by this society, which was organized two years ago, are taken from the New York Post-Graduate Hospital, and it has been the practice to send the patients to Morristown, N. Y., where they are boarded in private families under the supervision of a competent physician and a matron who visits them each day. The reason for establishing the special hospital is that most of the families object to taking children suffering from tuberculosis. The site for the institution has not as yet been determined upon, but it will probably be at no great distance from New York.

PRACTICING WITHOUT LICENSE. — Acting upon information furnished by Dr. J. McP. Scott, Secretary of the Board of Medical Examiners of Maryland, the New York County Medical Society has caused the arrest, on the charge of practicing medicine without due qualification or license, of "Drs." Charles Conrad and J. White Bushnell, who have been advertising extensively and doing a quack business under the style of The Platen Institute, Incorporated. It appears that Conrad wrote to Dr. Scott seeking a license to practice in Maryland, and in the course of his letter he stated that he held a diploma from the "Vetus Academia Physio-Medica," an institution, the founder and president of which he announces himself to be in his advertisements and circulars. He also acknowledged that he was not licensed in any state.

INTERFERENCE WITH HEALTH DEPARTMENT NURSES. — Some of the trained nurses employed by the health department to look after the children of the public schools having reported to President Darlington that they had been interfered with in the performance of their duties by the school principals, Dr. Darlington requested Superintendent Maxwell of the department of education to take some action in the matter. As a result, the superintendent has addressed a communication to all the principals, in which he calls attention to the fact that friction has developed and points out that the nurses were assigned to look after the children sent home by the medical inspectors, in order that the children might get back to school as soon as possible. The letter goes on to say: "In many cases, were it not for such attention the children would not

be given proper medical care, and prolonged absence, necessitating the intervention of the truancy department, would result. It will be seen, therefore, that the nurses, if given proper opportunity, will aid the principals in maintaining a high percentage of attendance. You are requested therefore to co-operate with these nurses in the proper discharge of their duties. If questions of authority arise, please communicate with me, and I will endeavor to adjust matters satisfactorily with the department of health."

Annual Report Department of Health. — In his annual report, just submitted to the Governor, Dr. Daniel Lewis, Commissioner of the State Department of Health, says that the most conspicuous feature of the sanitary condition of the state during 1903 was the epidemics of typhoid fever at Ithaca and West Seneca, near Buffalo, and he points out that similar conditions to those which prevailed at these places menace the health of many municipalities, as well as of various summer resorts which are patronized by citizens of other states beside New York. Many millions of dollars, the Commissioner asserts, are annually lost to the people of the state through preventable diseases. "If the monetary value of a human life is assumed to be $5,000," he says, "the deaths from but five of the preventable diseases during 1903 represent a loss of $94,000,000. These figures seem appalling, and yet millions upon millions can properly be added to this sum, in loss of wages, expense of the care of the sick, and many other expenses incidental to the management of these epidemic and infectious diseases." The deaths from the five diseases referred to were as follows: Pulmonary tuberculosis, 13,194; diphtheria, 3,056; typhoid fever, 1,665; scarlet fever, 1,057; smallpox, 41; total, 18,992. Dr. Lewis says that the paltry $20,000 a year which is available for the purpose of a systematic supervision of the water supplies, sewer systems and drainage is quite inadequate to meet the required conditions and enforce the law. A new bureau of water supply and drainage in the Health Department is recommended, and immediate action is urged, since a serious epidemic now in progress (at Watertown) has exhausted the available funds. In the report of the cancer research laboratory which accompanies the Commissioner's report it is stated that the past year has not been characterized by any marked discoveries which can be safely announced to the world, but has been marked by a steady, earnest and laborious study along the lines of investigation. The vital statistics of 1903 show a state death-rate of 17.6 and a birth-rate of 21.8.

Miscellany.

THE INOCULATION OF APES WITH SYPHILIS.

Reference has already been made in the *British Medical Journal*[1] to the successful inoculation of a female anthropoid ape with syphilis by Metchnikoff and Roux. Lassar of Berlin has also apparently succeeded in producing the disease in another anthropoid ape.[2] The animal in this case was a male between four and five years old. The inoculation was carried out somewhat in the same manner as in Metchnikoff's experiment. Scarifications were made in the skin of the forehead in several places, and the secretion taken from a primary sore rubbed in. This was also done upon the lips. In addition, in this case small pockets were made in the skin of the forehead and ears, and minute portions of the chancre inserted into them. All the inoculations were made on the same day. No inoculation was made upon the genitals. The primary sore referred to above was an untreated extragenital chancre of several weeks' duration, situated on the arm of a man who had become infected in the operation of tattooing. This patient also undertook the care of the ape, since, in the event of the experiment proving successful, scratches or bites inflicted by the animal would naturally be fraught with danger to any person not himself suffering from the disease. In order to ensure that the material did not get rubbed off, the ape was kept rolled up in a sheet for an hour or two after the operation. The various sites of inoculation healed in forty-eight hours without disturbance, and in fourteen days two apparently characteristic lesions appeared on the forehead. These were still quite evident when the animal was exhibited at a meeting of the Berlin Medical Society held six weeks later. In this case, as in Metchnikoff's, definite secondaries followed — namely, papular rashes on the soles of the feet, the palms, the brow, and round the anus. Cervical adenitis was also present, and the front of the scalp became bald. In the Paris experiments, it will be remembered, the virus of more than one patient was used, and secondary as well as primary material was employed, the primary material being applied to the genitals, and the secondary to the forehead. Further, the inoculations on the genitals were performed on two separate occasions, five days intervening between them. The resulting chancre appeared on the genitals (clitoris). Thus in both experiments it is extremely interesting to note that the inoculation was effected by means of primary virus. — *British Medical Journal.*

Deaths reported, 4,247; under five years of age, 1,143; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 995; acute lung diseases 925, consumption 467, scarlet fever 45, whooping cough 9, cerebrospinal meningitis 35, smallpox 7, erysipelas 26, puerperal fever 17, measles 66, typhoid fever 61, diarrheal diseases 144, diphtheria and croup 104.

From whooping-cough, New York 5, Chicago 1, Philadelphia 1, Pittsburg 2. From smallpox, Chicago 1, Philadelphia 5, Pittsburg 1. From cerebrospinal meningitis, New York 29, Somerville 2, and Boston, Worcester, Brockton and Southbridge 1 each. From erysipelas, New York 10, Chicago 2, Philadelphia 3, Baltimore 1, Pittsburg 2, Providence 1, Boston 3, New Bedford 1, Springfield 1, Somerville 1, Pittsfield 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending March 26, the death-rate was 18.7. Deaths reported 5,469; acute diseases of the respiratory organs (London) 195, whooping cough 200, diphtheria 46, measles 176, smallpox 6, scarlet fever 32.

The death-rate ranged from 8.7 in Wildensen to 30.0 in Stockton-on-Tees: London 18.4, West Ham 15.2, Brighton 20.6, Southampton 19.5, Plymouth 24.2, Bristol 15.0, Birmingham 23.3, Leicester 14.7, Nottingham 19.3, Liverpool 19.8, Bolton 20.5, Manchester 24.3, Bradford 19.8, Leeds 19.9, Hull 16.8, Cardiff 16.9, Rhondda 21.3, Merthyr Tydfil 12.2, Hornsey 9.6, Warrington 24.8.

METEOROLOGICAL RECORD.

For the week ending April 9, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

RECENT DEATHS.

DR. PHILIP BISSELL, of the resident staff of the New York Hospital, died at the hospital from pneumonia, on April 13. He was twenty-seven years of age, and a graduate of the medical department of Columbia University in the year 1902.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.— The Society will meet in Sprague Hall, Medical Library Building, on Monday, April 25, 1904, at 8.15 P. M. Subject, Aciduria (Acetonuria) Associated with Death after Anesthesia. Papers and reports of cases on this subject will be presented for the Staff of the Children's Hospital by Drs. Brackett, J. S. Stone and Low.

ARTHUR K. STONE, M.D., Secretary.
543 Boylston St.

SUFFOLK DISTRICT MEDICAL SOCIETY.— There will be a meeting of the Section for Obstetrics and Diseases of Women in Sprague Hall, Boston Medical Library Building, 8, The Fenway, Wednesday, April 27, 1904, at 8 P. M. Papers, Dr. E. L. Twombly, "Conservative Surgery of the Uterine Appendages with Especial Reference to the Ovaries." Dr. Henry O. Marcy, "The Technic of Wounds Incident to Laparotomy."

W. H. GRANT, M.D., Secretary.
DANIEL H. CRAIG, M.D., Chairman.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING APRIL 14, 1904.

GREENE, J. B., passed assistant surgeon. Granted extension of leave of absence, on account of sickness, for sixty days from February 25, 1904. April 2, 1904.

WARREN, B. S., assistant surgeon. Granted extension of leave of absence for one day. April, 11, 1904.

WARD, W. K., assistant surgeon. Granted extension of leave of absence for four days from April 7. April 8, 1904.

STILES, C. W., chief of Division of Zoology. Detailed to attend meeting of Medical Association of Mississippi at Jackson, Miss., April 20–22. April 12, 1904.

GREGORY, G. A., acting assistant surgeon. Granted leave of absence for three days from April 12. April 12, 1904.

JACKSON, J. M., acting assistant surgeon. Granted leave of absence for five days from April 20. April 12, 1904.

RODMAN, J. C., acting assistant surgeon. Granted six days' leave of absence from April 12. April 9, 1904.

BOARD CONVENED.

Board convened to meet at Stapleton, N.Y., April 18, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon Preston H. Bailhache, Chairman. Passed Assistant Surgeon A. C. Smith, Recorder.

BOOKS AND PAMPHLETS RECEIVED.

Herter Lectures.[1]

BY PROFESSOR PAUL EHRLICH, M.D., LL.D., FRANKFURT, GERMANY.

LECTURE I.

THE MUTUAL RELATIONS BETWEEN TOXIN AND ANTITOXIN.

Abstract.

INTRODUCTION.

THE importance of practical and theoretical study of immunity. Influence of the side-chain theory. Cellular origin of antibodies. Relations between the constitution and distribution of chemical substances and their pharmacological action. Complexity of apparently simple functions.

Opposing views. Criticism of their experimental basis eliminates errors and reverses their significance. Importance of hypothesis to scientific advancement. Heuristic value of theory of immunity. Utility of succinct nomenclature and symbolic representation (algebra, chemistry).

HISTORY OF SIDE-CHAIN THEORY.

Studies upon the localization of various dyes and their relations to cellular chemistry (methylene-blue, neutral-red). Production of immunity with poisonous proteids; independently of Behring (ricin, abrin, robin). Immunity not only bacterial, but a general principle. Quantitative studies on augmenting immunity and determining its degree. Older obscure conceptions of the relations between antitoxin and toxin (union, destruction, cell-protection). Experiments in vitro eliminate obscurities of those on animals. Chemical nature of union demonstrated. Warmth and concentration hasten union.

TOXOIDS.

Difficulty in applying purely chemical conceptions in the case of diphtheria toxin. Law of equivalence apparently violated. Definitions of immune unit; technical toxin-values, lethal dose ("Dosis lethalis"), limit zero ("Limes null" = Lo), limit death ("Limes Tod" = L †). Different lots of diphtheria toxin though neutralized by a single immune unit contain different numbers of lethal doses. Investigation shows that upon standing the diphtheria toxin loses toxicity, but retains undiminished its affinity for antitoxin. The toxin molecule is quantitatively transformed into non-poisonous toxoid. Chemical illustration (anilin and sulphanilic acid). The simplest explanation of toxoid formation rests upon the assumption that the toxin-complex contains two groups of different functions: *a*. Haptophores, by which the complex enters into chemical unions; *b*. Toxophores, which occasion toxic action. Behring's objection, exemplified in hydrocyanic acid, not justified, because of the simple constitution of that poison. Complex organic compounds have repeatedly been shown to contain groups which confer definite properties upon the whole molecule. Anesthesiophore function of the benzoyl group in cocain; functions of the chromophore and auxochrome groups in dyes; color reactions of proteids due to definite groups (tyrosin, tryptophan, etc.). Evidence of this complex character of toxins also furnished by studies of hemolysins and bacteriolysins, which have their origin in the union of an amboceptor and complement and are analogous to toxins, the amboceptor representing the haptophore and the complement the toxophore group. Kyes' studies on cobralecithid.

SIDE-CHAIN THEORY.

Haptophore Group. — The conception of the duplex nature of toxins, etc., forms the basis of the side-chain theory. Views regarding protoplasm. Fundamental nucleus and side-chains (receptors). These receptors subserve normal assimilative processes which are of synthetic character. Only those substances can be chemically incorporated with the protoplasm (assimilated), which possess a grouping most closely related to some constituent of the cell, fitting into its constitution as a key into a lock. The toxins represent, to a certain extent, toxic foodstuffs. It is mere chance whether they encounter suitable receptors in the cells of a particular animal species or not, as is shown by the irregularity in the action of given toxins in the animal kingdom (botulism). Elaboration of the side-chain theory. The antitoxins are receptors, produced in excess, and liberated from the cells. Appearing in the fluids they unite with the toxins for which they have specific affinity and thus protect the cells which have receptors of similar affinity from damage (analogy to lightning-rods). Not only toxins, but also toxoids, call forth antibodies. It is therefore chiefly the haptophore group which causes the cell-reaction, yielding antibodies by occupying the specific receptors. It is doubtful whether this cell reaction is purely regenerative. The great disproportion between the amount of toxin introduced and the quantity of antibodies obtained points to a concomitant cell-stimulation (Bindungsreiz of Wassermann). This is supported by the fact that a single immunization with suitable bacteria (*e. g.*, cholera) or toxin (*e. g.*, that of diphtheria) may induce an abundant production of antibodies.

EVIDENCE IN FAVOR OF THESE THEORETICAL CONCEPTIONS.

(1) The demonstration of specific receptors in organs susceptible to a particular poison. Wassermann's experiments: union of tetanotoxin with cerebral tissues. Disproof of opposing views of Behring and Besredka. Locking of native and experimental hemolysins by susceptible erythrocytes.

(2) The demonstration by Pfeiffer that during the latent period, before free antibodies appear in the serum, they may be obtained from the

[1] Delivered before the Medical Department of Johns Hopkins University April 12, 13, 14, 1904.

bone-marrow with salt solution (loosely bound, partially liberated receptors).

(3) Demonstration of the presence of receptors produced and fixed in definitely localized tissues. Increased abrin-locking by the immunized conjunctiva (Römer).

(4) Local production of specific precipitins for maja-albumin after intraocular injection (v. Dungern).

(5) All attempts to produce antibodies with alkaloids, antipyretics and antiseptics have failed. These substances do not enter into the composition of the protoplasm, they encounter no suitable receptors and therefore fail to call forth a specific antigenetic reaction.

TOXOPHORE GROUP.

The toxophore group need not necessarily be simple but may comprise various constituent groups which may be identical or different. Illustrations from alkaloidal chemistry; strychnine contains two oxygenated radicles both of which produce convulsions, and the drug owes its extraordinary toxicity to a combination of the two. Substances of the filicic acid series are active in proportion to the number of filicic butanon groups they contain. Ricin probably contains two toxophore groups, one agglutinating erythrocytes, the other causing its general toxicity. Three varieties of toxoids may be obtained from ricin, one non-toxic but agglutinating, one toxic but not agglutinating; both of these are incomplete toxoids. The third, complete, is neither toxic nor agglutinating (Tarobi). Tetanotoxin and diphtheria toxin also appear to contain various toxophore groups. In the former there may be a lethal toxophore group and a morbific group; and in the case of diphtheria we may have to distinguish between complexes which cause the chronic effects and those occasioning acute manifestations. It is possible that certain partial groups act more powerfully on certain animal species than on others, and this may explain the observations emphasized by Behring that modified toxins meet with a range of susceptibility in the animal kingdom different from that of the original, unmodified toxin. Of practical importance is the question whether for the rapid production of antitoxin it is more advantageous to use only toxoids, or whether the presence of partial components of the toxophore groups exert a more favorable cell-irritation.

The action of the toxophore groups is generally slow. Since the intravenous injection of toxins is rapidly followed by their locking in the tissues and disappearance from the blood, the incubation-period, which in the case of diphtheria *toxones* may last for weeks, can only be explained by the slow action of the toxophore complexes. This is further exemplified in the hemolysins. Other factors may enter into the production of a period of incubation (studies of Hans Meyer and of Roux on tetanus). It is difficult to express definite views regarding the mode of action of the toxophore groups. Hueppe's hypothesis; experimental evidence wanting.

RECEPTORS. SUSCEPTIBILITY TO TOXINS. RELATIONS TO METABOLISM.

The receptors of the cells are constituents of the protoplasm possessing a certain independent individuality, as is shown by the possibility of causing their augmented reproduction. In respect to the toxins they act as localizers or condensers and may from an infinitely dilute solution occasion a concentration of toxins in particular cells similar to the concentration of picric acid which takes place when wool is immersed in a dilute solution. Susceptibility to toxins may be divided into the following varieties:

(1) Great susceptibility. Toxophilic receptors exclusively in vital organs. Antitoxin production very difficult because of damage to cells, only possible through use of toxoids (guinea pig or mouse and tetanus).

(2) Slight susceptibility because of wide distribution of toxophilic receptors in indifferent tissues, *e. g.*, connective tissue, which lock the greater part of the toxins, and thereby protect more important tissues (fowl or rabbit and tetanotoxin).

(3) Insusceptibility, though toxophilic receptors be present, because toxophore groups do not act on protoplasm. Abundant production of antibodies. Rare condition (crocodile and tetanotoxin).

(4) Insusceptibility through lack of toxophilic receptors. Numerous examples clearly established (crotin, arachnin, specific hemolysins).

Definite receptor-complexes are associated with definite forms of metabolism. Uniform metabolic processes imply uniform receptor-complexes and therefore a uniform susceptibility to toxins (diphtheria toxins and guinea pigs; tetanotoxin and mice). Individually varying functions reveal themselves in extraordinarily variable susceptibilty (*e. g.*, crotin and rabbits). The embryonic erythrocytes of chicks possess no receptors for arachnolysin and are therefore not destroyed by this toxin. Immediately after hatching, the development of susceptible erythrocytes begins.

The study of the receptors has been of particular importance in elucidating the processes of assimilation. Former methods applied to damaged cells were not sufficiently refined. Isolated receptors obtained by immunization make an accurate study of assimilation and katabolism more approachable. The reproach brought forward by some controversialists that the theory of receptors should also explain regeneration is extravagant. It is an advance to be able to isolate certain wheels in the complex mechanism of the assimilation-processes and to ascertain their utility. The actual motive power is not revealed and the problem of regeneration of living matter will long remain unsolved.

The demonstration that erythrocytes possess extraordinarily numerous and various receptors

is particularly important. It indicates that these corpuscles, in addition to their function as oxygen-carriers, play an important rôle in metabolism in storing intermediary bodies.

Investigation has been greatly aided by a knowledge of the receptors, since they can be used in the analysis of animal and vegetable poisons to separate them into partial-toxins having different haptophore groups. Thus it is possible by specific locking with specific antibodies to analyze snake poison into neurotoxic, endotheliotoxic and two hemotoxic components. Of the latter, one agglutinates, and the other, through the formation of lecithid, hemolyses the blood (Meyer, Flexner, Kyes). Similar analyses of tetanotoxin and diphtheria toxin are possible. The method is a great advance in a most difficult field of research.

CONCLUSION AND PRACTICAL FORECAST.

The immunization industry which has for its aim the production of sera of highest potency, has made marked progress. Sera of much higher antitoxic value than have hitherto been obtained will be the result. The knowledge that the immunity reaction is reduced by too highly toxic treatment of the animals is spreading. An effort is being made to restrict this immune reaction to tissues of slight vital importance (connective tissue) and to protect vital organs from injury. In this direction are the methods of immunization with toxin and antitoxin injected separately or after admixture. Thus an apparently neutralized toxin may cause antitoxin production (Park). This is due, as will be explained in the next lecture, to the presence of ultra-toxoids.

Progress in the production of curative sera is to be expected only when it becomes possible to obtain antitoxins of greater avidity than those now procured. That this is theoretically possible is shown by the investigations of Kyes who demonstrated that through the immunization of rabbits with cobra-lecithid it is possible to obtain an antibody of considerably higher avidity than that obtained by Calmette with cobra-venom in horses (antivenin). The selection of particularly favorable animal species and the use of toxins of least avidity or ultra-toxones will, most probably, bring this problem much nearer its final solution.

LECTURE II.

PHYSICAL CHEMISTRY *V.* BIOLOGY IN THE DOCTRINES OF IMMUNITY.

Abstract.

INTRODUCTION.

Physico-chemical investigations of Arrhenius and Madsen concerning the application of physical chemistry to the study of toxins and antitoxins. Their belief that tetanolysin is a uniform substance possessing only a weak affinity to its antitoxin and that its neutralization occurs in accordance with the law of Guldberg and Waage. Attack upon my doctrine of plurality of toxic constituents. Favorable reception of these opposing views in certain scientific circles lacking special competence in sero-therapeutical questions. Protest against the attempt of these authors to claim exclusive priority in the development of these questions. The path of biological investigation — the method of partial neutralization of toxins — followed by them was first opened and by long years of work developed by me. The contention that my investigations represent merely an application of Thomsen's principles in his study of affinities between strong acids and bases is incorrect.

Equally unwarranted is the reproach made by these authors that my investigations are inaccurate and have been conducted without sufficient consideration of sources of error. The most important of my results have been confirmed by them, especially as regards the existence of toxoids and their occurrence with varying degrees of avidity, as "prototoxoids," "syntoxoids." On the contrary, the researches of myself and collaborators have been conducted with the utmost precision and care without consideration of cost or time. Nor can I admit that I have violated the principle of choosing the simplest possible explanations. Such explanations received always my first consideration and, as in the case of diphtheria-toxin, gave place to more complex ones only when the experimental results made this necessary.

POINTS OF DEPARTURE. METHODS AND RESULTS OF PARTIAL NEUTRALIZATION.

It was to be determined whether in the production of toxoids a change in avidity for antitoxin occurred. The only available method for this was that of partial saturation or neutralization. A prerequisite of this method is the exact determination of the test-constants, viz., the simple fatal dose, and the Lo and the L† doses, which have reference to the immunity unit (I. E.), and each of which may be the starting point of the investigation. It is then determined by how many fatal doses the toxicity of a given quantity of toxin, as for example the Lo dose, is lessened by its mixture with a fraction, say one tenth, of the immunity unit of antitoxin. Then with another mixture containing a larger amount of antitoxin a second determination is made, and so on. If the toxin were a single substance of uniform composition and the antitoxin possessed for it a strong affinity, like that between hydrochloric acid and potassium, the quantities of toxin which disappear or are neutralized in these mixtures would be in direct ratio to the quantities of added antitoxin. In fact, however, the process of neutralization takes places after a quite different scheme, as is shown by a glance at the exhibited charts.

It is advantageous to present these experimental results in graphic form, and for this different methods are available:

(1) The original, designated by me as the "spectral" mode of representation, which shows step by step the extent of diminution in the number of toxic doses effected by a definite small quantity of antitoxin, to wit, 1-200th of the immunity unit (which quantity I have called the "combining unit"), in the different zones of neutralization.

(2) The "linear" method, employed by Arrhenius, in which the quantities of antitoxin added are represented on the abscissa, and those of the active toxic doses present on the ordinates, is merely another form of graphic representation which has no advantage over the former. On the contrary this method chosen by Arrhenius, which is based upon estimation of the dissociation constants, is objectionable, because the graphic line corresponds only in its middle part with the values actually found, and toward the beginning and the end shows considerable deviations. Moreover its construction rests upon false premises.

INTERPRETATION OF THE PHENOMENA OF NEUTRALIZATION.

From the exhibited charts it is apparent that by employing the Lo mixture three different zones can be distinguished in the spectral mode of representation. In the first zone one combining unit of antitoxin removes on the average either one half or one entire lethal dose. As there is reason to assume that in the case of an ideal, absolutely pure toxin one combining unit removes exactly one lethal dose, the foregoing result indicates that in this zone (1) pure toxoid, or (2) pure toxin, or (3) a mixture of equal parts of toxin and toxoid, designated by me as "hemitoxin," is neutralized. The existence of hemitoxin is possible only in case the toxoid has precisely the same avidity as the toxin; from this it follows, as I have from the beginning assumed, and as Arrhenius has confirmed, that in the transformation of toxin into toxoid no change in avidity occurs.

Pure toxoid occurs often in the form of a prototoxoid, which possesses a stronger avidity for antitoxin than all other components of the toxin and thus manifests its presence by the fact that to the solution of toxin containing it a certain quantity of antitoxin can be added without lessening in the slightest degree the toxicity. The existence of prototoxoids has been recently denied by Arrhenius as a result of his recalculations of toxins studied by Madsen. His criticism, however, is certainly not applicable to a toxin which has been continuously tested by me, nor to another investigated with the utmost precision by Theobald Smith. Furthermore, prototoxoids have been positively demonstrated in the case of other poisons and analogous substances, ferments, agglutinins. Inasmuch as no change of avidity occurs in the formation of toxoids, the demonstration of prototoxoids points to the existence of a partial toxin of strong avidity — "prototoxin."

The second zone in the spectrum is of relatively short extent and is characterized by the fact that one combining unit removes only a fraction — one fifth to one tenth — of the lethal dose. This is the zone of decisive significance for Arrhenius's hypothesis.

The third zone I call the "toxone-zone." Toxone is one of the primary products of secretion of the diphtheria bacillus, possessing the same haptophore group as the toxin, but of far less avidity, and in the process of partial neutralization entering, therefore, last into combination with antitoxin. Its toxophore group differs from that of toxin, being incapable of producing acute effects, cutaneous necroses, death. Toxone is responsible for the diphtheric paralysis occurring between the fourteenth and thirtieth day in guinea pigs. Mixtures of toxin and antitoxin in which all the toxin-components are neutralized, while only the toxone remains unneutralized, produce in guinea pigs, without any local or general lesion, the phenomena of diphtheric paralysis.

PHYSICO-CHEMICAL OBJECTIONS AND THEIR REFUTATION.

Arrhenius by following a plan of experimentation introduced by Danysz has shown in the neutralization of ammonia by boric acid, that if 1 part of boric acid lessens the hemolytic effect of a given quantity of ammonia by 50%, the subsequent addition of 2, 3, 4 parts causes a further diminution of only 16.7, 8.3 and 5% respectively. It would be absurd to conclude from these experiments that ammonia is not a single substance but is composed of several constituents of various degrees of toxicity, of which those with the strongest chemical affinity are first neutralized. Arrhenius, therefore, concludes that inasmuch as the neutralization of tetanustoxin proceeds in the same way it is superfluous to assume the existence of different components and sufficient to assume a single, uniform toxin with weak affinity for its antitoxin.

In reply I may state that at the outset of my investigations I was led to assume a strong affinity between toxin and antitoxin. This opinion in the first place was supported by the experiments of Dönitz and of Heymann who demonstrated the extraordinary rapidity with which diphtheria toxin introduced into the circulation combines with the toxophile receptors in the tissues, which must therefore possess a high degree of avidity. The protective and curative properties of the specific serum indicate that the antitoxins possess at least as strong avidity as the tissue-receptors. Furthermore, the therapeutic experiments of Dönitz on the animal body and of Madsen on red corpuscles prove that the toxin when once bound becomes so firmly fixed that the specific serum after a time fails to produce any curative effect. This indicates that after-fixation of the toxin secondary, chemical modifications transform the primary, labile combination into a stable one.

The large interval between the values of Lo and L† seemed to oppose the acceptance of a strong affinity between toxin and antitoxin. Designate by D the amount of toxin which represents the difference between L† and Lo. From chemical examples it can be easily shown that with poisons of strong avidity the value of D must correspond exactly to one simple fatal dose, whereas with poisons of weak avidity D may be much larger. At last, however, I succeeded in finding a toxin in which D was precisely of the theoretic value 1. Thereby it was in principle shown that toxin and antitoxin unite with strong affinity, and the great variations (from 0–300%) in the value of D presented by different specimens of toxins could be referred to the presence of toxone. Not until I had found this toxin did I come forward with my theory, which I believe to have been framed with due care.

What then is the evidence advanced by Arrhenius in favor of the view that toxin and antitoxin are actually substances of weak avidity? The biological facts which speak against this view are either entirely ignored by the authors or set aside under arbitrary assumptions of an inexact investigation. The sole support is the tetanus-curve, concerning the value of which I shall speak presently. Experimental investigation should in the first instance have attacked this question.

The entire calculation and reasoning of the authors proceed from the assumption, adopted by so prominent an authority as Professor Nernst, that neutralization of toxin and antitoxin is an interchangeable or reversible reaction. If it can be shown that the process is not a reversible one, then the basis is withdrawn from all the reckonings and deductions of Arrhenius. Unaccountably Arrhenius has presented no experiments upon this point, but Dr. v. Dungern has taken up the subject by applying the procedure used by Danysz for other purposes of successive additions of toxin to antitoxin. By way of example the processes in the production of acetic ether may be selected. Mix 1 equivalent of alcohol with ⅓ equivalent of acetic acid, allow the mixture to stand for a length of time and then add ⅔ equivalent of acetic acid (mixture A); at the same time mix simultaneously 1 equivalent of acetic acid and 1 equivalent of alcohol (mixture B). It is self-evident that the state of equilibrium, when two thirds of the added substance have been transformed, is reached sooner in A than in B. If the two mixtures are examined at a time when equilibrium is established in B, both liquids have of course the same composition. Before this point is reached, however, the transformation is advanced further in A than in B. If we assume in this example that acetic acid corresponds to toxin, alcohol to antitoxin and the ester to the neutral antitoxin-toxin mixture, it is readily seen that by the addition of acetic acid in two periods the mixture A is deprived of toxicity sooner than is the control B with simultaneous addition.

Von Dungern's experiments were made with a diphtheria poison of which the Lo dose was 0.6 ccm. and the L† dose 0.78. To 1 immunity unit of antitoxin he added first one third of the Lo dose — 0.2 toxin, and after twenty-eight hours determined the fatal dose of toxin. It was found that this mixture after the addition to it of only 0.39 ccm. of toxin was fatal to guinea pigs. Thus in accord with Danysz's previous observations, it was demonstrated that an increase of toxicity appeared when the toxin was added in two portions, since under these conditions the L† dose was reduced from 0.78 (in the case of simultaneous mixture) to 0.59. (If antitoxin was added in successive fractional portions of the immunity unit to the toxin solution the L† dose of course remained 0.78.) From his experiments von Dungern concludes:

(1) The union of diphtheria toxin and antitoxin does not proceed in accordance with the ammonia-boric-acid scheme.

(2) The observed phenomena of combination are explicable only upon the assumption of a complex constitution of the diphtheria poison.

(3) The facts find their best explanation in the action of a toxone and epitoxonoid. Epitoxonoid is present in considerable quantity in toxic broth. The immunizing action of apparently completely neutralized toxins can thereby be explained.

(4) Constituents of the diphtheria poison with weak affinity after combining with antitoxin may eventually become so firmly bound that this union can be only incompletely broken by toxin of stronger avidity. The strength of the combination is of significance for the action of antitoxin. (Demonstration of the relations by schematic charts.)

At my suggestion Dr. Sachs has undertaken the same experiments with tetanolysin. In one experiment 0.02 ccm. tetanus serum served as the immunity unit. This neutralized completely 0.3 ccm. (Lo dose) of a definite toxin solution, while a mixture containing 0.7 (L†) toxin effected complete hemolysis. By adding to the serum the Lo dose (0.3) and again after twenty hours adding more toxin the L† dose was found to be reduced to 0.45. It is consequently demonstrated also for tetanolysin, which is the axis of Arrhenius' investigations, that the premises underlying his entire calculations and construction of graphic curves are inapplicable. Hereafter the linear representation of the calculated values of toxins, as demanded by Arrhenius for all cases, must be rejected wherever the phenomenon of Danysz is present.

Also from the purely physico-chemical point of view, as I am authoritatively informed, the conceptions of the authors present numerous vulnerable points which will soon be exposed by competent authority. I confine myself here to the presentation of certain opposing arguments of a biological nature, and begin with tetanus.

Tetanolysin, on account of its ready decomposability and the difficulty of conducting hemolitic experiments with absolute accuracy, is ill adapted for precise determinations of the kind

under consideration. Neutralization experiments with this substance encounter on the one side the Scylla of incomplete union and on the other the Charybdis of destruction of the poison.

It is incomprehensible that the calculations should be based on the assumption that the toxin consists of molecules of poison with uniform composition. On the contrary, it is highly probable that specific toxoids are present, which, of course, must enter into the calculation as well as the toxins. The amount of toxoid was, however, unknown and indeed at present is indeterminable. To escape from this dilemma Arrhenius, as he has kindly informed me, assumes that the production of toxoid results from an equable weakening of all the toxic molecules. Thus the toxic solution would not be a mixture of dissimilar components. This assumption must be rejected on general grounds (examples) and is disproven by the demonstration of prototoxoids, as well as by the investigations of Tarobi on ricin-toxoids.

It is likewise incomprehensible that Arrhenius should leave entirely out of account the tetanophilic receptors of the red corpuscles and make no calculation of the amount of poison fixed by the corpuscles. These anchor no small part of the simple dissolving dosis, which is the dominating factor in the experimental procedure.

Even upon the assumption of a toxin of uniform composition the calculation of the state of equilibrium must, therefore, take into consideration three factors capable of combining with antitoxin — toxin, toxoid and receptor.

To meet these objections, which might easily be augmented, Arrhenius has scarcely anything of a positive character to offer save the tetanolysin table No. 19, which corresponds fully with the theoretical calculation. It must here be emphasized that in contrast with a large number of unsuccessful results this favorable one was secured but once. I have lately become very skeptical as regards the demonstrative value of this curve, inasmuch as both of Madsen's diphtheria curves, which on account of their correspondence with the calculation was published as a complete refutation of my conceptions, have since been shown to be erroneous. I communicated by letter to Professor Arrhenius that the numbers underlying these curves were in entire harmony with my conceptions, and I was astonished to be informed that a recalculation occasioned by my criticism showed that a part of the figures underlying the construction of the curves were wrong. Without my letter Madsen's curves would probably have stood for decades as an argument against my views. At any rate these considerations demonstrate that from erroneous figures, curves in entire harmony with the theory may be constructed.

At present there are no satisfactorily demonstrated facts which warrant the application of Arrhenius' conceptions to the diphtheria toxin. It may be mentioned that an extensive investigation by Morgenroth has positively overthrown Madsen's assumption that the toxone-effect is merely an expression of the action of toxin modified by antitoxin.

The large variations of the dissociation-constants, as determined by the calculation, necessitate the assumption of an extraordinary multiplicity of poisons, whereas my conceptions are satisfied by the acceptance of a much smaller number.

It is unnecessary to have recourse to further arguments when I mention in conclusion that my views furnish a far better explanation than those of Arrhenius of numerous facts in the domain of toxins, such as the process of spontaneous enfeeblement of toxins, their passage into a state of stability, the reduction of the toxone zone, the capacity of completely neutralized poisons to produce antitoxin (Park) by means of von Durgern's epitoxonoids. I am convinced that what I have established through long years of work concerning the nature of the diphtheria poison will withstand the Northern storm and with the course of time prove itself to be real and vital.

LECTURE III.

CYTOTOXINS AND CYTOXIC IMMUNITY.

Abstract.

DEVELOPMENT of our knowledge concerning bacteriolysins and cytolysins. Bacteriolysins (Pfeiffer's phenomenon in cholera) and their mode of action. Agglutinins (Gruber, Durham and Widal). Cytolysins (Belfanti, Metchnikoff, Bordet, von Dungern, Landsteiner).

Importance of this domain constantly increasing. Literature of recent years almost too great to master.

The hemolysins especially suitable for theoretical studies; they made it possible for me to explain quite simply the manner in which these substances arise, and the mode of their action.

MODE OF ACTION OF AMBOCEPTORS AND COMPLEMENTS.

The interpretation of Pfeiffer, Metchnikoff and Bordet's demonstration of the participation of two substances in producing bacteriolysis was made clear by means of absorption experiments and experiments at low temperatures. Establishment of the amboceptor theory. The amboceptor (the specific product of immunization) unites by means of one haptophore group with the receptor of the susceptible cell, and by means of another haptophore group with the complement. The complement has one chemical group suitable for union with the amboceptor, and another, the zymotoxic complex — which causes the injury to the cells. Bordet's opposition; his theory of "sensitization."

For the theory of direct union (between cell-receptor, amboceptor and complement) the following evidence may be given:

(1) Demonstration of well-established chemical analogues.

(2) The side-tracking of complements by an excess of free amboceptors, as was proved in the case of bacteriolysis by Neisser and Wechsberg, and firmly established by Morgenroth for hemolysins by the employment of anti-amboceptors.

(3) The existence of products from the breaking down of amboceptors — amboceptoroids (Wechsberg, Muller, Mereschi), which no longer are anchored by the cell, but still are able to divert complements. The amboceptor, then, acts like a dye-mordant. The complete hemolysin forms thus an analogue of a toxin, in which one part, the amboceptor, corresponds to the haptophore group, the second part, the complement, to the toxophore group.

The complement, contrary to the conception of Bordet, is not a simple unit, but is made up of a great many partial-complements, which side by side and simultaneously become attached to the amboceptor. Accordingly the amboceptor contains a whole series of complementophilic groups, and not a single one, as was at first supposed. The diverse amboceptors which can belong to one animal species differ specifically only in those haptophorous groups which are concerned in the union with the cell, while they are identical, or at least very similar, as far as their complex complementophilic component is concerned.

Proof of the multiplicity as opposed to the unit of complement can be brought:

(1) By the method of partial absorption.

(2) By the selective destruction of single partial-complements.

(3) By the demonstration of anticomplements which inhibit only a certain part of the complement action.

(4) By the evidence brought forward by Metchnikoff, that by the disintegration of microcytes or of macrocytes, at least two complements arise, which differ in their effects, one producing hemolysis, the other bacteriolysis.

In each individual instance of lytic action it is not necessarily the whole series of complements, but only a certain fraction of them (the dominant complements), which is concerned.

THE THEORY OF AMBOCEPTORS.

Amboceptors are cell products. In the protoplasm of cells, in addition to the simple receptors which give rise to antitoxins, there are more complicated receptors, which serve in the absorption of the more complex albuminous molecules. Two varieties of these receptors are to be distinguished:

(1) Receptors of the second order, which, in addition to their anchoring, haptophore group, possess a chemical complex, which is distinguished by its power to set going coagulative processes, and which is generally quite resistant to heat. As the result of immunization with cells or albuminous material, receptors of this order appear in the serum as coagulins or agglutinins.

(2) Amboceptors arise from receptors of the third order, which are concerned with the fixation and assimilation of the very largest food-molecules. For the katabolic changes of these molecules there are needed a whole sequence of processes, which can only be carried out by a multitude of fermentative agents such as the complements. Corresponding to this conception these receptors possess a multitude of complementophilic groups. The reason why these adjuvant groups do not actually occupy the receptors — which would present the simplest solution — may be looked for in their extraordinary lability, which may render necessary a continual rehabilitation and renewal of the fermentative apparatus. This view is favored by the fact that such an arrangement does exist in the case of the receptors of the second order, whose agglutinophore complex, as has been mentioned, is relatively stable.

The purpose, however, of protecting these complements from destruction would not be attained if the affinity of the complementophilic groups were such that the complements were continually being absorbed by the receptors. From the teleological point of view a most wonderfully well adjusted mechanism controls the complement-absorption, for by union of the haptophore group with a nutrient molecule the avidity of the complementophilic group of the receptor is so augmented as to permit its combination with a complement. This is then a sort of economy which enables the labile ferment to reach the cell at exactly the favorable moment for its utilization. The proof of the actual occurrence of this increase in avidity is furnished by "Bordet's phenomenon," in which a selected material, after it is laden with amboceptor, is able to remove complement suitable for itself and also for all other combinations.

Amboceptors can be produced by immunization which are specific antibodies for a great number of albuminous materials, and it is to be hoped that the study of these amboceptors will give us a much clearer view than we can now obtain, into the process of assimilation.

We must suppose that those parts of the protoplasm which are bearers of the receptors of the second and third orders must be completely immune to the destructive action of the zymotoxic groups of the complements. Although it is impossible with the means at our disposal to bring forward direct proof of the spatial separation of these particles of protoplasm, yet we are forced to believe that such a separation exists, from the circumstance that complements are able to destroy their own cells if they are artificially brought into relationship with certain other constituents of the cell. This is effected with extreme ease by the aid of cytotoxic amboceptors, which can be readily produced for nearly all kinds of cells. Thus the erythrocytes of a sheep, which are laden with specific hemolytic amboceptors, will show no sign of injury so long as they are suspended in normal salt solution, but they will be dissolved at once upon addition of the very same serum which was removed from the sheep with the erythrocytes. Thus the most

important agents of the body economy are turned into most deadly weapons if brought into a false relation to the protoplasm. In an analogous manner Kyes has shown that lecithin, the existence of which in the envelope of the red blood corpuscles preserves their integrity, undergoes, in the presence of the cobra-amboceptor, an intracellular displacement — heterotopy — which is a condition leading to the destruction of these corpuscles by the venom.

PLURALISTIC CONCEPTIONS.

The cells are complexly constructed systems. Each of them possesses an extremely great number of separate components which from a purely theoretical point of view are capable of producing an equally great number of specific reaction products. It is probable that each morphologically different cell constituent — protoplasm, nucleus, cilium, etc. — is capable of producing a serum specifically antagonistic to this particular structure, which serum in turn may be made up of a whole series of partial components (*cfr.* Theobald Smith's investigations of antibodies directed against the flagella and body substance respectively of bacteria).

Review of the conditions which lead to the result that the number of specific antibodies produced by immunization is usually much smaller than the number of different antigenetic substances inoculated. Deficiency of suitable receptors in the immunized species of animal; insufficient formation or insufficient shedding of these receptors; protection against auto-intoxication (*horror autotoxicus*).

Description of methods for demonstrating phenomena of plurality. Crossed absorption experiments and employment of anti-amboceptors. Examples from hemolysis. von Dungern's attempt to separate an antigenetic group common to two substrata for the production of a single, isolated anti-serum. An immune serum in the former restricted sense of absolute specificity does not exist, we can speak only of the specificity of *one* amboceptor type for *one* definite causative substance (antigen). Since, however, the immune sera contain a great number of different fractional components, which in turn can occupy a correspondingly great numoer of receptors, furthermore, since not the whole number of receptors of any one cell are peculiar to this cell, but a variable number of them are also common to other nearly related cells, we must conceive that a serum produced oy immunization with a certain type of protoplasm, while it exercises its chief action against this protoplasm, also exhibits its action upon a whole series of other substrata of protoplasm. The more closely related the receptor apparatus of two immunity-producing agents is, the more completely do the sera produced by them correspond in their action.

It is possiole at this time to refer only to certain topics from the extensive domain pertaining to the pluralistic conceptions.

(1) The controversy over alexins. These, formerly supposed to be simple units, correspond to a very great number of different agglutinins and amboceptors. These normal substances, destructive to the cell, may arise homologously (for example, the colilysins), or heterologously (cholera-amboceptors in the goat; trypanosomacides of human serum). An aim of therapeutics should be the obtaining in serum not only of complements but especially of the powerfully curative amboceptors of normal organs.

(2) Alterations in the receptor apparatus of the blood corpuscles and their relations to the isolysins. R. Koch's studies of isolysins in coast fever.

(3) Determination of philogenetic relationship. Uhlenhuth's and Wassermann's blood test.

(4) Relationship between the virulence of bacteria, the receptor apparatus, and the development of immunity (Welch, Walker, Hamburger, Pfeiffer, Wassermann).

(5) Practical results from the production of bactericidal sera.

TREATMENT OF PROSTATIC HYPERTROPHY.

THE following papers on the general subject of "The Treatment of Prostatic Hypertrophy," were read at a meeting of the Section for Surgery, Suffolk District Medical Society, March 2, 1904.

SURGICAL ANATOMY OF THE PROSTATE.

BY L. R. G. CRANDON, M.D., BOSTON,

Assistant in Surgery, Harvard Medical School; Third Assistant Visiting Surgeon, Boston City Hospital.

THE normal prostate is classically and well described as a chestnut-shaped body adjoining the neck of the bladder, inclosing the first part of the urethra. The urethra runs nearer the anterior than the posterior aspect of the gland, that is, about .7 cm. from the former and .9 cm. from the latter, but it varies. The narrow end or apex of the prostate is directed downward and forward to within 1.5 cm. of the symphysis, to which it is connected by thickenings of pelvic fascia. The posterior part or base is close to the rectum, through which it may be felt, about 6 cm. above the anus. Its measurements are about 3.5 cm. across at its widest, *i. e.*, bilaterally; 3 cm. from base to apex, and about 2.5 cm. in thickness, *i. e.*, in the direction of the urethra. The weight of the normal prostate ranges from 13.6 gm. to 21.4 gm., the average being 18 gm. These limits are not strict. A sheath derived from the rectovesical fascia incloses the prostate and contains the prostate veins. This capsule is fairly distinct. The rectal surface shows two grooves which meet in front and indicate the course of the seminal ducts. The gland presents a lateral lobe on each side of the base, and a middle portion or isthmus which is included between the ejaculatory ducts and the neck of the bladder.

The prostatic urethra, about 3 cm. long, is

FIG. 1. Nerve-plexus between prostate and rectum; mostly non-medullated fibers.

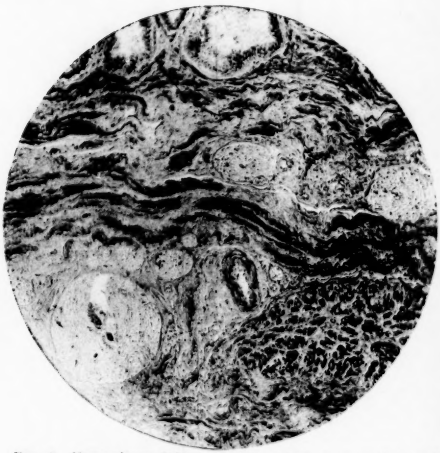

FIG. 2. Nerve-plexus behind prostate — mostly cross sections and largely of sympathetic origin.

FIG. 3. Nerve ganglia in recto-prostatic plexus.

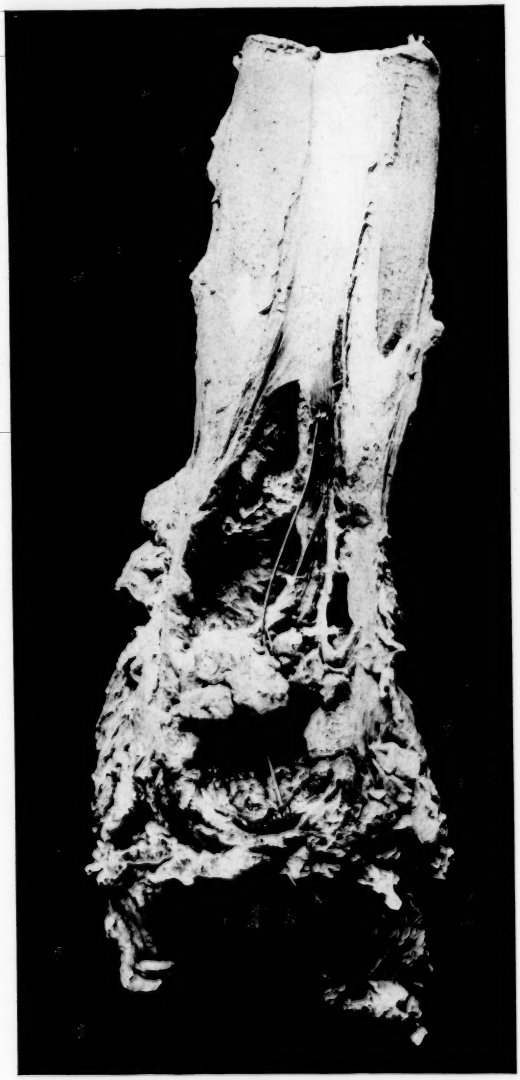

FIG. 4. Straw shows where the urethra was before perineal prostatectomy by "combined operation." Specimen removed post-mortem, three days after operation.

dilated in its middle, where there arises from its floor the verumontanum (Colliculus seminalis, Caput gallinaceum). The ejaculatory seminal ducts, passing forward from the seminal vesicles, traverse the lower part of the prostate and empty into the urethra by two slit-like openings on or very near the crest of the caput. The prostatic ducts empty through the wall of this portion of the urethra by from 12 to 20 openings, most of them on the floor of the urethra in a fossa on each side of the caput, called the prostatic sinus. The two largest prostatic ducts empty at the caput just behind the mouths of the ejaculatory ducts. In the middle line, close in front of the orifices of the ejaculatory ducts, in the forward part of the caput is the prostatic utricle. This is a blind pocket, about .8 cm. long, extending upward and backward beneath the isthmus.

Histologically speaking, the prostate normally is made up of smooth muscle-fibers, of rather cellular connective tissue, and of true gland-tissue in the proportions roughly of 1: 1: 2, together with more or less elastic tissue.

The principal anatomical points of the prostate which are of importance to the surgeon are, (1) its nerve supply; (2) its relation to the urethra; (3) its relation to the peritoneum.

The nerve supply of the prostate is derived from the inferior hypogastric plexus which in its turn has sympathetic origin from the superior hypogastric plexus and central origin from the sacral nerves and ganglia. Filaments from the inferior hypogastric plexus come to surround the posterior or rectal aspect of the prostate in a fine meshwork of relatively large nerves and many ganglia. The double origin of these nerves is clearly shown when they are stained for axis-cylinders (Pal-Weigert). (Figs. 1, 2.) The medullated or central nerve-fibrils stain black and take up about $\frac{1}{10}$ to $\frac{1}{20}$ of the total cross-section. The ganglia are fairly large (Fig. 3). This is the network of nerves mostly of sympathetic origin, which must be torn through in a perineal prostatectomy.

The relation between the prostate and the urethra is not only intimate from the passage of the urethra through the body of the gland, but the mucosa of the urethra is closely bound to the prostate by the ejaculatory ducts and the prostatic ducts which empty into the urethra and thereby attach urethra to prostate by from 14 to 22 points of adhesion. In a strict anatomical sense, therefore, the normal prostate may not be removed without tearing the urethra. That this anatomical condition is rendered much worse to the surgeon by the changes of the sclerosis of age and inflammation is shown by this specimen (Fig. 4).

The relation between the prostate and the peritoneum is variable. In measuring the distance from the depths of the rectovesical pouch to the central point of the perineum it was found in 20 cases to vary between 5 and 9 cm. and increases when the bladder is full. In perineal prostatectomy the lacerations may be found from $\frac{1}{2}$ to 2 cm. from the peritoneum, and virulent infection of this pouch, without macroscopic injury, has been demonstrated in at least two fatal cases, to my knowledge.

The Gross Pathology and Mechanism of Prostatic Obstruction.

by arthur l. chute, m.d., boston.

The frequent, painful feeble and usually incomplete emptying of the bladder seen in elderly men, which we term prostatic obstruction or prostatism, is not dependent on any single lesion of the prostate, either when considered from the point of view of its gross or its microscopical pathology.

The etiology and pathological histology of these changes in the prostate and of the changes secondary to the urinary obstruction are of great interest; they are, however, for the most part beyond the scope of this paper and do not so intimately interest us as do the gross anatomical changes. These gross changes are what we have to deal with in our operative attempts to relieve prostatic obstruction, and the success of our attempts will depend largely on our knowledge of them.

Mere general enlargement of the prostate, as shown by digital examination, does not necessarily produce prostatism, even a considerable increase in size may be symptomless; on the other hand a marked degree of obstruction and even complete retention may occur with a prostate which shows little if any appreciable enlargement. To have symptoms it is necessary that the changes in the prostate be such as to produce an obstacle to emptying the bladder. This obstacle is usually situated at the vesical neck or entrance to the prostatic urethra. Occasionally obstruction has been caused by the jutting of an enlarged lateral lobe into the prostatic urethra in such a way as to occlude it by lateral pressure; instances are also recorded where a small prostatic out-growth has blocked the lumen of the urethra in its course, but as a rule the obstruction is at the bladder outlet. The changes occurring in the shape and distensibility of the prostatic urethra are undoubtedly contributory; it is, however, very doubtful if in most instances they are the chief element in causing the urinary obstruction.

Whatever the conclusions of the pathologists and those particularly interested in the etiological aspect of the question, we have clinically two types of disease — First, the type characterized by a small, hard, fibrous prostate, which has the outward appearance of being of inflammatory origin, and second, the type in which the gland is enlarged, softer than in the first type, often irregular or lobulated on digital examination. The latter is usually spoken of as hyperplastic, adenomatous, fibro-adenomatous, or fibro-adenomyomatous, depending upon the relative proportions of the various constituents which different observers have found.

In the small fibrous prostate, the obstruction in a few cases seems to be due purely to the infiltration about the vesical end of the prostatic urethra, and the decreased distensibility of it. This destroys its normal funnel-shaped entrance and offers a difficulty to passing urine. If this condition is progressive the resistance becomes greater than the bladder can overcome, even with its compensatory hypertrophy, and we have a residual urine and the formation of a slight bas-fond. This places the already weakened bladder at a still greater disadvantage, since now the outlet is not at the lowest part of the organ. The repeated and unsuccessful attempts of the bladder to completely empty itself lead to further muscular atrophy and fibrous infiltration of its walls which lessen the expulsive power of the organ. This may be steadily progressive and is not necessarily attended with subjective symptoms other than frequency and diminution in the size and force of the stream. In an uninfected bladder the overflow of distention, or complete retention due to some purely circulatory change, may be the first real sign the patient has that something is radically wrong. With these fibrous prostates there is often an outgrowth at the urethral opening.

The second type of obstruction is characterized by a considerable enlargement of the prostate. There seems reason to believe that this may at times be a hyperplasia, though in the greater number of instances it is a benign neoplasm. The enlargement of the gland may be general or the growth may affect one lobe or part more than another.

With a general enlargement of both lateral lobes the extension will be upward to a greater or less degree. Extension downward is prevented by the firm triangular ligament, while the pubic arch prevents extension forward. There is opportunity for extension backward toward the rectum and this usually takes place to a considerable degree, but the lack of resistance in the direction of the bladder, together with the fixation of the bladder end of the urethra, leads commonly to an extension into the floor of the bladder. This encroachment of the prostate carries with it the urethral opening and raises it above the lowest part of the bladder, producing a condition in which the bladder cannot completely empty itself without extra work. This leads in time to a residual urine. Once we have a residual urine, a vicious circle is established, which in the natural order of things will be slowly progressive. This applies to all cases of prostatic obstruction. A symmetrical growth of the lateral lobes may, at the same time that it extends backward into the bladder, roll forward so as to embrace the anterior surface of the prostate, producing a projection into the bladder not unlike an os uteri. As there is more prostatic tissue below the urethra than above, the posterior lip of this projection is usually the larger. Variations in these last two types produce the so-called "horse-collar" obstructions.

In another arrangement both lateral lobes extend into the bladder and an off-shoot from one lobe bulges up under the trigone. These three globular masses about the bladder outlet may so dilate the prostatic urethra as to convert it into a cavity which holds more or less urine.

In obstruction by hypertrophied lateral lobes the prostatic urethra is elongated and is shown on cross section as a vertical slit. There is atrophy of the mucous membrane and the submucous tissue. The urethra will show a marked lateral deviation if one lobe encroaches more than the other. It will not show so marked a prostatic curve as in the cases with the median obstruction. The lateral pressure on the prostatic urethra is probably not so important a factor in producing the obstruction as the raising of the bladder outlet, though where one lobe presses so sharply as to cause a lateral deviation of the urethra it may add a considerable element to the obstruction.

The irregular forms of prostatic growths are found in the greater number of cases of obstruction. They are usually adenomata, and produce obstruction in direct ratio to their proximity to the bladder neck. Thus a considerable adenoma in the outer part of a lateral lobe will cause less obstruction than a smaller one nearer the urethral opening. These irregular growths show an almost infinite variety. A growth from one lateral lobe may extend into the bladder and an off-shoot project forward under the trigone in the form of a middle lobe. If sessile, it raises the bladder outlet, if pedunculated, it may form a valve. These out-growths from the lateral lobes may appear in other positions than under the trigone. In a patient on whom I operated a few days ago a pedunculated adenoma from the left lateral lobe had formed a very thick flattened valve, hinged on the left and a little above, completely closing the bladder outlet and making the patient wholly dependent on a catheter for more than two years. As the greater bulk of prostatic tissue is below the urethra these outgrowths commonly appear behind the urethral orifice, but are by no means confined to this position.

Beside these several variations which are the outcome of growths derived from the lateral lobes there are growths arising from glands which are not supposed to be anatomically connected with the prostate. These usually take the form of a middle-lobe obstruction.

There are glands which have a similar structure to prostatic tissue, and which have been found by some observers with considerable frequency *in* the mucous membrane at the trigone and outlet of the bladder. It is supposed that certain sessile and pedunculated growths take their origin from this tissue.

Certain other foci of glandular tissue, supposed to be aberrant bits of prostate gland, have been found *under* the mucous membrane in the region of the bladder outlet, and are considered to be the probable cause of some instances of third-lobe obstruction, and also as the cause of some cases of obstruction by a posterior lip or Mercier's bar. In theory, growths which project into the

floor of the bladder and have muscular fibres in front of them are derived from the lateral lobes; those that have muscular fibres behind them are supposed to be derived from the glands in the mucous membrane or from centers of aberrant prostatic tissue.

An important element in prostatic obstruction and one which, in its time of appearance may precede all inflammatory phenomena, is the occurrence of enlarged tortuous veins about the bladder outlet. These veins increase the frequency and pain of urination and are a common cause of hemorrhage; sometimes they undgero attacks of phlebitis and become thrombosed. They are supposed to play an important part in the causation of nocturnal frequency. Their engorgement is usually the determining factor in sudden retentions coming on after fatigue and exposure. Instances have been reported in which these veins have formed hemorrhoidal masses which have played an important part in obstructing the bladder outlet.

The back pressure due to urinary retention is an important factor in the changes secondary to prostatic obstruction. To it is largely due the thinning, trabeculation and sacculation of the bladder walls. Under this back pressure the ureteral openings become distended and incompetent, permitting a dilatation of the ureters and kidney pelves, while the pressure on the kidney substance leads to an interstitial process.

When by any of the above mentioned means the obstruction has become such that the bladder does not completely empty itself, conditions are most favorable for urinary infection. The urinary stasis destroys to a large degree the resistance of the bladder, and renders it almost certain that the entrance of organisms will be followed by cystitis. Cystitis, though not a necessary result of prostatic obstruction attended with residual urine, occurs in a large proportion of cases, and plays a large part in producing the classical picture. With its advent the seriousness of the condition is much increased. This infection of the bladder usually takes place by way of the urethra and is due most often to catheterization, although it is supposed that at times the infection takes place through the intestinal and bladder walls, or by way of the kidneys. The cystitis makes the bladder more irritable, the edema increases the obstruction to urination, while the infiltration diminishes the expulsive power of the bladder walls. If the ureteral orifices are incompetent the infection spreads to the kidneys, producing on its way a ureteritis and possibly a peri-ureteritis. In the kidneys a pyelitis develops, sometimes a pyelo-nephritis, and occasionally foci of suppuration are found in that organ. It is hard to over-estimate the importance of urinary infection.

The retained ammoniacal urine makes stone in the bladder a very common complication, especially in long standing cases. Where these stones are in a bas-fond or in pockets, the classical symptoms are often lacking and their diagnosis difficult. Their recognition is important from the standpoint of therapeutics.

Some recent work of Wallace[1] is of great interest on the much discussed point whether in hypertrophy of the prostate this organ develops a distinct capsule. He finds that adenomatous prostatic growths are often surrounded by a laminated layer of tissue which allows of their easy enucleation. He demonstrates with apparent conclusiveness that this is not a thickening of the true fibrous capsules of the prostate, but that it is formed from prostatic tissue surrounding the growth, which has been compressed as the growth has increased in size. This capsule varies in thickness and is densest where the pressure is greatest. In the walls of this pathological capsule Wallace has found glandular elements, which he believes are the remains of the compressed prostatic tissue. This capsule has the greatest surgical importance. Upon it depends the feasibility of enucleation, the probability of being able to spare the prostatic urethra and the possibility of a recurrence after enucleation.

A review of the gross pathological lesions found in prostatic obstruction demonstrates very clearly that no one operation is equally adapted to all cases, that our hope for better results lies in the more accurate diagnosis of the obstructing lesion in the individual case, and the selection of the operative procedure best calculated to meet its requirements.

Choice of Operation for Prostatic Hypertrophy.

BY F. S. WATSON, M.D., BOSTON.

No one method has established an exclusive monopoly in the surgical field of prostatic operations. The last twenty years' experience has eliminated from the list, a number of operative procedures devised for the treatment of this malady and its consequences and left us the following from which to choose:

(1) The palliative operations of perineal and suprapubic drainage.

(2) The Bottini operation.

(3) The total removal of the hypertrophied masses by various perineal operations and their modifications.

(4) The same by the suprapubic and the combined operations.

(5) The indirect, or sexual operations of castration and vasectomy.

The primary factors determining the choice of one or another of several surgical procedures, all having the same object in view, are —

(1) Their relative dangers.

(2) Their relative limitations.

(3) The character of their respective results.

Operative Dangers.

These are of two sorts. (1) Those to which the patient is exposed in a general way, and they

[1] Brit. Med. Journ, 1903, Vol. i, p. 764, and 1904, Vol. i, p. 259.

are shown by the mortality attending the performance of the various operations. (2) Those which are in a greater or less degree peculiar to one or another of the operations, and these we learn by the study of the causes of death in the fatal cases in connection with each particular method of operating.

In order to determine these factors, I have collected and analyzed 2,600 cases in which various kinds of operations have been done. This series does not include all the cases reported, by any means, but may be taken as a fair presentation of the experience in the operative treatment up to the present time.

In calculating the mortality, only such deaths as occurred within two months after operation have been considered as operative deaths. All deaths occurring within this period which were clearly due to other causes than the operation have been excluded. All those in which there might be a doubt as to whether the operation was the cause of death or not, were counted as operative deaths.

Briefly summarized, the mortality percentages of the various methods which are represented in the series, are as follows:

Method of Treatment by Catheterization	Cases.	Deaths.	Mortality.
Rovsing	126	10	
Casper	51	3	
Watson	30	3	
	207	16	7.7%
Palliative Operations. Drainage	146	49	33.0%
Partial Prostatectomies	133	13	10.2%
Total Removals — *Perineal*	530	33	6.2%
Total Removals — *Suprapubic*	243	28	11.3%
Bottini	1,164	69	6.3%
Castration	210	34	16.2%
Vasectomy	252	21	8.3%
	2,678	247	

Two hundred and seven cases treated by the catheter in the ordinary way have been included for the sake, so far as possible, of allowing a comparison of the operative methods with this one.

It will be seen that the mortalities of the Bottini and the perineal operations are the lowest of all the methods, and that they are practically the same as compared with each other. So far as this factor is concerned, therefore, they are on an equal footing, and are both preferable to the other methods.

The high mortality of the palliative operations — 33% — does not represent deaths due to the operations *per se*, but is owing to the fact that the majority of the patients were in a dangerous condition at the time, and catheter treatment being for one cause or another impossible, and something to relieve suffering being imperatively demanded, the only course open was that of the operations for drainage. Another purpose of the palliative operations has been that of improving the patient's condition in order to enable him to support a more radical procedure.

And finally these operations have been employed as final measures, the surgeon being content if he has succeeded in securing a reasonable degree of comfort for his patient by means of drainage. This Sir Henry Thompson used to advocate many years ago and reported some cases in which the patients had lived on in comfort for a long time with suprapubic drainage.

The high mortality of castration together with the uncertainty of its results has displaced it from favor recently, after it had been welcomed with strong hopes that it might prove the royal road to successful solution of this difficult problem; the same has been true of vasectomy in a great degree, and the profession has, after according these two methods a very fair trial, once more become faithful to its former methods of treatment by means of the three operative procedures, the Bottini, the perineal and the suprapubic radical operations. These three only will therefore be dealt with in what follows.

DANGERS MORE OR LESS SPECIAL TO EACH OPERATION, AS SHOWN BY ANALYSIS OF CAUSES OF DEATH.

The four factors, uremia, sepsis, shock and pulmonary complications, account for all but a very small number of deaths, and are therefore the only ones included in this analysis.

Bottini	27.0%	Uremia
Perineal Operations	35.0%	Uremia
Suprapubic Operations	34.0%	Uremia
Bottini	52.0%	Sepsis
Perineal Operations	17.8%	Sepsis
Suprapubic Operations	8.6%	Sepsis
Bottini	5.0%	Shock
Perineal Operations	21.4%	Shock
Suprapubic Operations	30.0%	Shock
Bottini	8.0%	Post-Operative Pulmonary Complications
Perineal Operations	17.8%	Post-Operative Pulmonary Complications
Suprapubic Operations	22.0%	Post-Operative Pulmonary Complications

Uremia is, as we know, the most serious danger in connection with prostatic operations, but there is not enough difference in the percentages of deaths due to it attaching to any one of the methods as compared with the others to give it value in determining the choice between them.

The largest share of danger from sepsis belongs to the Bottini operation, which on the other hand has a minimal proportion from shock and post-operative pulmonary complications, while the contrary is true of the other two methods.

LIMITATIONS OF THE INDIVIDUAL OPERATIONS IMPOSED BY LOCAL CONDITIONS.

The following are the limitations to the employment of the *Bottini operation:*

(1) Inability to obtain a good cystoscopic view of the bladder beforehand.

(2) A contracted thick-walled bladder.

(3) A large middle lobe extending far up into the bladder.

(4) Inability to enter the bladder with the instrument.

There is but one obstacle to the performance of the *perineal operations*. It is the same as that numbered three under the Bottini operation above.

The *suprapubic operation* is made difficult by the presence of a contracted thick-walled bladder, or one that is adherent to the posterior surface of the symphisis pubis.

The following objectionable features attach to the Bottini operation:

(1) Insufficient drainage of the bladder.
(2) Liability to secondary hemorrhage.
(3) Liability to epididymitis and orchitis.
(4) The necessity of performing the operation more than once in a considerable proportion of the cases. (13% of those in which the reports were accurately given had to have the operation repeated.)

In the performance of the perineal operations there is greater liability of injuring the membranous urethra and the rectum, and resulting urinary incontinence and recto-urethral fistula, than in the other two methods.

IMPROVEMENTS IN TECHNIQUE WITH REFERENCE TO THE CHOICE OF OPERATION.

The recent "boom" — if one may use the vulgar term with reference to this subject — which has recently carried the operative treatment of this malady forward so rapidly, especially in France, has been due to two things, chiefly, (1) the more careful selection of the cases, and (2) the improvement in technique. We have said all that is needed with regard to the first; it only remains therefore to speak of the second. The improvements in the technique have been made principally in connection with the perineal operations, and in these the two features which have been made better are (1) The removal of the hypertrophied masses with less injury to the parts included in the operative field, and (2) making the gland more accessible.

In the performance of the perineal operations the latter is accomplished by downward pressure above the symphisis pubis or by the use of one or another of the various forms of tractors, or by the drawing down of the gland by the tips of two fingers in the rectum as was done by Celsus when cutting for stone. Personally, except in very fat subjects, I have always found the suprapubic pressure, either alone or in combination with the use of the finger tips in the rectum, sufficient and a satisfactory means of bringing the gland within reach. There is one objection to the use of tractors having metal blades, which is this: It is at the time when one is separating the most distant parts of the intravesical projections from their attachments that the greatest traction is required, but it is also at that very moment that it is dangerous to apply it, for it is then that the resistance which has up to that time been opposed to the tractor blade by the hypertrophied lobe when still fixed to its surrounding structures is taken away, and if care is not taken the instrument's blade is very liable to tear through the bladder and urethral coverings of the lobes and cause extensive destruction of them.

By whichever of these various means the individual surgeon learns by experience he can best accomplish the purpose, that one is the best for him personally to use.

With regard to the other features of the perineal operations, there are the following things to be considered: (1) The incisions of approach to the gland. (2) The incisions of its capsule. (3) The manner of removing the hypertrophied lobes by which the least injury is inflicted upon the ejaculatory ducts and the urethra, and by which the danger of hemorrhage may be avoided.

These things are accomplished by employing the incision which gives the most open field of operation. This incision is the crescentic cut which passes transversely across the perineum in front of the anus from one ischial tuberosity to the other, and is that introduced by Celsus in his lithotomy operation. It has been modified by carrying an additional cut forward from its center in the median line of the perineum and known as the inverted Y incision. The original cut is sometimes pitched more sharply into the form of a V inverted, which gives enough room usually, but less than the inverted Y incision. This incision has been reproduced several times under different names, but so far as I am aware, it was first applied to the removal of the prostate by Leisrink in 1882.

The ejaculatory ducts may be avoided by, (1) making an incision of the capsule in the median line, opening the urethra well back, in order to avoid so far as may be the membranous urethra, which is one of the most important parts to protect, and then effecting the removal of the gland in two or three portions according as there are bilateral, or bilateral and median hypertrophies present, the lateral lobes being reached, exposed and enucleated from the lateral aspects of the prostatic urethra. Or, (2) by making two parallel incisions in the capsule, one on either side of the median line (not opening the urethra) and just outside each of the ducts. The enucleation is then carried on through first one and then the other of these cuts.

Hemorrhage is avoided by keeping within the outer capsule or sheath of the gland.

RESULTS.

Freudenberg considers the patient *cured* so far as the local conditions are concerned, when he has not more than 50 cc. of residual urine and can but for that amount empty the bladder freely, painlessly and spontaneously. He classes, however, under the single heading of "good results," the cases cured together with those in which marked benefit has followed the operation.

The latter custom is certainly lacking in accuracy, for it permits a wide divergence of opinion as to what degree of improvement shall be considered as sufficient to allow cases to be included in the class of "good results." However, for the sake of uniformity and comparison, I have, in analyzing this present series, adopted the same standards and applied them impartially to all the operations with respect to the use of the terms "cure" and "good results." Analyzed

with these restrictions imposed, the following things are shown:

Bottini's Operation	Cured 30.4%	Good results	84.4%
Perineal Operations	" 60.0%	" "	88.0%
Suprapubic Operations	" 66.0%	" "	90.0%

The proportion of accidents which are shown to have been associated with one or another of the operations is as follows:

In a series of 267 Bottini operations there were 31 or 11% of failures recorded, and incontinence of urine resulted in 7 or 2.6% of them.

In 59 cases reported by Willy Meyer in which the Bottini operation had been performed by him, there were 6 in which epididymitis and 2 in which orchitis occurred. In one of the former suppuration ensued, also in one of the latter, while in another of them there was gangrene of the testicle. Perineal abscess and urinary infiltration occurred in 4 cases owing to the membranous urethra having been injured. In one other case the rectum was injured and recto-urethral fistula resulted. Altogether, then, there were more or less serious complications in 22% of the series.

In 245 cases of perineal operations, there were 2 in which the peritoneum was opened — 7 in which urethro-rectal fistula resulted — and 9 in which incontinence followed the performance of the operation. Altogether 7.2% of accidents.

A small proportion of incontinence and of persistent fistulæ only ensued upon the performance of the suprapubic operation. Altogether about 6% of accidents occurred in connection with it.

CONCLUSIONS.

It will be readily conceded that the following surgical axiom is a sound one.

Of a number of operations all having the same object in view, that one is to be preferred, other things being equal, which accomplishes the object as completely as any other, with the least destruction of tissues involved, and with the greatest safety to the patient.

There can be no doubt but that the above ends are best attained by the perineal operations when done in accordance with their best technique; this fact has been amply demonstrated with regard to the relative dangers, the relative limitations and the relative effectiveness of the results obtained by the three methods we have had under consideration. It is consequently the method of choice. This is not to say, however, that it is the only operation which should be used. On the contrary, both the suprapubic and the Bottini have a well defined place. The former is the operation to be preferred in cases in which a very large middle lobe makes the perineal operations especially difficult. The Bottini operation is to be preferred to either of the others if the patient's condition is such as to expose him to the danger of shock or post-operative pulmonary complications; and finally if one or another of the limitations to the performance of the Bottini operation is present, or there is too grave a general condition of the patient to warrant the employment of the Bottini, and if something must be done to relieve him, we will perform a palliative operation for drainage. The nature of the local conditions we shall have determined beforehand by means of the cystoscope.

RESULTS OF OPERATIONS UPON THE PROSTATE, MASSACHUSETTS GENERAL HOSPITAL,

From Jan. 1, 1892, *to July* 1, 1893.

BY HUGH CABOT, M.D., BOSTON.

This period has been selected because prior to 1892 operations upon the prostate were few and far between and the cases operated upon since July, 1903, are too recent to be of any value as showing results. It is hardly necessary to indicate that in considering these statistics they should not be treated as comparable with the results of any one operator. They represent the results of many operators, both experienced and inexperienced, and they also represent in many cases the results of operation done under conditions so desperate as to give little hope of a successful issue under any method of treatment. Up to within a very few years the cases selected for operative treatment were always the unfavorable ones and must not, therefore, be compared with the results of operations upon cases of election. No selection has been made; all cases have been tabulated; and the results may be taken as showing the most unfavorable aspect of the question.

TABLE 1. This table deals with the mortality of three operations. In the first group were placed the cutting operations upon the prostate; in the second, operations done with the Bottini electrocautery, and in the third group the results of castration. This latter group was added to show that an apparently trivial operation upon men of this age is attended by considerable mortality. In calculating the mortality the number of operations and not the number of patients has been taken. Thus in some cases three operations, separated by an interval of months or years, had been done upon one patient, thus considerably affecting the mortality if only the number of cases had been considered.

TABLE I.

	Number.	Av'age Age.	No. Deaths	Mor'ity
Cutting Operations	53	63+ yrs.	9	17.0%
Bottini Operations	8	61+ yrs.	0	0.0%
Castration	34	66.7 yrs.	5	14.7%

This table gives a fair idea of the mortality of cutting operations in a general hospital during the last ten years. That very much better results may be obtained at the present time by individual operators may be taken for granted. The number of Bottini operations is too small to give any proper idea of the mortality, and the operation will certainly carry with it a quite noteworthy death rate.

TABLE 2. This table deals with the results as far as they can be collected. No case was entered as a result that was not seen or heard

from at least one year after operation. Cases were regarded as cured when they were symptomatically well and either regarded themselves or were regarded by their physicians as cured. No attempt was made to apply the absolute test that the patient should completely empty his bladder at normal intervals. Cases are marked "relieved" when their condition is much better than that prior to operation, but when some frequency or a small amount of residual urine keeps them from being regarded as cured.

TABLE II.

RESULTS OF CUTTING OPERATIONS.

	Cases Heard From.	Well.	Relieved.	Same or Worse.
Number	36.0	11	6	8
Per Cent.	69.3	44	24	32

From this table it appears that about two thirds of the cases operated upon by all methods were improved by the operation. The remaining third were in most cases not essentially worse than before operation, though in two cases their present condition was distinctly more uncomfortable than before operation.

Table 3. In this table I have attempted to compare the results of partial operations with those of complete operations. By partial operations are meant those in which only a portion of the prostate was removed. This was generally a third lobe, removed by the suprapubic route. In some cases a considerable amount of tissue was taken, in others only a small pedunculated growth was removed. The complete operations were largely done either by the combined method, suprapubic and perineal (Alexander), or by one of the modifications of the perineal method.

TABLE III.

RESULTS OF CUTTING OPERATIONS.

	Well or Relieved.	Same or Worse
Partial Operations	57%	43%
Complete Operations	83%	17%

This table shows that the complete operation has given much better permanent results and there are no cases recorded as the same or worse which were not at least as well as before operation. All the cases that were made worse by operation were partial operations.

Table 4. In this table I have grouped all the patients who entered the hospital for treatment of enlarged prostate during the ten years from 1892 to 1902. It will be of interest as showing the number of cases recorded as surgical, that is, requiring surgical treatment. It is also interesting as showing the point of view in regard to the cases suitable for operation and as indicating the waves of surgical opinion which have passed over this community. It will be noted that the statistics reflect very accurately the opinion of the general practitioner in the surrounding country as well as that of the hospital surgeon. Thus during the years 1894 and 1895 the operation of castration was being advised and patients were evidently sent to the hospital for that purpose. The following two years show the reaction which followed the failure of this operation to do all that was claimed for it. The years 1898 and 1899 show the impetus given to prostatic operation by the free discussion of Alexander's combined method which followed his paper read here on that subject. The year 1900 shows a temporary reaction, while the following two years show the influence of the belief in perineal prostatectomy and the increased use of the Bottini operation.

TABLE IV.

Year.	'92	'93	'94	'95	'96	'97	'98	'99	1900	'01	'02
Total No. Cases	4	6	13	28	3	17	37	43	24	36	27
No. Operated	1	1	4	10	1	4	23	17	7	19	13

If the year 1903 had also been added to the list the tendency to operate upon more cases out of the total number submitted would be still more obvious as the records of that year show very clearly the influence of perineal prostatectomy.

In closing I would say that I have collected these cases at the request of the surgical staff, and think that some credit is due them for their willingness to allow their cases to be thus roughly grouped together since they give a very unfavorable idea of the condition of operative surgery if taken at their face value. It is to be hoped that the limitations of such a series of statistics will be borne in mind and that they will be allowed only such weight as they deserve and that no attempt will be made to draw definite conclusions from such a small series of cases.

The Use of the Cystoscope in Determining What Operation is Advisable in Prostatic Hypertrophy.

BY F. C. BALCH, M.D., BOSTON.

Few people would care to decide what operation was advisable in prostatic hypertrophy from a cystoscopic examination alone, but in connection with the other methods of examination commonly used it often gives us very valuable information as to how we should proceed with the case. Usually the examination is easily made without the use of a general anesthetic, as the use of cocaine takes away nearly all the pain. The urethra must be large enough to admit the instrument and the bladder must be capable of holding about five ounces of fluid without trying to expel it. The absence of these two conditions may make general anesthesia necessary as may also extreme sensitiveness of the prostate, as for instance where there is much ulceration. The view of the prostate may save us in some cases from serious mistakes. Thus in a recent case where the Bottini operation had been advised the cystoscope showed the growth in the prostate to be cancerous and a suprapubic operation was advised instead. Until comparatively recently the use of the cystoscope has been a difficult proceeding requiring very careful manipulation and often failing to demonstrate conditions which operation later proved had existed. Improvement in the older instruments and the

invention of new ones has greatly simplified the process and made it certain that in almost all cases we can see conditions as they actually exist. For the examination of the prostate the Kollman is a very satisfactory instrument. It gives a large, clear field and has the great advantage that even in a very dirty bladder or one in which there is considerable hemorrhage the fluid can be removed and returned again so quickly that we are sure of a transparent medium. All this can be accomplished without removing the tube from the bladder. As the insertion of a catheter or an instrument is often a cause of hemorrhage in these cases it will be readily appreciated that it is an advantage to be able to do all our washing without further irritation to the urethra than is involved in the primary insertion. It has the disadvantage that in certain forms of prostate it is not possible to see the whole of the mass, but it is perfectly practical to see enough of the tumor to decide what operation is advisable. It is not a catheterizing instrument, but catheterization is very rarely necessary and is usually not advisable in old men with hypertrophied prostate. The question of whether blood or pus is coming from either kidney can usually be determined by the examination of the fluid as it comes from the ureter. In many cases of enlarged prostate the distortion of the bladder is such that a ureteral catheter cannot be inserted.

After our examination there are many factors which must influence us in our choice of operations, such as the patient's condition, age, condition of kidneys, etc., but as far as the cystoscopy goes one can say that in that form of enlargement when there is a thickened ring about the internal meatus or a thick posterior lip the case is a very favorable one for the Bottini operation. Where the obstruction is from a ball valve it is very questionable whether the Bottini operation would succeed whereas the suprapubic route affords easy access to the growth. In the case of the pedunculated tumor it is very doubtful whether the cautery blade would hit it at all as there is no form of cauterizing instrument wherewith we can see just what we are burning. Again there is the chance that the pedicle might be cut through and the tumor left in the bladder. Where the obstruction is on one side only we can easily see where the cut should be made. If we find on examination that the growth is not so much intravesical as back toward the rectum, one of the operations for enucleation would be the operation of choice, other things being equal.

In a word the value of the cystoscope as an aid in operation is more apparent when the galvano-cautery is to be used than when the more radical operation of enucleation of the prostate is intended. It is, of course, a great help in all cases to know just what the condition of the bladder is and whether we have to deal only with an enlarged prostatic gland or some complication in combination with it, such as a stone or some tumor of the bladder wall.

A BRIEF RESUME OF THE PRESENT STATUS OF THE TREATMENT OF THE ENLARGED PROSTATE.

BY ARTHUR TRACY CABOT, A.M., M.D.,
Surgeon to the Massachusetts General Hospital.

IT would be hard to name any other surgical problem which has led to such differences of opinion or has been approached by such diverse attempts at solution as the management of the enlarged prostate. A simple enumeration of these will give a good bird's eye view of the subject.

CATHETERIZATION — OCCASIONAL AND HABITUAL.

False Routes { *a.* Suprapubic (Hunter McGuire)
b. Perineal

Prostatomy — Incision of Obstruction { *a.* Perineal
b. Per urethram (Bottini)

Prostatectomy { Partial { Suprapubic / Perineal
Complete { Suprapubic / Perineal

Orchidectomy — Vasectomy
Ligature of Iliac Artery

While experience has led to the rejection of a number of these methods, those now most in vogue are of such comparatively recent adoption that it would be presuming to suppose that we have yet reached the final solution of the problem.

The very great recent advances in methods of exact diagnosis and in operative technique have, however, put the subject on a much sounder footing than ever before. We begin to feel firm ground under us, and we can stand erect and look about us to see where we have reached and whither next.

The two things that the prostatic patient wishes to know when comparing a future catheter life with the chances of a prostatectomy are, the risk of the operation, and the probability of an effective and lasting removal of obstruction. The cases are still too few, and the time elapsed in many of them too short, to give us all the data we could wish for the answer of these questions.

The statistics collected for this meeting, as well as the results presented in the accumulating literature of the subject, seem to show that the complete removal of the prostate may be expected, in the majority of cases, to restore the power of voluntary urination. Perineal prostatectomy may now be done with so little disturbance of the prostatic urethra and of the voluntary sphincter of the bladder that we may expect in all but the most exceptional cases to avoid the distressing incontinence which followed many of the earlier enucleations of the prostate, both intravesical and perineal. By the use of Young's tractor, the prostate is brought down so close to the surface of the perineum that the incision of the capsule and the enucleation of the gland are carried on under the operator's eye. By this improvement in technique, the danger of the operation has been greatly diminished, and many patients who would formerly have shrunk from subjecting themselves to the risks and uncertainties of a suprapubic prostatectomy and

would have clung to the troublesome and annoying catheter, now can hear a frank statement of the mortality rates of perineal prostatectomy and cheerfully prefer that risk to the tyranny of the catheter with its more remote, but still very real, dangers.

I have been asked to say a few words this evening upon the treatment of prostatics with the catheter. There is not time nor is there need to rehearse here the details of catheterization, often so difficult in these patients. It is equally unnecessary to dilate upon the care with which one of these patients should be introduced to the catheter life.

I shall, perhaps, best employ the few minutes at my command by a consideration of the conditions under which at the present time, a resort to the catheter may seem preferable to an operation for the removal of obstruction. It happens not infrequently, that the disease runs an insidious course and is first discovered when the kidneys, and perhaps the heart and vessels too, are already seriously affected. Under these conditions, the dangers of an operation are enhanced, and if the patient is made reasonably comfortable with the catheter, it may be better to temporize in this way for the short time remaining to him of life. Even in these cases, however, it is often possible to do a Bottini operation under cocaine anesthesia and thus restore a reasonable power of urination with a minimum of operative risk. When these advanced prostatics have already reached a degree of renal insufficiency so great as to have led to a decided state of uremia, evidenced by nausea, vomiting, somnolence or great restlessness, they are not in a condition to bear operative interference. Such patients may be greatly benefited by the judicious use of the catheter.

In a recent paper, I have shown that by constant drainage through an in-lying catheter, the function of kidneys already seriously disabled may be restored, and patients in a pronounced uremic condition may be brought back to a state of health in which they can safely undergo operations which would have been almost certainly fatal if done during the existence of uremia. In very fat men with large prostates, the depth of the perineum and of the suprapubic approach add greatly to the difficulties of the operation; and as such patients do not bear operations well, it may be the part of good judgment to introduce them to the catheter life, rather than to subject them to the unusual operative risk that their condition entails. It is hard to decide upon the best course for such cases, and the results are so often unsatisfactory that, whichever method of treatment we choose, we are likely to regret that we did not select some other. Lastly, there will be a certain number of patients with hemorrhagic diathesis, with diabetes, or with some other complicating disease that prohibits any operation that can possibly be avoided, and in which we shall fall back upon the catheter as a "*pis aller*."

The catheter will also continue to play an important rôle in the immediate relief of cases of sudden complete obstruction. To the majority of other prostatic patients we may properly, I think, recommend a consideration of operative treatment. We can tell them that in proper hands they may undergo a prostatectomy with a mortality risk of between five and ten per cent., and that the chances are about nine to one that this operation will bring relief of their condition. We must also not forget to state to them that the risks of a catheter life, while more remote, are very real, for the chances of pyelitis, of epididymitis and of prostatic abscess are not inconsiderable. There will doubtless be many patients who will still shrink from operation and prefer the uncertain perils of the catheter life. It is my feeling, however, that as we become more and more able to give confident assurance of good functional results after operation, the community will gradually be educated to regard a prostatectomy with a degree of favor approaching that which they now show for appendectomy. We shall then get our cases earlier, before the kidneys have begun to suffer, and old age will be robbed of one of its serious terrors.

If the above considerations have led us to select an operation for one of our patients, the next step is to determine what that operation shall be. As I have indicated in my earlier remarks, in some patients too feeble, and with organs too unsound to bear a dangerous operation, a Bottini done with cocaine anesthesia, may be possible. The functional results of this operation are much less certain than after the more extensive prostatectomies, and the operation will, therefore, be kept for occasional use, rather than as an operation of choice in any but very rare cases. When a prostatectomy is decided upon, we have the choice between a partial prostatectomy done through the bladder and a complete prostatectomy done either suprapubically or through the perineum. When a complete prostatectomy is planned, my own personal preference is very strongly for the perineal route.

It has been my experience to find the perineal operation more exact in what it accomplishes, and, therefore, less dangerous and more sure of procuring a good functional result. When the prostatic urethra is torn in the operation, it is usually in its outer part and along its floor. The roof of the urethra is preserved and keeps the membranous portion of the canal in proper relation with the deeper portion of the prostatic urethra. I have found that a few stitches of cat-gut attaching the membranous urethra to the deeper parts are often useful in greatly diminishing the rent which has to be closed by granulation. The fact that the whole prostatic urethra can be removed, and that a good functional result is often thus obtained does not absolve us from the attempt to preserve the canal as far as possible. As a matter of fact, a certain proportion of the cases in which the gland is somewhat blindly shelled out have lacerations of the urethra which leave flaps that act as valves, hindering or preventing micturition. The gradu-

ally accumulating evidence as to the completeness and permanency of the functional result is so favorable to the complete prostatectomy, that this is properly selected as the operation of choice in all suitable cases. It is well, however, not to forget that a thorough removal of the third lobe will in many cases accomplish as good a restoration of function as the complete removal of the gland. I have seen this demonstrated in cases that I have watched for years. The operation leaves a cleanly cut surface at the internal urethral orifice, which is not favorable to the infiltration of urine; forms no pocket in which urine collects and stagnates, and, in short, leaves a wound which heals rapidly. This operation, therefore, is by no means one which should be neglected, and will be often found wholly efficacious. The cases in which it will have its most rational use are those in which the bladder is opened for other cause, such as the removal of a sacculated stone, and this condition of the prostate found. The removal of the third lobe under such circumstances adds little or nothing to the danger of the operation, and offers a very fair chance of restoring the power of urination.

PROSTATECTOMY. — SPINAL ANESTHESIA.[1]

BY F. B. LUND, M.D., BOSTON.

JOHN E. JONES, sixty-two years old; married; carpenter by occupation, was seen at the Out-Patient Department of the Boston City Hospital, by Dr. F. C. Cotton, the latter part of December, 1903. His previous history was unimportant, until five years ago, when he began to have difficulty in passing his water, and scalding, and frequency of micturition. He had sounds passed five or six times, with no relief of symptoms, and after that gave up treatment. During the intervening years his scalding had grown worse and his stream had diminished in size, so that it now dribbled rather than ran. The frequency had increased greatly, so that he had to get up fifteen or twenty times a night, passing only a teaspoonful at a time. He had had one or two attacks of retention and had been catheterized, when he presented himself at the Out-Patient.

Dr. Cotton found the bladder much distended, containing about two quarts of septic urine. He was catheterized, and his bladder was washed, but the cystitis did not improve.

On Jan. 2, 1904, he was admitted to the service of Dr. H. L. Burrell, who kindly placed him in my care. Examination showed that he had arterio-sclerosis of the radials, and a systolic heart murmur, heard best in the sixth space below the apex. He had a tracheitis and his voice was quite hoarse. He had a slight cyanosis of the lips, and conjunctivæ. He was seen in consultation by Dr. John L. Ames, who thought the heart murmur was due to an old organic lesion, and on examining the lungs found nothing abnormal. He suggested that, on account of the possibility of a latent process in the lungs, it might be wiser to wait a while before subjecting him to anesthesia. It was brought out that on account of his heart murmur he had once been refused by a life insurance company, but was subsequently accepted by another company.

[1] Patient shown at the meeting of the Surgical Section of the Suffolk District Medical Society March 2, 1904.

Examination of the urine showed specific gravity, 1020 acid, a trace of albumen, considerable pus, and squamous epithelium. Rectal examination showed a moderate uniform enlargement of both right and left lobes of the prostate.

He was put on daily bladder irrigations, and the condition of the urine improved somewhat. The catheter, however, was introduced with difficulty, and the bladder did not drain satisfactorily. Therefore, on the 8th of January a suprapubic cystotomy under local anesthesia was done. The incision was made down on the bladder without much difficulty, but on catching up the bladder walls, and attempting to examine the bladder with the finger, so much pain was caused that there was involuntary muscular contraction. An examination of the interior of the bladder could not be made. As, however, further operative procedures were contemplated, no prolonged attempt was made to make such an examination.

A drainage tube was placed in the suprapubic wound, and under treatment by bladder irrigations his general condition improved considerably, but the tracheal irritation continued. He did not seem a good subject for general anesthesia. Therefore, on Jan. 20, a partial prostatectomy was done under spinal anesthesia, as follows:

At 11.15 A.M., a hollow needle, five inches long, of No. 19 steel tubing, was introduced between the third and fourth lumbar vertebræ into the spinal canal, the patient lying on his side on the table, with the spine flexed. Clear cerebral spinal fluid began to flow at once, and a sterilized glass syringe, containing three-tenths of a grain of powdered cocaine, was attached to the needle. On withdrawing the piston, about two drams of spinal fluid entered the syringe, dissolving the cocaine, and was at once injected into the spinal canal. After covering the puncture with collodion dressing, the patient was placed in a lithotomy position, and the perineum was prepared as usual in preparation for a perineal section, perineal prostatectomy, according to Young's method, being the operation which was proposed. At the end of five minutes after the injection it was noticed that the pouring of ether on the perineum and rectum caused no pain, although the patient felt the shaving and knew what was being done to him, the process was not painful.

At the end of seven minutes a perineal section was made, and the dissection carried on according to Young's method, until the uretha had been opened and Young's tractor introduced. It was then found that the tractor did not bring the prostate well down into the field, which may possibly have been due to certain anatomical peculiarities of the case, or because the muscles were not relaxed by anesthesia. Determining to aid the use of the tractor by pressure from above, a sound was introduced, and on the point of this sound the suprapubic wound, which had almost closed, was reopened. Then, with the finger in the bladder, examination showed that there was a very large pedunculated middle lobe, which fell forward, so as to occlude the vesical opening of the urethra, and it became evident that this lobe was the chief if not the entire cause of the obstruction. As this could be very well reached from above, it was determined to remove this lobe through the suprapubic opening, which was done by incising the mucous membrane over it, and enucleating it with the forefinger passed through the suprapubic incision, the operator being aided by a pressure of two fingers of the other hand, which was gloved, introduced into the rectum, and lifting up the prostate. The enucleation was a difficult one, as the lobe seemed very firmly attached. After considerable effort it was accomplished, however.

During this procedure the patient suffered some pain, but it was not nearly as marked as what he had gone through during the suprapubic cystotomy under cocaine. The whole operation lasted forty minutes. The patient did not struggle, or make more than slight complaint. He aided the operator by changing his position when requested and during the whole proceeding a constant conversation was kept up between the operator and the patient.

As soon as the lobe was removed the patient asked to see the specimen. He was in excellent condition. Had hardly any rise of pulse, and absolutely no shock. After washing out the bladder, a tube was tied in through the perineal wound, and a strip of gauze passed in the suprapubic wound to the base of the bladder. It was not thought advisable to remove the lateral lobes, as the passage of the finger into the urethra through the suprapubic opening showed that the prostatic urethra was apparently not compressed by the lateral lobes. The patient's pulse was somewhat rapid the night after the operation, and he was somewhat flushed, but his general condition was excellent, and at no time did he show symptoms of shock. The gauze was removed from the bladder the afternoon of the operation, and the bladder washed out three, four or five times daily.

On the second day after the operation the patient sat up in a chair for an hour, and after that he was up out of bed for more or less of the time every day. The tube was removed from the perineum on the fourth day. The urine came through the suprapubic opening until the 7th of February, when he began to pass a little through the penis. He has to pass his water only two or three times during the night, and passes twelve ounces to a pint at a time. He says he is feeling better than he has for twenty years, and is able to pass a good forcible stream. On Feb. 29, he returned to the Out-Patient, and is very comfortable and satisfied so far as the results of the operation are concerned. He now has about an ounce of residual urine.

The method of spinal anesthesia adopted in this case is that recommended by Morton, of San Francisco, and has the advantage of not increasing the amount of fluid in the spinal canal. The cerebral spinal fluid is sucked into the syringe, dissolves the powdered cocaine, and is immediately replaced in the canal. Morton, in a paper read before the American Medical Association, states that he has used the method 673 times without a failure of analgesia, and 60 of these operations were above the diaphragm. He states that, during the past year it has been tried by most of the surgeons in the country for operations below the diaphragm, and by many of them given up on account of objections of various kinds. It has been used in a few thousand cases, but not enough to establish its safety as compared with general anesthesia. Its analgesic properties cannot be doubted for operations on the lower extremities.

Of the 673 cases which Dr. Morton stated he has treated, there was only one fatality which could in any way be attributed to the use of the anesthesia, and that, he thinks, can hardly be attributed to it, from the condition of the patient and the post mortem findings.

The case was that of a strangulated umbilical hernia. The woman weighed three hundred pounds, had a very weak heart, was semi-comatose at the time of the operation, having been unable to take a reclining position for several days. The patient died during the operation, after the removal of fourteen pounds of pendulous omentum, and at the time the intestine was reduced. It would seem that this death would have occurred in any other method of anesthesia.

Among the operations for which Morton has used this method of anesthesia are amputations of the breast, empyema, enucleation of the eye, mastoid operations, abscess of the antrum, etc.

It seems to me that with such a record as this the method will prove of value in cases where a general anesthetic is contra-indicated on account of diseases of the lungs or kidneys. It ought to be of value in operations on the larynx or about the mouth, where there is danger of blood entering the air passages. Morton states that the great advantage to be gained in operations about the buccal cavity can hardly be appreciated until tried.

For some years the writer has been in the habit of operating upon strangulated herniæ, in which constant vomiting is present, under local anesthesia by infiltration with cocaine solutions. This method, while far preferable to a general anesthetic, has been rather tedious to the operator, and in certain cases, painful to the patient.

The experience with this case of prostatectomy was so successful as to lead to the belief that these injections will prove a much more satisfactory method than local infiltration anesthesia for this class of operations, and it is the writer's intention to give it a trial in the future. It was certainly surprising in this case to be able to carry out the more or less forcible manipulations attendant upon enucleation of the prostate through a suprapubic incision upon a conscious patient, who is able, to a certain extent, to aid the operator, to change his position when required, and whose first inquiry when the prostate was removed was to be allowed to see what had been taken from him. The entire absence of vomiting and the consciousness of the patient made the immediate after-care of the patient extremely easy. There was even no nausea. The patient's condition for the first two days was better than the writer has noted in a case of prostatectomy.

In regard to the bearing of this case upon the question of prostatectomy aside from the anesthesia, it certainly shows a favorable result, temporarily at least, by the removal of the obstructing middle lobe, and that for relief of the symptoms it is not always necessary to remove the lateral lobes. The writer further believes that it is better in the majority of cases to remove the entire prostate. Whatever method is employed, pains should be taken to damage the urethra and vesical mucous membrane as little as possible. If this point is attended to, free drainage provided, and frequent and copious irrigation practiced in the after-treatment, the writer believes that prostatectomy will give satisfactory results and a low mortality.

SUFFOLK DISTRICT SOCIETY.

SECTION FOR SURGERY.

DISCUSSION.

A MEETING of this section was held on March 2, DR. F. B. HARRINGTON in the chair; on the subject of

THE TREATMENT OF PROSTATIC HYPERTROPHY.

DR. B. TENNEY: Two years and a half ago, a man of forty-six came to me with a story of inability to pass urine for six weeks, and some slowness of urination preceding this. He was able to pass a good-sized soft rubber catheter without difficulty, but was beginning to feel some irritation as a result of its use. Rectal examination showed a prostate very little above normal size and of uniform shape. With a cystoscope a small median projection could be seen which acted like a ball valve. Two or three years before this, I had been practicing ureteral catheterization on the male subjects in the dissecting room of the Harvard Medical School, and had been using an open tube of my own devising. Through this tube I found on one subject a projection almost exactly like the one which the patient presented.

It occurred to me that I could destroy this projection, using a long cautery point through an open tube, and I had one made up for me by Codman & Shurtleff which I have here. It is a tube 28 French and seven inches long, with a curve and conical end to facilitate introduction. The convex side of the curve has been cut away so as to leave an elliptical window which is apparently circular when seen from the expanded end, and an obturator has been fitted to close this opening.

The patient came to my office, had his urethra and bladder cocainized and took the knee-chest position on my examining table. The introduction of the tube was easy and the small tumor came into plain view with the help of a head mirror. With a rather heavy cautery point bent to a right angle with the shaft I made three furrows about one-fourth inch deep in the lobe. There was no bleeding, less complaint of pain than one often hears when dilating a stricture, and the patient rode some four miles to his home in a street car. Three hours after the cauterization, he passed his urine without the assistance of a catheter. Six months ago I examined him and found no symptoms of any trouble, no night urination, and less than a drachm of residual urine.

This procedure has, of course, a very limited application, but it worked so happily in this case that I thought the Section might be interested to see the instruments with which it was accomplished.

DR. PAUL THORNDIKE: I came here this evening hoping to hear two points in the treatment of prostatic hypertrophy discussed. First, the role of the catheter in such cases and, second, the range of usefulness of the Bottini operation.

(1) The rôle of the catheter. Dr. Cabot has summed up this question in a few words, and though his summary is not one which I should have made, it is certainly more nearly like my own than I should have been willing to admit a few months ago. He gives the catheter a place in the therapeutics of this affection only in those somewhat exceptional cases when, for some reason or another, no operation either radical or palliative is proper. I have always believed, and I am not yet quite prepared to change my views, that all prostatics should be made comfortable with a catheter if such palliation is, and so long as it is, possible and efficient; and that then, at the moment when the use of a catheter becomes an abuse, operation of some sort is indicated. I am quite aware that such a catheter life results in an infection of the bladder with all its possible consequences in many or most of the cases within a comparatively short time, but I also know that such infections do not by any means always persist, that they do clear up often, and that such catheter patients become acclimatized to the use of the instrument, and are progressively less liable to subsequent infections as the months and years go by. Therefore, while recognizing the dangers of a catheter life, and while realizing that our knowledge of both radical and palliative operations has enormously decreased their dangers and has increased their efficiency in the last two or three years, I am still inclined to give the catheter a larger place in prostatic therapeutics than Dr. Cabot has assigned to it to-night; and I say this with a full recognition that the accumulating experience with operations, both radical and palliative, may in the next few years change all this and may gradually push the routine use of the catheter out of the category of prostatic therapeutics.

(2) The range of usefulness of the Bottini operation. For a number of years I have believed and have frequently stated that prostatectomy, aiming at a radical removal of the obstructing masses, is always the operation of choice in prostatic cases. That is to say, I believe that when once an operation has been decided upon the procedure selected should be a prostatectomy in all possible cases; and that partial removals or palliative procedures like the Bottini operation should be held in reserve for such cases as are unfit for the more severe and more complete operation. I have, however, up to the present time, believed that in the large variety of cases presenting themselves for relief, the greater number were unfit subjects for a complete prostatectomy and that most of this unfit class were best treated with a Bottini operation. I do still believe that a very large range of prostatic cases are more fit for a Bottini operation with all its uncertainties than for the more severe procedure. The operative experience of the last two or three years has made such enormous changes for the better in both the technique and efficiency of prostatectomy and has rendered the complete removal of the gland so much safer than it was a short time ago that the field for the Bottini operation is steadily growing smaller; and now that spinal anesthesia has been shown possible and efficient for prostatic work, so that the dangers of the general anesthetic may be eliminated from our prostatectomy mortality statistics, it seems certain that the range of usefulness of this procedure will steadily increase and that the complete operation is gradually pushing the less radical procedures to the wall just as it is the routine use of the palliative catheter.

I was much impressed a short time ago, in talking with two surgeons of large experience with the Bottini operation, to have them both tell me that they were doing more and more prostatectomies and fewer and fewer Bottini operations, and that spinal anesthesia was largely instrumental in making this change in their choice of operation. So that while I believe that a Bottini operation with a proper preliminary cystoscopy is safe enough and accurate enough to continue to hold a large place in our scheme of prostatic operating, I also believe that the improvement in our knowledge of and technical skill with prostatectomy is diminishing its dangers and is increasing its efficiency so rapidly as to render this operation more than ever our first choice in all possible cases.

DR. G. S. WHITESIDE: I recently saw a man, whose

case was one of those mentioned in Dr. Hugh Cabot's table, as being in a worse condition now than before prostatectomy was done. He was operated on at the Massachusetts General Hospital, three or four years ago, the entire prostate being removed by the combined suprapubic and perineal methods. He has no residual urine because he has very little control over the sphincter muscle; the bladder now remains empty all the time. He wears a rubber urinal. He tells me that when he is in the recumbent position, he does not so often pass his urine involuntarily but that, nevertheless, this accident is liable to occur at least once in the course of the night. Otherwise his health is good. Cystoscopy shows the reason for the incontinence. The entire prostatic and membranous portions of the urethra have been converted into a cicatricial tube, preventing the compressor urethræ from acting as it should do. I have also seen several other cases which have been operated on by various surgeons, in none of which has the operation been a complete success. Some have cystitis, in spite of the fact that no residual urine can be demonstrated. I presume the successful cases operated by other surgeons would go back to those who successfully operated upon them rather than come to me.

We are undoubtedly educating the public and ourselves to earlier and more radical operations for enlargement of the prostate, as Dr. Harrington has just said. There is, however, a class of cases which I have frequently seen, but about which I should like some advice from those more experienced than I. Given a man, about forty-five to fifty-five years old, in good general health, with sound heart, sound kidneys and apparently normal arteries, whose urine contains neither albumen nor casts, is acid and free from pus. This man can entirely empty his bladder at all times. He complains of slight nocturnal frequency, occasional burning sensations deep in the perineal region, and a feeling of uneasiness after micturition. On examination, such a man will show an enlarged, soft, boggy prostate as felt by rectum. It encroaches somewhat upon the lumen of the bladder and the mucous membrane over it is somewhat thickened and contains many abnormal blood vessels. All of these facts are plainly seen on cystoscopic examination. There is, however, no obstruction to the outflow of urine. Several such cases have come to my notice during the past five years and in three, at least, I have had the opportunity to examine them with the cystoscope once a year, and to note a gradual but surely progressive increase in the size of that portion of the prostate which projects into the bladder. What are we to do for these cases? Are we to employ palliative measures which give relief but no promise of cure, or are we to do an early prostatectomy in view of the fact that they will probably need to have it done later when their general condition may not be as good? They do not want to be operated upon; they do not feel sick; their difficulties are annoying but slight. Shall we wait for the signs and symptoms of obstruction before advising surgical interference?

DR. J. G. MUMFORD: The following case of a death following prostatectomy is instructive and worth reporting:

Mr. A. F. C., age sixty-three, consulted me in September, 1902, regarding frequency of micturition. He was a large, heavy, phlegmatic man of previous good health and moderately addicted to alcohol. He gave no venereal history. He had no distressing symptoms, but was annoyed by having to pass urine every two hours at night, and every three hours in the daytime. He had a residual of seven ounces. At that time urine was normal in color, acid, specific gravity 1017 with the slightest possible trace of albumen, and no sugar. The sediment, amorphous phosphates, an occasional bladder and epithelial cell, an occasional leucocyte, an occasional small round cell; rare abnormal blood corpuscles and rare calcic oxalate crystals. The prostate presented large, firm, lateral lobes, each apparently the size of a pigeon's egg. The situation was explained to the patient and the advisability of prostatectomy was urged. He preferred, however, to lead a catheter life, which he did for a year.

Until July, 1903, he was very comfortable, passing his catheter twice daily and having his bladder irrigated occasionally. Under this treatment the urine cleared up, and on July 21 showed nothing whatever abnormal. A week after this date, however, the patient developed complete retention, but was able to keep comfortable by catheterizing himself every six hours.

In August he consulted me again and stated that he had decided to have an operation done, electing a well-known Boston surgeon and friend of my own, in whom I have great confidence, to do the work for him. I was myself present at all consultations and at the operation, and approved of all the subsequent proceedings which were carried out in a most workmanlike manner. The surgeon decided, as is his custom, to divide the operation into two sittings, securing drainage by a simple suprapubic cystotomy at first; ten days later removing the prostatic lobes by the combined method.

On Aug. 17, the supra-pubic drainage was established. At this time exploration with the finger in the bladder discovered two large lateral lobes, the left being the more prominent internally. Its consistency suggested malignancy, but it was well encapsulated and there was no sign of metastasis. The patient rallied well from the operation and ten days later was in excellent condition, with a normal urine passed by urethra and a fairly sound heart action.

On the 27th of August he was again etherized and a secondary operation undertaken. On removing the drainage and making bimanual examination, it was found that the two enlarged lobes had very greatly diminished in size during the preceding ten days, so that they felt but slightly larger than normal. My notes state that the right lobe was not abnormal, the left lobe appeared to be a punky mass of connective tissue about the size of a walnut. This collapsed on being opened through the perineum; drainage was established and the patient did well for two or three days, when his kidneys began to show involvement and gradually became severely affected. Nine days after the operation he died with suppression.

It might be asked why the secondary operation was done when the first operation had so greatly relieved symptoms as to enable the patient to pass urine freely by urethra. It was the opinion of my consultant and myself that the second operation should not have been done; but as the patient greatly feared cancer of the prostate, and as we could not deny its possibility, he insisted upon the removal of the small remaining nodule, and we felt ourselves forced to yield to importunities which were really commands, although contrary to our better judgment.

The striking lesson in this case is that in certain forms of enlarged prostate due to a chronic inflammatory process, simple drainage may suffice completely to relieve symptoms.

The presumption is that our patient was one of a numerous class in which a long antecedent gonorrhea was the cause of the difficulty.

Recent Literature.

Gynecological Nursing. By NETTA STEWART, Sister in the Extra-Mural Gynecological Wards of the Royal Infirmary, Edinburgh. With a preface by SIR HALLIDAY CROOM, M.D., etc. pp. 174. New York: William Wood & Co. 1903.

This little book represents in an authoritative way gynecological nursing as practiced in the Royal Infirmary, Edinburgh. In the preface the author acknowledges her indebtedness to such well-known gynecologists as Dr. Barbour, for help and instruction, and Dr. Berry Hart, for reading the proofs.

The book is clearly and concisely written, the arrangement of the subjects is logical and there are several especially good chapters, notably those on the use of the catheter, on the use of the cantharides blister and on gonorrhea. From the standpoint of the English gynecologist there is little to criticize in this work; to the American such terms as bidet, jaconet, Higginson's syringe and swabs sound unusual, but they are for the most part explained by the illustrations.

As representing a system of gynecology there is much to criticize from an American view point. The author congratulates herself that the era of passing the catheter by touch rather than by sight has passed away; she does not seem to realize that the era of false modesty and unnecessarily painful manipulations still exists in Edinburgh. On page 2 it is stated that, "no young girl or unmarried woman is examined by inspection of the external genitals or by the vaginal method, unless under an anesthetic," and on page 66, speaking of a cystoscopic examination, "this examination being of such a nature that exposure is unavoidable, the patient is anesthetized."

The nurse is instructed to tampon the vagina and to remove uterine and vaginal gauze packing without the use of instruments, a procedure unnecessarily painful for the patient and difficult of performance even in the hands of the skilled gynecologist. In discussing the preparation of a patient for a bimanual vaginal examination no mention is made of the necessity for loosening every band about the waist, without which no proper diagnosis can be made. The rubber glove does not appear in the book, and, although the aseptic technique is, in the main, excellent, it is difficult to see why in preparing for plastic operations the advice is given to boil the instruments half an hour, while in preparing for an abdominal operation they are to be boiled an hour. In the after-care of a case of perineorrhaphy the nurse is told to give a warm antiseptic vaginal douche twice daily, and after each douche she should carefully dry the vaginal walls with "the index finger of the right hand, round which a thin layer of sublimated wool has been wound," a proceeding not only excessively painful for the patient but meddlesome to a degree, as tending to separate and infect the lips of the wound.

Another source of discomfort, the old plan of keeping the bowels constipated for a week after this operation, apparently still obtains in Edinburgh.

The portion of the book on nursing in abdominal surgery is more modern in tone and is, on the whole, good, although here also the Spartan methods of preparatory and after-care, common in this country fifteen years ago, still hold sway in modified form. The book presents a handsome appearance, being printed in large type on heavy, glazed paper and bound in green cloth.

The Treatment of Fractures, with Notes upon a Few Common Dislocations. By CHARLES LOCKE SCUDDER, M.D., Surgeon to the Massachusetts General Hospital. Fourth edition. Thoroughly revised. Philadelphia, New York and London: W. B. Saunders & Co. 1903.

This is the fourth edition of this work since 1900, a period less than four years. Again one is called to comment on the energy and activity of its author in this special line of surgery and the popularity of his book. As formerly, it is still intended to serve as a guide to the practitioner and student in the treatment of fractures of bones. As before, its striking features consist in the graphic, precise manner in which the actual condition of fractured bones are presented by anatomical description, clinical symptoms, reproductions of photographs and skiagraphs; also in the details of treatment and especially of apparatus. The chapters on the application of the Röntgen ray to fractures, the employment of plaster of Paris, and the ambulatory treatment of fractures still attract attention. In this edition (still an octavo) the number of pages has been increased from 488 to 534, and the illustrations from 645 to 685. Many "half-tones" are introduced, increasing the effectiveness of illustration. Additions have been made to the text in various places. Radiographs of the epiphyses at different ages will greatly facilitate the study of these lesions.

A chapter on the common dislocations is a new feature of the work. Also many of the former tracings of x-ray prints of fractures are replaced by half-tones of the actual negatives.

The book may well be said to represent the best modern treatment of fractures.

Plain Hints for Busy Mothers. By MARIANNA WHEELER, Superintendent of the Babies' Hospital, New York, since 1891, and author of "The Baby." 54 pp. New York: E. B. Treat & Co.

The publishers in their announcement state that this little handbook is intended as an aid to mothers whose means are limited and who must care for their own babies, at the same time attending to their housework. Looked at even from this point of view, this book is not at all satisfactory. Viewed from a medical standpoint, it is not worthy a serious consideration. The directions as to feeding are in many respects bad. The English is execrable.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 28, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

INTERCHANGE OF MEDICAL TEACHERS.

WE have from time to time commented on the increasingly intimate relations which are coming to exist between men of science in this and in foreign countries. The custom of inviting distinguished foreigners to deliver lectures in this country has steadily increased during the past few years. Professor Ehrlich, for example, has recently concluded such a course of lectures at the Johns Hopkins Hospital, and Professor Sherrington is about to begin an elaborate course under the auspices of the Silliman foundation at Yale University. Last year, it will be remembered, Professor Welch went to England for a like purpose, as well as Professors James, Royce and Wendell in recent years, and many other instances might be mentioned of the interchange of ideas brought about by such visits of men from other countries.

The relative ease of communication between this country and Europe, together with the increasingly greater uniformity of work being done in the two countries, has naturally brought about a closer relationship than has hitherto existed. It is unquestionably of great value to learn the differences in method, as well as the actual results of research, of those working in other countries but in allied fields. Not only is this stimulating to the investigators themselves, who find a willing audience for their results, but it is also of much significance in stimulating increased interest among men engaged in similar work.

The healthy rivalry, which the intimate personal acquaintance with each other's work produces, is certainly salutary. It would be well if in our large institutions of learning it were possible to so extend this plan that the student body, as well as those further advanced in their studies, might also have the benefit of foreign ideas. The suggestion has, in fact, been made by President Eliot of Harvard University that an actual interchange of professors might be arranged in various branches of research to the end that for a considerable period of time, extending over months or perhaps a year, students might be brought under the influence and direct teaching of foreigners. We are under the impression that at the present time in the academic department of Harvard University two such interchanges have been made, which permit the residence of foreign instructors at the university for an academic year, providing in exchange two men for the institutions from which they came.

It occurs to us, as at least a possible plan, that the same method might be adopted in medical institutions. Obviously, the difficulties would be great in providing for the long continued residence of a practicing physician in a foreign country, but in many of the theoretical branches of medicine it would certainly be possible for teachers in foreign universities to spend a year in this country, during which they would be expected to give to the widest possible audience the results of their methods of investigations. There can be no question, judging from the experience we have already had, that the occasional infusion of new ideas from foreign sources into the routine of the medical curriculum would be highly stimulating to students as well as to teachers, and that an enthusiasm might thereby be aroused for special branches of medical work which is now too often dormant. Whether or not so radical a departure might be made, we are convinced that the closer the interrelationship between universities in Europe and America the more comprehensive will be the products of their work.

We are not aware that Germany has ever extended a particularly friendly hand to American investigators in medical lines, but there can be no question that the time is not far distant when this barrier will be removed and the same hospitality extended to the work of our competent investigators as we have long extended to theirs. Recent events lead us to think that this time is near at hand.

INTERMEDIATE REPAIR OF THE INJURIES OF CHILDBIRTH.

A PROMINENT obstetrician and gynecologist, the author of one of our most popular text-books, recently wrote: "If every woman were given

the attention she ought to receive after childbirth, three fourths of the diseases of women would disappear."

The present practice of the profession is to repair injuries of the perineum immediately after labor, if the patient's condition permits; the patient being across the bed, often in a poor light and the assistance at hand meagre, injuries of the anterior vaginal wall and cervix are left to nature with the possibility of the subsequent development of cancer and other uterine diseases, or to a secondary operation months or years afterwards.

Dr. B. C. Hirst of Philadelphia and Dr. L. R. Dickinson of Brooklyn, two distinguished obstetricians, have adopted a different plan in their clinics with most successful results. They point out that immediately after delivery the birth canal having been subjected to great trauma, especially in difficult cases where the injuries are most extensive, the tissues are swollen and distorted so that it is impossible to recognize landmarks. An expert obstetrician and pathologist who made frozen sections of a woman dying five minutes after delivery was unable to make out the position of the os externum in the sections. It is likewise difficult to obtain a correct understanding of the condition of the anterior vaginal wall, injury to the muscles and fascia of which result later in cystocele.

Immediately after delivery the patient has been through a more or less severe strain and it is out of the question to subject her to a prolonged examination on a table in a proper light, and for the same reason, a properly performed operation with an anesthetic is inadvisable. Besides there is apt to be much bleeding and the tissues are so bruised that they do not well hold sutures.

On the other hand, months or years after labor chronic hyperplasia has thickened the lips of a torn cervix, partial cicatrization has taken place and cysts have formed in the unhealthy tissues; the vaginal walls have sagged, permitting displacement of bladder or rectum and there is present atrophy of the muscles from disuse. Small wonder that operations undertaken at this time are so frequently unsuccessful in restoring the parts to a normal condition.

From five to ten days after delivery hemorrhage has ceased, the vulva is still relaxed permitting easy access to the vagina and cervix and the patient has recovered from the shock attending labor. Now she can be placed on a table in a good light, she can be thoroughly examined and, if necessary, anesthetized and operated upon with suitable assistants and preparations just as in the usual secondary operations. The tissues are soft, the needle passes easily, and accurate opposition can be secured. Ten days after labor granulations appear and these must be removed with the curette. Previous to this time the torn surfaces need only to be freshened by wiping them with a piece of gauze held in a forceps in order to obtain primary union.

The practice of repairing all the injuries of childbirth during the puerperal convalescence it may be argued is impracticable because it is too much trouble, the remuneration would not be sufficient and it would not be tolerated by many patients. The same arguments could be urged against almost any advance in medicine, and, if valid, would stop all progress. The plan has been carried out with the most satisfactory results in Dr. Hirst's private practice and in the University Maternity in Philadelphia during the past year and in Dr. Dickinson's practice in Brooklyn for several years.

To the mind of the unprejudiced observer there is something illogical in neglecting two thirds of the injuries of childbirth and in repairing in a slipshod manner only the injuries of the perineum. It is within the realm of possibility that in the not distant future the parturient woman will demand that her accoucheur shall be equipped to diagnosticate and repair all the injuries which she may receive during labor and that these shall be attended to during the puerperal convalescence.

CESARIAN SECTION AT THE BOSTON LYING-IN HOSPITAL.

THE report of the Boston Lying-In Hospital for its seventy-first year contains an interesting statement in regard to Cesarian section at that institution. According to this report, the most notable event during the hospital year which has closed has been the successful performance, for the fiftieth time in the history of the hospital, of the Cesarian section. The first performance of this operation at the Boston Lying-In Hospital was on July 15, 1894, a little less than ten years ago. The operation had been performed but rarely in this country, and the successful result obtained in this case was regarded as an important achievement in obstetrical practice.

During the ten years the Cesarian section has been performed 55 times in the hospital, and notwithstanding the fact that in several of the

cases the operation was resorted to under adverse circumstances, the result has been fatal to the mother in only 5 cases, the remaining 50 patients having been discharged well from the hospital. By a coincidence, 50 children were born and discharged well, and there were 5 fatal cases of children, including one still-born. In but 2 of the whole 55 cases was the result fatal to both mother and child. In 5 cases the operation was performed upon the patient for the second time at the hospital and in one case for the third time.

The operation has been performed 10 times during the past year, and in all these cases the children were successfully delivered, and there was but one fatal result among the mothers.

The progress — if it be not more properly termed the revolution — which this hospital has thus prominently assisted in bringing about in the practice of obstetrics and in the saving of life in the time of maternity, instances the value of its work. The entire community has shared in the benefits of the experience and skill which have been acquired in the hospital.

Incidentally it may be remarked that the general work of the hospital during the past year has been larger than that of any preceding year. The total number of patients treated and attended was 2,519, being 90 in excess of the record of last year, the largest previous number.

The 654 patients treated in the hospital were afforded 10,618 days' treatment, and to the 1,865 patients attended in their homes 27,975 visits were made.

Financially, receipts and expenses have about balanced each other, but needed repairs and improvements are restricted and increased donations are earnestly desired.

A PROPOSED NEW BELLEVUE HOSPITAL.

The city recently made an appropriation of $75,000 for securing plans for a new Bellevue, as well as new Harlem and Fordham hospitals and the enlargement and improvement of Gouverneur Hospital, and on the occasion of a lecture delivered by Dr. Brannan in Havemeyer Hall, Columbia University, on April 22, the architects, Messrs. McKim, Mead and White, presented the drawings and plans proposed for these institutions. If these plans are approved, the city of New York will for the next ten years be building in instalments at Bellevue the greatest hospital in the world. The cost of the new Bellevue Hospital is placed at $11,000,000, not including an electric light plant estimated at $1,000,000, nor the expense of condemning the East River block between 28th and 29th Streets, just north of the present hospital site. That block, which will make the grounds cover three whole blocks in all, is now in process of condemnation. Neither does the $1,000,000 include the filling in of a large strip to be taken from the East River. The United States War Department, by special action, has consented to the extension of the bulkhead line so that it will include enough space to make a rectangle out of the three blocks. At present the Board of Estimate and Apportionment has been asked for $702,000 to erect the first pavilion, and it is expected that this sum will be appropriated before long. There are to be twelve pavilions in all, and in the center of the buildings will be a great dome, in which ample accommodations for the large house staff will be provided. Fresh air, plenty of it all the time, Dr. Brannan regards as the main thing in a modern hospital, and in no other institution, he says, has this idea been carried out as it will be in Bellevue. Special attention will be paid to the lighting and ventilation of the wards, and, in addition to a multitude of balconies, there will be enormous roof gardens, to which many elevators will run. At certain points on the roof will be glass-inclosed sections, and for bad weather these covered areas will be capable of extension.

MEDICAL NOTES.

A Departure in Advertising.—A tea planters' company of Paris is offering an insurance policy for one month against death by accident to prospective purchasers, of a quarter, a half and one pound of tea.

The American Confederation of Reciprocating Examining and Licensing Medical Boards. — A meeting of this association will be held at the Great Northern Hotel, Chicago, Tuesday, May 24. Hitherto eleven states have entered into the confederation, and it is hoped that a still wider interest will be taken in the meetings of the society.

Centenarians. — The following persons are reported to have lived beyond one hundred years: Mrs. Donald Macdonell of Glengarry, Ontario, has died at the reputed age of one hundred and six. Denneth McGillivray, also of Ontario, died at the age of one hundred and one years. Tom Fitzgerald, reputed the oldest man in Munster, Ireland, reached the age of one hundred and six.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, April 27, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 59, scarlatina 11, typhoid fever 6, measles 167, smallpox 0.

MODELS OF THE GROUP OF NEW BUILDINGS OF THE HARVARD MEDICAL SCHOOL. — A very excellent model of large size in plaster by John Evans of the group of new buildings of the Harvard Medical School has been forwarded to St. Louis for the Louisiana Purchase Exposition.

APPOINTMENT OF DR. JAMES B. SHEA. — The mayor has appointed Dr. James B. Shea as a member of the Boston Board of Health, in place of Edwin L. Pillsbury, whose term is expiring. Dr. Shea has been connected with the department since 1888, but this appointment comes as a promotion.

ADDITION TO THE LYNN HOSPITAL. — A new ward for the Lynn Hospital was opened last week. This new ward building consists of a main ward and fourteen private rooms, giving space for thirty-three beds. On the second floor is a small ward for children. A surgical dressing room is also provided.

CAMBRIDGE VISITING NURSES ASSOCIATION. — A visiting nurses association has been established at Cambridge, Mass., under the charge of Miss Read of the Waltham Training School. $5000 is required for the first year's work. At a recent public meeting of the association Dr. Henry P. Walcott spoke of its prospective work.

THE MASSACHUSETTS HUMANE SOCIETY A DISTRIBUTOR OF USEFUL INFORMATION.— The Massachusetts Humane Society has issued and has for distribution a booklet giving instructions how to save drowning persons, how to restore persons apparently dead from drowning, and what to do in other cases of emergency. There is always a growing demand for this sort of literature at this season of the year.

WORCESTER CITY HOSPITAL. — According to the recently published annual report of the trustees of the Worcester City Hospital, it appears that the number of patients admitted to the hospital was 2,955, which was 528 more than last year, a gain of 21%, as compared with 13% last year. The number of accident cases treated, but not admitted to beds, was 482, against 516 last year. The proportion of minor accident cases treated is annually becoming smaller, owing, probably, largely to the establishment of emergency hospitals by corporations and individuals.

NEW YORK.

HOSPITAL SATURDAY AND SUNDAY ASSOCIATION. — The distributing committee of the Hospital Saturday and Sunday Association met at the mayor's office on April 23 to distribute the undesignated fund of the collection for 1903 and '04. Owing partly to a stormy Hospital Sunday and partly, no doubt, to the times being less prosperous than last year, the general collection declined from $83,000 to $75,000, and the undesignated fund, from $68,000 to $64,000.

OFFICERS OF NEW YORK COUNTY BRANCH STATE MEDICAL ASSOCIATION. — At a meeting of the New York County branch of the State Medical Association held April 18 the following officers were elected: president, Dr. Francis J. Quinlan; first vice-president, Dr. H. A. Dodin; second vice-president, Dr. S. Busby Allen; recording secretary, Dr. W. R. Stone; corresponding secretary, Dr. J. J. Nutt; treasurer, Dr. Charles E. Denison. Dr. Alexander Lambert, the retiring president, was elected to the executive committee.

DEATH OF MRS. ELIZABETH MORTON. — Mrs. Elizabeth Morton, the widow of Dr. W. T. G. Morton of Boston, died on April 21 at the Hotel Martha Washington, New York, from pneumonia, following a long previous illness. She was born in Farmington, Conn., in 1826, and was married to Dr. Morton in 1844. No recognition of any sort from the American Government ever came to the widow, although the reports of six congressional committees during her husband's lifetime had recommended an appropriation of several hundred thousand dollars in acknowledgment of the benefit derived from ether anesthesia during the civil war. Two of the five children surviving Mrs. Morton are Dr. William James Morton of New York and Dr. Bowditch Morton, now practicing in Monterey, Cal.

QUARTERLY REPORT OF HEALTH DEPARTMENT. — The condensed quarterly report of the Bureau of Records of the Health Department for the last three months of 1903, just issued, shows that during the quarter the mortality in the city represented an annual death-rate of 17.45 as against 16.62 for the corresponding period. The corrected death-rate (excluding non-residents and infants under one week old) was 15.67, as against 15.74 in 1902. The estimated population was 3,732,703, and as the average number of deaths for the corresponding quarter of the

preceding five years, upon an estimated population of 3,448,567, gave a death-rate of 17.82 per 1,000, there was a decrease of one third of a point. The noteworthy increases found in comparing the deaths in this quarter with the preceding quinquennial average of the corresponding quarters were among the diseases affecting adults and old people, as follows: Apoplexy, 77; organic heart disease, 105; pneumonia, 426; Bright's disease and nephritis, 102; pulmonary tuberculosis, 96. There were 782 more deaths between the ages of five and sixty-five, and 270 more at sixty-five and over. Diphtheria and croup showed an increase of 50, and measles 12 above the quinquennial average. The decreases noted were in whooping-cough, 39; acute bronchitis, 99; malarial fever, 28; typhoid fever, 50; influenza, 40; and under five years of age, 127.

Illness among Physicians at Bellevue. — A number of the house staff of Bellevue Hospital have recently been suffering from illness as a result of the overwork and strain attendant on the crowded condition of the hospital, in addition to the totally inadequate accommodations for the physicians. Two of them are stated to have contracted tuberculosis, and Dr. Brannan, president of the board of trustees, is in receipt of a letter from Dr. Haven Emerson offering to furnish a list of at least 20 Bellevue internes who have developed that disease in the past. For the 43 physicians now living in the hospital there are only 16 rooms, and in some cases there are 4 and 5 in a room together. As to the crowding of the wards, the average number of patients applying in a day is 250, and of these the average number admitted is 125. In order to accommodate these at all, an average number of 125 must be discharged each day. The strain upon the physicians is unremitting. There is perhaps no hospital anywhere in which such a variety of acute cases, requiring constant attention, is treated, and every discharge must be signed by the attending and the house physician or the attending and house surgeon. On the grounds of the hospital there was erected during the past week a portable pavilion for the open air treatment of tuberculosis. It is 16 feet, 6 inches by 33 feet in its dimensions, and is designed to accommodate 12 patients. The roof is made of canvas, having adjustable ventilating traps, and over it there is a canvas fly, leaving a space of about 18 inches, by which arrangement a free circulation of air is readily secured. The building can be taken down and re-erected on another site in a short space of time.

RECORD OF MORTALITY

For the Week ending Saturday, April 16, 1904.

Cities.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 4,043; under five years of age, 1,062; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 963; acute lung diseases 860, consumption 378, scarlet fever 51, whooping cough 15, cerebrospinal meningitis 53, smallpox 6, erysipelas 21, puerperal fever 13, measles 49, typhoid fever 69, diarrheal diseases 108, diphtheria and croup 89.

From whooping-cough, New York 8, Chicago, Philadelphia, Baltimore, Boston, Springfield, North Adams and Gardner 1 each. From smallpox, Philadelphia 5, Pittsburg 1. From cerebrospinal meningitis, New York 45, Baltimore 2, Providence 2, Boston 1, Worcester 1, Southbridge 2. From erysipelas, New York 5, Chicago 2, Philadelphia 4, Pittsburg 3, Boston 5, Lawrence 1, Chicopee 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending April 2, the death-rate was 18.7. Deaths reported 5,464; acute diseases of the respiratory organs (London) 212, whooping cough 234, diphtheria 71, measles 211, smallpox 8, scarlet fever 32.

The death-rate ranged from 8.4 in Walthamston to 28.6 in Rochdale; London 18.8, West Ham 16.3, Brighton 19.8, Southampton 15.3, Plymouth 20.1, Bristol 18.4, Birmingham 24.5, Leicester 13.5, Nottingham 18.4, Liverpool 22.6, Bolton 19.6, Manchester 24.5, Bradford 18.5, Leeds 20.7, Hull 14.0, Cardiff 16.3, Rhondda 16.2, Merthyr Tydfil 22.9, Hornsey 9.0, Wildensen 11.0, Stockton-on-Tees 21.0.

METEOROLOGICAL RECORD.

For the week ending April 16, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

RECENT DEATHS.

ROBERT MCLELLAN READ, M.D., M.M. S.S., of Boston' died in Santa Barbara, Cal., April 21, 1904, aged fifty-five years.

LORENZO J. KOHNSTAMM, M.D., up to the time of the beginning of his illness a very successful New York practitioner, died at the Manhattan State Hospital, Ward's Island, on April 18. He was forty-two years of age, and a graduate of the medical department of the University of the City of New York in 1888.

SOCIETY NOTICES.

THE TRI-STATE MEDICAL SOCIETY OF IOWA, ILLINOIS AND MISSOURI.— This society will meet in St. Louis, June 15, 16 and 17.

W. B. LA FORCE, President.

ASSOCIATION OF AMERICAN PHYSICIANS.— The nineteenth annual meeting of the Association of American Physicians will be held in the New Willard Hotel, Washington, D.C., on May 10 and 11, 1904.

AMERICAN CLIMATOLOGICAL ASSOCIATION.— The twenty-first annual meeting of the Association will be held in the Banquet Room of the Aldine Hotel, Chestnut Street, above 19th, Philadelphia, June 2, 3 and 4, 1904.

GUY HINSDALE, M.D., Secretary.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING APRIL 21, 1904.

BROWN, B. W., passed assistant surgeon. Granted leave of absence for two days from April 25. April 19, 1904.

BLUE, RUPERT, passed assistant surgeon. Granted leave of absence for three days from April 19. April 18, 1904.

GREENE, J. B., passed assistant surgeon. Relieved from duty at Havana, Cuba, and directed to report to the medical officer in command at New York (Stapleton) for duty and assignment to quarters. April 20, 1904.

HOLT, J. M., assistant surgeon. To report to medical officer in command at San Francisco, Cal., for duty and assignment to quarters. April 20, 1904.

MCLAUGHLIN, A. J., assistant surgeon. Granted leave of absence for four days from April 20. April 20, 1904.

WARREN, B. S., assistant surgeon. Granted extension of leave of absence for one day from April 17. April 20, 1904.

ASHFORD, F. A., assistant surgeon. Leave of absence for ten days from March 28, 1904, granted Assistant Surgeon Ashford, amended so that said leave shall be for eleven days. April 19, 1904.

ALTREE, G. H., acting assistant surgeon. Granted leave of absence for five days from April 19. April 19, 1904.

BAILEY, C. W., acting assistant surgeon. Granted leave of absence for eleven days from April 22. April 20, 1904.

DUKE, B. F., acting assistant surgeon. Granted leave of absence for six days from April 18. April 18, 1904.

MARSH, W. H., acting assistant surgeon. Granted leave of absence for five days from April 26. April 20, 1904.

MONCURE, J. A., acting assistant surgeon. Department letter of March 31, 1904, granting Acting Assistant Surgeon Moncure leave of absence for thirty days from April 10, 1904, amended so as to read thirty days from April 12, 1904. April 20, 1904.

ILTIS, G. W., pharmacist. Granted leave of absence for twenty-five days from May 5. April 14, 1904.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING APRIL 23, 1904.

E. P. STONE, surgeon. Detached from the "Mayflower," and ordered to the naval academy.

J. C. PRYOR, passed assistant surgeon. Ordered to the naval hospital, Newport, R.I.

R. C. HOLCOMB, passed assistant surgeon. Detached from the naval hospital, Newport, R.I., and ordered to the "Mayflower."

C. E. STRITE, acting assistant surgeon. Appointed acting assistant surgeon from April 13, 1904.

C. H. T. LOWNDES, surgeon. Detached from the naval academy, and ordered to the "Chesapeake."

C. M. DE VALIN, passed assistant surgeon. Detached from the "Rainbow" and ordered to the "Albany."

J. P. TRAYNOR, assistant surgeon. Detached from the "Albany" and ordered to the "Rainbow."

W. F. ARNOLD, surgeon. Retired from active service April 19, 1904.

BOOKS AND PAMPHLETS RECEIVED.

A Manual of Clinical Diagnosis by Means of Microscopical and Chemical Methods, for Students, Hospital Physicians and Practitioners. By Charles E. Simon, M.D. Fifth edition, thoroughly revised and enlarged. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1904.

A Bill to Increase the Efficiency of the Medical Department, United States Army, Together with Endorsements by the Secretaries of War and the Brief of the Surgeon General, showing the Necessity for Legislation. February, 1904.

On Disease of the Heart due to Over-Indulgence in Alcoholic Drinks. By W. Hale White, M.D. Reprint.

Some Observations on the Movability of the Apex of the Heart. By W. J. Pettus, M.D. Reprint.

The Value of Ureteric Meatoscopy in Obscure Diseases of the Kidney. A Study in Clinical and Operative Surgery. By E. Henry Fenwick, F.R.C.S. Illustrated. London: J. & A. Churchill. 1903.

Twenty-eighth Annual Report of the Managers and Officers of the New Jersey State Hospital at Morris Plains for the year ending Oct. 31, 1903.

Elements of Water Bacteriology with Special Reference to Sanitary Water Analysis. By Samuel Cate Prescott and Charles Edward Amory Winslow. New York: John Wiley & Sons. London: Chapman & Hall, Limited. 1904.

Anesthesia in Dental Surgery. By Thomas D. Luke, M.B., F.R.C.S.E. Illustrated. New York: Rebman Company. 1903.

Manual of Clinical Microscopy and Chemistry. Prepared for the use of Students and Practitioners of Medicine. By Dr. Hermann Lenhartz. Authorized Translation from the Fourth and Last German Edition, with Notes and Additions by Henry T. Brooks, M.D. Illustrated. Philadelphia: F. A. Davis Company. 1904.

A Study of Normal and Pathological Conditions of the Bursæ of the Neck, with Special Reference to the Subhyoid Bursa. By Willis S. Anderson, M.D. Reprint.

Intratracheal Injections: Experimental and Clinical Study of their Value in Diseases of the Lungs. By Willis S. Anderson, M.D. Reprint.

Translations of the Obstetrical Society, of London. For the year 1903. Vol. XLV. Part IV, for October, November and December.

CONTRIBUTION TO THE ETIOLOGY OF IDIOCY AND IMBECILITY.

BY WILLIAM N. BULLARD, M.D., BOSTON.

The following cases have all been taken from the Neurological Clinic of the Children's Hospital of Boston. All the earlier records were taken and written by me personally; the later ones under my supervision. In addition I have personally interviewed one or both of the parents in a considerable proportion of the cases. The trustworthiness of the statements has always been carefully weighed. The positive ones may almost invariably be accepted as true; the negative ones very generally. In the large proportion of cases I have found the parents, when personally questioned, willing to answer the truth — as I believe — to the best of their ability.

In examining the results obtained in this investigation the cases naturally fall into two great groups:

I. The Congenital — those in which the affection has occurred previous to or during labor.

II. The Non-Congenital — those in which the patient has acquired the condition from some cause acting after birth.

We cannot always with certainty determine to which of these classes a given case belongs, especially where several factors may have contributed to produce the result. Doubtful cases or cases in which there is not a strong probability in favor of one class or the other have not been counted.

Out of the whole number of cases examined (258) there are 176 in which this can be determined more or less accurately. Of these 113 were congenital; 63 were non-congenital or acquired cases. The large proportion of the cases in which the condition was acquired after birth was a surprise. It is, however, quite certain that the greater number of those cases which were not counted for want of definite data belong to the congenital class because the cause is much more evident when it occurs after birth. A hemiplegia or other paralysis or a sudden mental defect following or accompanying an acute illness strikes the attention of any one who is present.

We will consider first the etiology of the non-congenital cases because it is much simpler than that of the congenital. The causes which act to produce idiocy and imbecility in children after birth are trauma and disease.

Trauma.— It is so well-known that patients are apt to attribute any affection or disease to an accident or injury that all experienced observers are accustomed to take this tendency into account and not permit themselves to be led astray by any general history or belief.

We have placed the following cases under this heading:

1. (12) Father has phthisis. Mother healthy. Three children, patient second child; others healthy. Labor normal. Never ill previous to accident. Is now three years old. Had a fall five months ago, striking the frontal region. Did not lose consciousness. One month later forgot how to talk. Six weeks ago first convulsion which was unilateral and lasted one hour, shortly followed by another lasting two hours.

2. (67) At seventeen months fell and struck head; convulsions for eighteen hours and left hemiplegia.

3. (81) Labor not severe; dry birth. No illness. Fell at seven months striking back of head; unconscious all day, afterwards fretful. One month later convulsions.

4. (85) Four children; patient third; others healthy. Labor easy, not remarkable. Is seven years old. Well till two years ago when she fell downstairs. No trouble at the time but a month later became confused and incoherent.

5. (102) When three years old fell off piazza, was unconscious fourteen days and had convulsions, aphasia and right hemiplegia. Father died of tuberculosis. There were two children, the patient first; the second died of meningitis when six years old.

6. (172) Parents healthy. Six children; one died of cholera infantum; others healthy. Labor normal. Fell from baby carriage when thirteen months old and then stopped walking until two and a half years old. No other apparent cause for condition.

7. (173) Had one convulsion attributed to teeth when three months old. Otherwise well previous to fall out of hammock when four years old.

8. (210) Seven children; others healthy; patient 4th. Had one convulsion with influenza during dentition. Otherwise bright and active. When five years old fell six feet, striking head.

These eight cases seem with much probability due to trauma. There are in our series four more cases in which trauma is a doubtful cause.

1. (24) Fell and cut head when five years old. Trouble began at six years. Parents healthy. Patient was 9th child. Eleven children; 6th, 7th, 10th and 11th died in infancy; others healthy. Labor normal. No other cause known.

2. (190) Only child. Labor easy. Fall at five months. Convulsions at one year.

3. (213) Patient is a city charge. There is no definite history but those who have the care of patient state that the condition was said to be due to injury.

4. (238) Five children; patient first; others healthy. Labor not remarkable. Born at eight months. Injury to head when two years old. Nothing wrong noticed until it was found when five years old that she could not learn at school.

Out of 63 non-congenital cases we have, therefore, 8 or about 13 (12.69) per cent., probably traumatic, and if we add the 4 doubtful ones we have 19%.

Disease. — The following cases are considered as due to disease:

1. (6) Patient born of healthy parents. Was the seventh child. Labor easy, natural. When eleven months old had an acute disease apparently encephalitis and two months later right extremities were found paralyzed, and child became feeble-minded.

2. (26) Parents healthy. Patient fourth child. Labor normal. Born at full time; blue at birth. When eighteen months old had measles, then varicella followed by meningitis and then convulsions.

3. (38) Affection followed cerebro-spinal meningitis.

4. (45) Affection followed meningitis.
5. (46) Affection followed measles.
6. (52) Measles followed by diplegia.
7. (101) Cholera infantum at eighteen months and twenty months. After cholera infantum spastic diplegia. Previous to this had been bright and healthy and had had no illness except pertussis at eleven months.
8. (103) Labor normal. Severe illness between one and two years old followed by strabismus.
9. (111) Cerebro-spinal meningitis at twenty months was the cause.
10. (122) Healthy until measles at ten months.
12. (131) When nine months old attack of convulsions with right hemiplegia. Meningeal hemorrhage? Family history negative. Four children, patient second; others healthy. Labor instrumental.
13. (143) Affection dates from the age of four years when patient had an acute illness of four weeks' duration with left hemiplegia.
14. (148) Meningitis at two years.
15. Well previous to scarlet fever at three and a half years, from which became deaf and dumb.
16. (156) Well till meningitis at nine months.
17. (159) Well till fifteen months old when she had an illness (called German measles) with fever and convulsions.
18. (175) Well till nine months old. Then convulsions and left hemiplegia.
19. (189) Well previous to measles when a year old. One month after the measles convulsions, and again one month later left hemiplegia.
20. (200) Convulsions and spastic hemiplegia at the age of two years followed by pertussis.
21. (211) Affection followed meningitis at four years.
22. (244) Pregnancy and labor normal. Well until pneumonia when seven weeks old, followed by convulsions.[1]

The above are with strong probability or with practical certainty due to disease which has occurred since birth. In addition there are a number of cases in which post-natal disease is the most probable cause but in which the evidence is not as strong as in those described. Of these there are thirteen. I shall not describe them in detail but mention three taken at random as examples.

(106) Healthy at birth. When six weeks old was ill for one month with convulsions (meningitis?) and the trouble began at this time. The family history is negative and labor was normal. Is blind, dumb and probably deaf.

This case might fairly be placed in the previous class.

(124) Parents healthy. Four children; patient third; others healthy. Labor normal. Walked at one year. At this time became feverish, had convulsions and became feeble-minded.

Here again the evidence is fairly strong in favor of post-natal disease.

(129) The feeble-mindedness in this patient seems to have come on after rheumatic fever when three years old: the first convulsions occurred when three years and three months old. Family history negative. Labor probably normal.

[1] In each case the feeble-mindedness is supposed to have come on at the time of the convulsions.

We have two cases also in which there is a slight predominance of evidence in favor of this cause.

The nature of the disease which produces the feeble-mindedness or idiocy is not always plain. That it is intracranial is evident. Sometimes the cerebral or meningeal symptoms occur alone or essentially so, and sometimes they seem to be concomitant with and forming a part of some acute disease, most frequently one of the exanthemata. In our first twenty-two cases the initial affection was classed as follows:

Encephalitis and meningitis, 6; meningeal hemorrhage, 1; cerebro-spinal meningitis, 2; acute illness usually with intracranial symptoms, 4; measles, 4; scarlet fever, 1; German measles (?), 1; pertussis, 1 (2); pneumonia, 1.

(We have also another case in which the probable cause is pertussis.)

In the case of those in which the cause of the idiocy was probably but not so certainly due to post-natal disease the character of the primary disease is essentially the same.

Encephalitis, 2; meningitis, 1; cerebro-spinal meningitis, 3; sunstroke, 1; acute illness, 2. (One not more fully described, one with intracranial symptoms); rheumatic fever, 1; pneumonia, 1; diphtheria, 1.

Congenital cases. — These number only 113.

The congenital cases are to be divided into intranatal and prenatal. The former, those occurring during labor; the latter, those having their onset during pregnancy before labor begins. It is so often impossible to determine even with probability whether a given case belongs in one or the other group that I shall not attempt to give figures but will offer such evidence as we have in the hope that hereafter with further material more definite conclusions may be drawn.

The longer I study these cases the more I am inclined to attribute them in the great majority rather to a prenatal than to an intranatal cause. This view is based more on the pathology of the cases than on their clinical history. The large proportion, however, of peculiar or unusual circumstances in labor in this class (congenital cases) suggests that labor and its attendant conditions has a distinct bearing and is at times at least the exciting cause.

The only clinical evidence of intranatal causation is: (1) The direct history of an accident or injury with visible signs, such as fracture or depression of the cranial bones. Even this is not certain proof that the cerebral condition was not pre-existent. Depression of the cranial bones during labor does not necessarily involve any intracranial injury, and a serious intracranial lesion is required to produce the conditions under consideration. We have in our series no cases of this character. (2) The occurrence of unconsciousness, convulsions or other acute cerebral symptoms immediately on birth suggests intranatal lesion.

The following cases have presented this condition:

1. (8) Patient third child. First died of spinal meningitis; second healthy. Parents healthy. Labor severe; lasted four hours; no instruments used. The cord was round the child's neck and he was asphyxiated. He cried for eighteen hours after birth.

2. (56) Mother had pains for four to five weeks before delivery. Labor pains severe for seven hours. Patient was blue when born and was unconscious for three hours after delivery. Head was much out of shape.

3. (74) Placenta previa. Child asphyxiated. Had "spasms" for three days after birth.

The next case is more doubtful: the cause may have been prenatal.

4. (99) When six months pregnant, mother while carrying coal upstairs felt something crack but had no further symptoms. Labor severe; pains for twenty-two hours, severe for ten hours; forceps used; patient asphyxiated. This patient had a right hemiplegia involving the face at birth and the left lower extremity was also affected. For seven days after birth refused to nurse.[2]

Whatever may be the part played by the processes of labor and delivery in these cases, it would seem from our records that there was a much larger proportion with difficult or troublesome delivery among the congenital than among the non-congenital. This cannot be due to the placing of those cases in which the labor was difficult among the congenital because we have counted as acquired only those in which we had a distinct history of trauma or disease.

In the twelve cases in which the lesion causing the idiocy or imbecility was most probably intranatal there was only one in which the labor was easy, and in this case (105) the child was said to have been asphyxiated. There was one case also of breech presentation (205) and one of twins (233). The other cases were as follows:

1. (8) Patient asphyxiated: cord around neck. (See above.)
2. (11) Patient asphyxiated. Waters broke two days before birth.
3. (56) (See above.)
4. (66) Severe; forceps were applied for three hours.
5. (74) (See above.)
6. (99) Labor severe; forceps; asphyxiated.
7. (100) Labor severe; twenty-six hours; forceps; difficulty in delivering body and child asphyxiated.
8. (170) Forceps delivery; mother having convulsions at the time (eclampsia).
9. (231) Pelvic obstruction.

In the 26 cases in which labor was a probable cause, but in which the degree of probability was not so great as in the preceding 12, we find that 17 were noted as severe, hard, difficult or long; 2 as medium. Breech presentation occurred in 3 cases and foot presentation was reported in 4 more. Twins occurred once and once there was a three months' fetus present when patient was delivered. Placenta previa occurred once and once there was obstetric paralysis.

We have, besides the above, 42 cases in which the cause was probably prenatal, excluding those in which heredity or inherited syphilis might exist. In these the character of the labor was unknown in 2. In 32 it was normal, one of these cases being twins, and in two others we have only records that forceps were used but no more definite statement — these were classed as normal. Six cases were noted as hard or severe; in none were forceps used; one child was said to have been asphyxiated; others no report.

If we compare the cases in which labor was a possible or probable cause with those in which the affection was supposed to be acquired we find a marked difference in the character of the labor. We have 12 cases of trauma and 41 of disease making 53 of acquired imbecility. Labor was reported normal in every case of trauma, except two in which its character was unknown. There was one case of twins. In the cases in which post-natal disease was considered the cause the labor was normal in 33 cases; unknown in 2; instruments used (no further information), 1; hard, severe, or very severe, 5, in one of which the mother had convulsions, forceps used in 3 of these; not used in the other two. In one of these child reported asphyxiated (this was the one in which the mother had convulsions); in 3 not asphyxiated; in one not reported.

Therefore out of 39 acquired cases labor was normal in all but 5, and in none of these does it seem to have been dangerous or really beyond natural limits except in the one in which the mother had eclampsia and the child was asphyxiated.

Out of the 38 cases in which the cause of idiocy was probably or very possibly intranatal we find that in 18 cases forceps were used; in 10 cases presumably of presentation of the head, forceps were not used; in 8 cases the presentation was breech or foot and in 2 cases it was not known whether or not instruments were used. Out of 36 cases, therefore, forceps were used in 18 — just one half.

I have not been able to find in these cases any evidence of injury from the forceps. It seems very probable that in cases of intranatal origin the affection is as liable to be caused by prolonged pressure on the head during delivery as by any injury from forceps. We have not sufficient data as yet to draw any certain conclusion but it is certainly possible that delay in the use of the forceps tends to produce this affection quite as much or more than their skillful employment.

Passing now to the prenatal causes, the only objective ones are the injuries which occur during pregnancy to the mother or child. When first obtaining the histories in these cases the importance of the conditions during this period was not realized and no special inquiries in this direction were made. Consequently we have only a small number of cases (39) in which we have records in relation to the conditions during pregnancy. In many cases probably only notes were made when there was something to call special attention to the maternal condition at that time. Out of those 39 cases in which definite statements were recorded we find that

[2] It is difficult to estimate the value of the term asphyxiated in these cases. We cannot distinguish from the history between those cases in which there was serious trouble and those in which the difficulty was slight.

the pregnancy was noted as normal or perfectly normal in 11. In 10 there was a history of much worry on the part of the mother during pregnancy, sometimes induced by the death of a relative; sometimes from other causes. In one of these cases it was noted that there was worry and fright, and we have two more cases with the history of a severe fright to the mother during pregnancy. There were 9 cases in which the mother had a more or less severe fall including one in which she was knocked downstairs, and in these the element of fright was often included. There were 2 other cases of trauma making 11 in all. There were 3 cases of illness of the mother at this time, one of heart disease, the mother dying three days after delivery; two of grippe. There were two cases also in which the mothers were very weak during pregnancy but with no definite disease, and one case was specially mentioned in which the mother was overworked in a factory.

I consider this at the present moment really the most important group for investigation from the standpoint of causation. In the first place because fewer statistics have been obtained in regard to the conditions which exist during pregnancy in this class of cases, and secondly because we need much more detailed knowledge of the value of the causes which are assumed or suggested as of influence in this direction during this period. We have no definite data to show us what probability there is that prolonged worry or anxiety at this time produce definite cerebral results; we do not know what significance to attach to a fall or other injury during pregnancy, when, as in most cases, no definite clinical symptoms follow. We are still almost wholly in the dark in regard to the diseases of the fetus or child before birth and how such diseases may affect the central nervous system. We can gain only a dim perception of these things from such knowledge as we possess of the causation of non-development of the fetal brain or of monstrosities.

I have purposely refrained throughout this paper from referring to the pathological conditions which may exist in these patients, but I must state here that there is strong evidence in many cases of affections of this class from the pathological standpoint that the disease occurred or began at some period previous to labor. If, therefore, we hope to diminish the number of the feeble-minded or idiotic children we must seek among other causes those which act previous to labor and determine whether or not they are remediable.

Heredity.— It is somewhat difficult to decide how large a part heredity plays in the causation of feeble-mindedness and idiocy but there can be little doubt that it is a potent factor in a considerable number of cases.

It is a matter of slight importance as regards results whether the inheritance be direct or what is sometimes, though incorrectly, termed indirect, whether the disease or affection appear in the immediate or collateral ascendants. The character of the inheritance is of more importance. We have reason to believe that where one of the parents is feeble-minded the offspring is more likely to be feeble-minded than is the offspring of healthy parents. We know that epileptics are liable to beget epilepties, and we believe that a person in whose family a non-traumatic epilepsy exists is more liable to epilepsy than one whose family is free from epileptic taint. In the same way we believe that where there is an epileptic taint in the family, feeble-mindedness is more probable. As to the importance of other diseases or affections of the central nervous system we must for the present take an undecided position and await further evidence. The relation of tuberculosis to feeble-mindedness is still doubtful. There is no sufficient evidence that it tends in any way to its production.

Besides these affections which are liable to run through or infect a family we have certain affections or conditions acquired by the parents which have unquestioned effect upon the offspring. The principal of these are syphilis and alcoholism.

In considering our own cases we find that in 183 in which the health of the parents was recorded, in 137 they were both reported healthy. In nearly all these cases we are justified in the presumption that the family history was negative, though this is actually stated in only 34. There are also 5 cases in which while the parents were healthy there was a poor heredity.

Descending to detail we find one patient whose father was imbecile; two whose mothers were of poor mental development, and two from the same family who had a cousin that was not bright. We find no cases in which either parent had epilepsy, but one patient had an epileptic uncle and another an epileptic cousin; while in a third case a paternal cousin died in a fit and 6 of the father's family had brain trouble. Besides these cases there was one in which the mother had hysteria and one in which the mother some time later committed suicide. One patient had an insane aunt; one had two uncles who died as infants in convulsions.

Out of these there are only three in which either of the parents was seriously affected and two more in which the mother had some indefinite nervous affection which might or might not have a bearing on the etiology of the affection in the child. We have seven with a history of nervous disease of more or less importance in the collateral members of the family. I should attach considerable weight to the existence in these of imbecility or epilepsy; much less to the presence of other affections of the nervous system. Too many children die of convulsions to make such an occurrence of more value than a possible indication of some tendency to cerebral weakness and hyperexcitability which would have but an indirect bearing on the affection of the collaterals.

Syphilis appears to play a smaller part in the production of feeble-mindedness than was formerly suspected. The following cases, 11 in

number, are those in which it was present or there were reasonable grounds for suspicion. There are only 4 in which the father was known to have syphilis. It is plain, however, that the mere fact that the father has or has had syphilis is not sufficient to determine that this is the cause of idiocy in the offspring.

SYPHILIS.

1. (188) Fourth child. Labor normal. Pregnancy normal. First, second, third children healthy; fifth and sixth stillborn. Sleepy for twenty-four hours after birth. Internal strabismus.

2. (189) Cretin. When two months old snuffles and trouble with throat. Four pregnancies, patient first; second and fourth miscarriages.

3. (92) Father had syphilis. Mother alcoholic. Pregnancies six; patient fifth; second a miscarriage at two months from fall. Sixth had imperforate anus; others healthy.

4. (94) Labor severe, instrumental. Father does not live with mother. Mother healthy. Children two; patient second; first had snuffles, died eighteen months, tonsilitis.

5. (49) Father syphilis. Mother healthy. Labor long; instruments. Twelve pregnancies, patient twelfth. First, miscarriage at six months from lifting. Second healthy; third died two and a-half years old of brain trouble; fourth, died, diphtheria; fifth healthy; sixth miscarriage at seven months, cause unknown; seventh healthy; eighth, ninth, tenth, eleventh, miscarriages at seven months, cause unknown.

6. (44) Father drinks and has deserted wife; mother healthy. Pregnancies six; four children all died young from icterus neonatorum. Sixth miscarriage due to variola. Patient is the first.

7. (43) Hydrocephalus. Snuffles as a baby; skin peeled off; intestinal trouble. Born at seven months. Eight pregnancies, patient eighth. Sixth and seventh stillborn; fifth clubfoot; first to fifth inclusive healthy; but second died at seventeen months of cholera infantum.

8. (29) Cicatrices on soft palate and tonsils with stenosis. Patient is third child. Five children; fifth stillborn from worry, others healthy. First child has ulcerated lymphatic glands in the neck. Frontal bones very prominent. Parents healthy.

9. (23) Snuffles. No eruption. Parents healthy. Labor natural. Pertussis with diarrhea at one year to which is attributed present trouble. Four children; first stillborn; second patient; others healthy.

10. (21) Labor natural. Spinal trouble at nine months; plaster jacket. Hydrocephalus at two years. Father syphilis fifteen years, but last symptoms after pregnancy of patient. Mother has uterine trouble. No other children.

11. (3) Father has syphilis. Labor natural; third child.

Alcohol in the parents undoubtedly plays an important part in the causation of the troubles we are considering — partly probably by direct action upon the tissues and constitution of the offspring, but largely indirectly through the exposure of the mother to injury, fright or worry during pregnancy. We find seven cases — one doubtful — in which this was a factor in the condition. There are two points to be mentioned in relation to alcohol as a cause.

On the one side is the difficulty of obtaining exact information on this subject; on the other, the fact that alcoholism is frequently combined with syphilis, and the effects of the two cannot always be distinguished. I believe, however, that in these cases by means of direct personal interviews with the parents the first difficulty has been reduced to a minimum.

The amount of alcohol taken is of great importance. It is only in cases of excess that any essential influence is to be feared. The question of alcoholic condition of the parents at the time of coition is of much importance, but this can unfortunately rarely be determined.

We find in our statistics only eleven cases in which an alcoholic history was obtainable.

1. (18) Father alcoholic.
2. (38) Father drinks steadily but not to excess; mother's brother alcoholic.
3. (39) Father alcoholic.
4. (44) Father drinks; has deserted wife; possible syphilis.
5. (61) Father alcoholic. Mother drinks a little.
6. (68) Father very alcoholic; mother alcoholic; patient has hydrocephalus.
7. (160) Father alcoholic; has deserted wife.
8. (185) Father alcoholic.
9. (251) Father drinks at times.
10. (90) Father alcoholic.
11. (92) Father has syphilis; mother drinks.

Lastly, we come to what is in my opinion an exceedingly important cause of feeble-mindedness on which sufficient stress has not been laid. This is maternal uterine disease. How often this acts we do not know. It seems to me possible that many otherwise unexplained cases are due to this. I find fifteen cases in which this cause is suggested. Frequent miscarriages may be due to this as well as to syphilis or other causes.

Attempted abortion undoubtedly also plays a part in the causation. It is not probably a very frequent cause. It is a cause which it is difficult to detect because it is almost the only one about which the parents under the most favorable circumstances cannot be expected to tell the truth.

While not discussing in this paper the pathological conditions existing in these patients I will note that we find among the 258 cases 11 cases of hydrocephalus as follows:

1. (No. 21) See syphilis. Father acquired syphilis eleven years preceding birth; the last symptoms (throat) came on after wife was pregnant with patient. Father does not drink. Mother healthy except for uterine trouble; has been married five years; no signs of syphilis. Patient is only child. No miscarriages. Labor easy, natural. Patient had spinal trouble (caries) when nine months old and wore a plaster jacket. When two years old was ill; stupid for two days and after this hydrocephalus was noticed. Is now three and a half years old.

2. (No. 39) See alcohol. Father alcoholic, healthy; mother healthy. Patient is an only child. No miscarriage. Labor not remarkable. Hydrocephalus first noticed when three months old.

3. (No. 43) See syphilis. During second month of pregnancy father disappeared and was never found; much worry during pregnancy. Labor easy; was born at seven months. Eighth pregnancy. Sixth

and seventh children stillborn at term. Hydrocephalus noticed while a baby.

4. (No. 35) Patient eight years old, has spastic diplegia. Has webbed fingers, hypospadias and hydrocephalus. He was the fourth pregnancy. The first and second were miscarriages at three weeks; third, a healthy child, died when nine months old of cholera infantum. Labor long and difficult; child had the cord around his neck and was asphyxiated; no forceps used. Had convulsions at birth. Parents healthy. One uncle epileptic. Tuberculosis on paternal side. Maternal grandmother died of phthisis.

5. (No. 57) Spastic paraplegia. Hydrocephalus. Mother well during pregnancy. Labor difficult. Feet presented. Child born while mother was standing and fell striking head on floor. Cried from birth. Convulsions when a year old. Ten children, three dead; others healthy. Patient ninth.

6. (No. 68) See alcohol. Father very alcoholic. Mother alcoholic. When three months old had spinal meningitis with hydrocephalus.

7. (No. 73) Parents healthy; labor normal. Hydrocephalus followed pneumonia when nine months old. Fifteen children; patient fourteenth; others healthy; six dead, two at birth, one when eleven days old, the other three of diseases having no bearing on patient's condition. Patient had meningitis when two years old.

8. (No. 78) Convulsions came on when six months old, followed by hydrocephalus. Had been bright previously. Parents healthy. Labor severe; forceps not used. Five children; first died when sixteen months old, of hydrocephalus; second has hip disease; patient fourth; third and fifth healthy.

9. (No. 91) Parents healthy. Five children; patient second; others healthy. Labor normal. Pneumonia when seven months; mumps at nine months.

10. (No. 108) Father subject to rheumatism; mother not strong. Two children; patient second; other healthy. Labor not severe; born at eight months; feet presented; was asphyxiated. Never healthy; convulsions frequent during dentition. When one year old cholera infantum and hydrocephalus.

11. (No. 133) Parents healthy. Six pregnancies; first died when a year old of pneumonia; second not strong, drags feet; third does not speak, rickets; fourth, patient; fifth miscarriage at three months, cause unknown; sixth healthy. Patient has rickets. Had cholera infantum at three months; otherwise well.

12. (No. 225) No family history. Labor hard. Forceps not used. Only child. Convulsions at three months. No other illness.

The statistics in this paper can only be considered preliminary to those which I hope may be obtained in the near future. Anything which may tend to the prevention of feeble-mindedness and idiocy is of the highest importance and I desire to turn the attention of all those who may have the opportunity to observe or investigate facts bearing on the etiology of these cases to the great value of such facts if properly recorded and published.

A SIGMOID BAND OF UNUSUAL ORIGIN. OPERATION — RELIEF.

BY ARTHUR L. CHUTE, M.D., BOSTON, MASS.

THE following case presents an intestinal band of very unusual etiology. While it would seem as if the literature must contain similar examples, I have been unable to find any.

In December, 1898, I saw a woman of twenty-two in her first labor. When seen she had been having more or less severe labor pains for nearly twenty-four hours, and was pretty well exhausted. A much moulded head was found arrested just below the brim of the pelvis. The patient was delivered immediately by a moderately difficult forceps operation. She had an afebrile and apparently normal convalescence. Her bowels were confined for a few days, because of repair of the perineum. When the patient had been about for some days, there developed a fissure of the anus for which the sphincter was dilated and the patient again discharged, her bowels moving regularly and without pain.

About a month later I was again called and found that the patient had had no movement of the bowels for seventeen days. Her abdomen was slightly distended but neither tender nor tympanitic; she had had no vomiting. The over-loaded bowel was relieved by enemata. Then for several weeks a large number of the usual cathartics were tried; at first with result, but gradually they all lost their efficacy. The patient even took for a few days two-drop doses of croton oil without effect. On one occasion she took, on her own initiative, five drops of croton oil which gave her very severe abdominal cramps but no dejection. In conjunction with the use of the cathartics, regulation of diet was carefully attended to, and abdominal massage was also tried; for some time electrical stimulation was used, but all without result. Except after a powerful cathartic there had been no pain; distention was variable but never excessive. There was a tender spot some three or four inches below the umbilicus and to the left of the median line, yet nothing could be felt at this point.

After the over-dose of croton oil, cathartics were given up. The patient took a daily enema and had a dejection almost immediately afterward. After the first gush of bowel contents all forced attempts at defecation were useless, and there was the feeling that the more she strained the tighter the obstruction became. It was noticed that only a small part of the injected water was returned, and that for an hour or two afterward the patient passed large quantities of very clear urine.

The condition remained unchanged, and in November, 1899, I opened the abdomen by a median incision, expecting to find some trouble in the pelvis. None was found and I closed the abdomen without making as extended a search as I should have done. The convalescence was uneventful. For a few days before leaving the hospital the patient had a daily dejection following seventy-five-drop doses of fluid extract cascara, given three times a day; however, on returning home her condition became as before.

In January, 1900, this patient became pregnant for the second time and delivered herself at term, after a moderately hard labor. The convalescence was afebrile.

From December, 1899, until February, 1902, the patient did not have a single natural dejection. In February, 1902, I sent her into a hospital for observation. At first she was fed large quantities of bulky food and given neither cathartics nor enemata. Two or three attempts of this sort showed its futility, as at the end of forty-eight hours she would have a violent headache and begin to vomit. Various cathartics in small doses produced no effect; in larger doses they caused vomiting and griping abdominal pain. Nothing but an enema would bring about a dejection. When given an enema of a quart, quantities varying from 8 to 14 oz. of stained water containing fecal masses

would be returned within a few minutes. The rectal tube, passed as high as possible, failed to recover the rest of the water. After each enema the patient would pass for an hour or more a greatly increased quantity of colorless urine. It was found that an enema of a few ounces acted quite as well as a larger one, and that after the first gush of bowel contents, straining accomplished nothing; also that enemata if repeated before a number of hours had passed produced no result.

General examination of the patient was negative except that the blood count showed a slight anemia, and that the urea was low — about half the normal. The patient's abdomen was slightly distended, everywhere soft and no masses could be felt. There was the same tender point below and to the left of the umbilicus. There was no visible peristalsis. Pelvic examination showed no abnormality. Rectal examination showed nothing except inability to introduce any instrument further than 6 or 7 inches. The instrument would then cause great pain and refuse to advance under the use of justifiable force.

I opened the abdomen for the second time in March, 1902. The omentum was lightly attached to the abdominal wall at two or three points along the old incision. When these were separated a considerably enlarged sigmoid came into view. A band between 2 and 3 mm. in diameter and 4 inches long arose from the free border of the sigmoid some 6 or 8 inches above the floor of the pelvis, and was attached to a point on the abdominal wall to the left of the median line. Its point of attachment to the abdominal wall corresponded to the place that had been tender. At a point a little above this band an appendix epiploica was attached to the omentum by a slight adhesion. These bands were tied and cut. The pelvis showed no adhesions. The sigmoid above the band seemed distended and thinned, instead of thickened, as one would expect to find it, in a segment of intestine that had been attempting for some years to overcome a not impassable obstruction.

Convalescence was uneventful. With moderate doses of laxatives the bowels moved daily, on several days she had more than one dejection. In the first three months after operation she had a dejection daily and used enemata but twice. When last seen, a year after operation, her bowels had moved daily, with one exception. She still depended on laxatives but required a smaller dose.

This case belongs to the general class of sigmoid adhesions causing chronic obstruction. Its greatest interest is in the etiology, though the nature of the band (an appendix epiploica) is not of common occurrence. The mechanism of the occlusion and its duration also present points of interest.

The fact that this patient had been well previous to her confinement, the absence of a febrile convalescence, the appearance of symptoms soon after her confinement, and the finding of no adhesions about the uterus, ovaries or tubes, lead to the conclusion that the band must have been the result of some injury received during labor. It seems probable that during delivery an appendix epiploica, or possibly the sigmoid, received some injury to its peritoneal coat, presumably by being caught between the edge of the pelvic brim and the child's head, or the edge of the pelvis and the forceps, and that this abraded surface became adherent to the abdominal wall during the few days the bowels were confined after delivery.

Sigmoid bands arising from mechanical injury during labor are very unusual. In a quite extended search of the surgical and obstetrical literature I have been unable to find a similar instance. Large numbers of bands have been reported following uterine sepsis and inflammation of the pelvic organs, and a number of cases are reported in which the sigmoid has adhered to malignant growths of either the uterus or an ovary, also a few in which the adhesion has been to cysts. In men this type of adhesion is rarer than in women. The usual causes in men are: disease of the appendix, dysenteric ulcers, tuberculous peritonitis and injury. These same causes may of course produce the condition in women.

In spite of the fact that these bands usually arise as a result of inflammatory processes or new growths, the many instances of post-operative bands, and the fewer cases in which bands have followed contusions of the abdomen, point to the probability of any injured or abraded peritoneal surface as being a sufficient cause for an intestinal band. Fagge, Franklin, Schwyzer, Kempe and Brown, Riedel and Kalloch all report instances where adhesions have followed non-penetrating injuries of the abdomen.

Several things make it more probable that the band in this patient developed from an injured appendix epiploica rather than from an injury to the serous surface of the sigmoid. The position of the band was above the point where the sigmoid crosses the pelvic brim; it was also on the free border which would be away from the bony edge. Also, the clubbed end of an appendix epiploica renders its incarceration between the pelvic brim and the descending head much easier than that of the smooth surface of the sigmoid. The position of the band, diametrically opposite the mesentery, and the absence of any scar on the intestine, also point to the probability of the band being of this origin. Had a bit of the circumference of the intestine been caught we should have had a condition like a Richter's hernia and undoubtedly attended with symptoms at the time. Bands which are the result of appendices epiploicæ forming adhesions are not very common. However, Ribes and Daniel, Dun and Riedel report such instances. In one of Riedel's cases the nature of the band was confirmed by microscopical examination.

As regards the mechanism of the obstruction in this case, the pull of the band apparently caused an incomplete occlusion by kinking at its point of attachment to the sigmoid, making it difficult, but not impossible, for bowel contents to pass. The inability of the lower segment of the sigmoid and the rectum to empty themselves without the help of an enema is not easily explained, except on the ground of some inhibitory reflex. Cabot reports a man of fifty-four in whom there were adhesions from the sigmoid to the bladder and pelvic wall, and in whom there was inability to empty the rectum without in-

jections, although in his patient, as in mine, the obstruction was not sufficient to entirely prevent the passage of feces into the rectum.

The length of time which some of these bands have existed before giving serious trouble is quite remarkable. In one of Cabot's cases symptoms first appeared thirty years before the time of operation. Watkins reports a patient who had symptoms for eight years, Rosenwasser one for six years, Treves, Elliot, Lotheisen, Riedel and Downes report cases in which the symptoms have covered shorter periods.

Constipation gradually increasing in obstinacy is the symptom which is most frequently seen in these cases of kinking of the sigmoid by bands. Tenderness in the left iliac fossa is common, though the seat of tenderness has varied with the point of attachment of the band. Occasionally defecation has been painful. The amount of distention varies but is usually moderate. Visible peristalsis is not common. Pain and vomiting are usually seen only during intercurrent attacks of complete obstruction, which are not uncommon in the course of these cases. Gurglings and attacks of diarrhea are not often mentioned. In a large proportion of cases examination has shown nothing more than local tenderness.

In making a diagnosis, the history of an abdominal operation, previous attacks of appendicitis, puerperal sepsis or pelvic inflammation is of the greatest aid. With such a history obstinate constipation, not affected by the usual treatment, particularly when accompanied by tenderness in the lower abdomen, should lead to a consideration of the probability of the obstruction being mechanical. In the light of the reported ease, and that of Cabot, the ability to secure dejections by enemata, when large doses of cathartics persistently fail, may be a diagnostic sign of some value.

A study of the reported cases of chronic obstruction by bands or adhesions to the sigmoid shows that many of these patients, though having had symptoms for years, have been supposed to be suffering simply from particularly obstinate constipation, until such time as an acute and often fatal obstruction has taken place.

These bands are especially apt to bring about an acute obstruction during pregnancy or the puerperal period, and their diagnosis at this time is attended with particular difficulties.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL.

CLINICAL MEETING OF THE STAFF, TREADWELL LIBRARY, FEB. 12, 1904.

In the absence of the President, DR. H. H. A. BEACH took the chair.

DR. R. G. WADSWORTH read a paper on "The Ultimate Results in some Gynecological Operations at the Massachusetts General Hospital." This paper was published in full in the JOURNAL for March 24, 1904.

DEVIATION OF THE NASAL SEPTUM.

BY A. COOLIDGE, JR., M.D., BOSTON.

A SYMMETRICAL nasal septum is an exception rather than the rule. When the deviation interferes with the normal functions of the nose it is of course desirable to correct it, provided this can be done with a fair chance of a successful result. Deviations are so varied in form and extent, and the access to the seat of operation is through so small an opening that it is only in recent years that any satisfactory or even promising methods of operation have been established. The problem is a peculiar one. A perpendicular plate of cartilage is inserted into a perpendicular plate of bone along three quarters of its edge, while the remaining quarter projects outwards to form the external nose. In infancy the septum is relatively small; after the second dentition it begins to grow in relation to the surrounding structures, and this growth in the white race is especially marked in a forward direction. It pushes outwards the external nose, both the nasal bones and the cartilaginous bridge. To appreciate this it is only necessary to compare the profiles of children with those of their parents. It is a matter of common observation that most of us have asymmetrical skulls, and it is easy to imagine the effect of even a slightly asymmetrical development upon this thin perpendicular plate of mixed cartilage and bone, held firmly in a bony frame, trying to grow forward. That it should twist and bend is almost to be expected, and although it may do so in many different ways there are a few general principles which are worthy of notice. In addition to varying curves of the septum as a whole, the first thing to be expected would be a bending along the weak

points, that is the synchondroses of the cartilage with the bones, the vomer and perpendicular plate of the ethmoid. This bending would easily result in a dislocation, which, as it takes place slowly, is more or less masked by processes of repair. In this way spurs and ridges of mixed cartilage and bone appear on the convex surface of the bending septum, while the upper edge of the vomer sometimes appears as a rounded spur in the concave side. A second result which might be expected is found towards the center of the cartilaginous plate, in front of the bony septum. This plate being held firm by the maxillary spine below and by the nasal bones above, but comparatively movable in front, is often bent on a perpendicular axis, at about right angles to the dislocation behind. This may vary from a slight bowing of the cartilage to a sharp bend at an acute angle, coming just opposite the nasal process of the superior maxilla at the introitus of the nasal cavity, where it most easily obstructs breathing. In many cases of extensive deviation these three processes, bowing of the septum as a whole, dislocation of the cartilage and vomer, and a purely cartilaginous bend from the nasal spine of the maxilla, at right angles to the other, may be easily traced. The external nose, that is the nasal bones, or cartilaginous bridge or both, may take part in the asymmetry.

During the past three months I have in the hospital operated upon 12 cases, of which I show 5 this evening. Deviations vary so much that widely different methods must be adopted for different cases. In these cases the type of deviation was that already mentioned, a septum more or less bent as a whole, with a sharp angle which could be demonstrated as due to a dislocation of the cartilage from the vomer, and more or less perpendicular bend of the cartilage above and anterior to the maxillary spine. In these operations I have used some of the principles or instruments of Asch, Roe, Watson and Gleason. Where there is a perpendicular cartilaginous angle on the obstructed side a piece of cartilage is removed from the whole length of the angle, care being taken not to injure the mucous membrane of the concave side. This is easily done by a steel cylinder, sharpened at one end, an instrument introduced by Dr. Mixter for removing a core of tissue for pathological examination. A saw is then introduced along the floor of the obstructed cavity, and the cartilage separated from the vomer and maxillary spine, by cutting obliquely upwards through the septum. The free lower edge of the cartilage can then be forced over the free upper edge of the vomer into the concavity of the opposite side, where it overlaps and maintains itself in position. This overlapping is due partly to the oblique incision, and partly to the fact that a bowing septum will of course have redundant tissue when it is straightened. It is well to curette away the mucous membrane from the line along which the lower end of the cartilage is to rest. If the septal bones are markedly deviated from the median line, they are then fractured and set as near the median line as possible. A hollow tube is put into the previously obstructed cavity for support, and retained for a few days to a few weeks. There is often at first considerable over-correction, which disappears in a few weeks. A good final position of the septum can be encouraged by leaving out or putting in tubes of the proper size and shape during the first two or three weeks. A tube is easily removed daily, washed and re-inserted.

In regard to an anesthetic, if the operation can be done by cutting cartilage only, it is often easy to do it with cocaine, but if any bone is involved, ether is advisable.

F. C., schoolboy, age eleven. Respiration on the left side much obstructed by deviation of the septum with a spur at the vomer-cartilage synchondrosis, and a perpendicular cartilaginous spur at nasal process. Operation with ether Dec. 17. Both spurs removed, cartilage separated from vomer, and incision brought forward anterior to nasal spine. Cartilage pushed over into concavity in right side; holds itself in good position. Hollow rubber splint.

Dec. 17. Over-correction. Smaller splint. Dec. 24. Slight over-correction, splint left out. Dec. 26. Small tube into left cavity. Jan. 13. Splint omitted. Jan. 30. Septum practically straight.

V. M., clerk. Age twenty-five. Nearly complete occlusion on right side of nose. Bend of septum along the vomer-cartilage synchondrosis. Anteriorly a bowing of cartilage without any sharp angle, nearly obstructing respiration behind the ala. Concavity in left side, with rounded top of vomer showing as a ridge.

Jan. 8. Operation with ether. Mucous membrane over upper part of vomer in left side curetted. An oblique cut with a saw from the right into the left cavity, separating cartilage from vomer and maxillary spine. Cartilage pushed easily into left side, good position. Jan. 19. Slight over-correction, splint omitted. Feb. 11. Septum nearly straight, slight over-correction.

J. B., mill operator, age twenty-three. Deflective of external nose, nasal bones and cartilage, to left. Septum much deviated into right cavity along lower edge of cartilage.

Jan. 30. Operation with ether. Both nasal bones separated by a saw from nasal processes of superior maxilla, and fractured. Placed in median line. Cartilage separated from vomer, and forced into left cavity. Vomer fractured and placed in median line. Long splint put in. Considerable over-correction. Feb. 4. Over-corrected. Splint removed. Feb. 11. Over-correction less marked.

M. R., cigar maker, age twenty. Patient complains of difficulty in breathing through right side of nose. Deviation of septum due principally to dislocation of septum from vomer; very slight bending of vomer, or of ethmoid or of cartilage anteriorly.

Feb. 9. Operation with cocaine. Mucous membrane curetted from upper part of vomer, incision along synchondrosis, cartilage pushed into other side, where it remains firm, forming a slight over-correction.

Feb. 16. Hollow splint removed. Slight over-correction.

F. C., clerk, age fifteen. Has always breathed through mouth. For three years the right side of nose has been nearly entirely occluded. External nose; nasal bones straight, cartilaginous bridge mark-

edly deviated to the left. An extensive deviation with sharp angle along the whole cartilage-vomer synchondrosis, also a sharp cartilaginous perpendicular bend occluding the introitus on the right. Deep concavity in the left side. A large mass of adenoid vegetations in the naso-pharynx.

Feb. 13. Operation with ether. Removal of sharp angle, reduction of dislocation and fracture of bony septum as already described. Also removal of adenoid vegetations.

Feb. 23. Tube replaced by pin inserted through the septum from the left side.

Feb. 25. Slight over-correction of septum, splints omitted. External nose deviation of cartilaginous bridge reduced one half.

USE OF THE SPHYGMOMANOMETER.

BY H. F. VICKERY, M.D., BOSTON.

On my last service I had every patient who came into my care measured with the sphygmomanometer upon entrance as a matter of routine. I have not the patients to show, but would like to speak briefly about things that interested me in that experience. There were 267 patients in whom the resistance of the radial artery was measured with the Riva-Rocci machine. Some patients were not measured because they were delirious or for other reasons.

I think the measuring of the pulse-tension a useful addition to the modes of studying medical cases, and I was impressed with the discovery of high tension by the machine in cases in which I had not suspected it. I was glad to see that Dr. Oliver of London and others in this country have made similar observations. Dr. Oliver says when the radial artery is of normal size one can tell the tension pretty reliably, but if the artery is not more than one half its normal caliber very good clinicians will fail to appreciate a tension of 160 or 200 mm. of mercury, whereas the average tension of a healthy man might be put at 140 and of women and children less.

In regard to diagnosis, first, it was present in all the cases of nephritis, I think without exception. It is said not to be present in a purely parenchymatous nephritis, but I do not think I had such a case. Some of the cases of nephritis were complicated with heart lesions, but that did not prevent the tension being high, and in fact, as we shall see in a moment, heart lesions are quite consistent with high tension apart from any nephritis. As improvement occurred in some of the nephritic cases the tension lowered.

I might mention incidentally as confirming the value of the manometer in diagnosis in nephritis that I have under observation two adolescents with constant albuminuria, one lasting some years, with absolutely no casts whatever, and they have a low tension, whereas a man of about forty who came to me lately with beginning interstitial had a tension of 210.

In aneurism Dr. Norris of Philadelphia and others have compared the two radial arteries. My house officer, Dr. Fitch, tried this and found in two or three cases a dissimilarity in the measurement, 110 compared with 132 in one patient, 112 compared with 123 in another. In a third case of aneurism there was no difference in the two arteries.

It is said that in hemiplegia there is also a disparity in the two sides. I had one hemiplegia case, but failed to measure the pulse except on one side. That was thought to be a thrombosis and the tension was low, 140, whereas if there is cerebral compression as in case of active hemorrhage that might be cut down on, the tension is high. We had an intracranial tumor with choked disc and severe headache in which the tension was only 130.

We were on the watch for typhoid perforation, but did not have any. The cardiac cases were astonishing to me. All sorts of cardiac lesions in different individuals are capable of presenting a high tension, persons with aortic regurgitation perhaps less often than the others; but mitral regurgitation, mitral stenosis, double mitral disease, aortic and mitral disease combined, and myocardial degeneration may all exhibit high tension. It seemed as though the majority of those with very high tension were not those with good compensation, but with ruptured compensation. For instance, a man who died in the hospital on the twenty-first day after entrance, sixty-eight years old, had arteriosclerosis, myocarditis and a tension of 198. A malignant endocarditis with trouble in both aortic and mitral valves died on the nineteenth day in the hospital, with a tension of 155. That was a very acute case, probably due to gonorrhea.

Cases with anarsaca and hydrothorax and irregular and intermittent heart with mitral disease had tensions of 215 and 232 and of pure myocarditis up to 235.

Now whether we can get any useful deductions as to treatment from these astonishing conditions in the systemic arteries in ruptured compensation remains to be seen. It would seem as if we see here the explanation of the clinical experience that digitalis often will not work in such cases until you have given a purge, preferably a mercurial, and unloaded the capillaries so the left heart when it is encouraged to work harder does not as you might say press against a stone wall. In one case with high tension we substituted nitroglycerine for digitalis, but the tension did not lower with that. Finally we resorted to purging and digitalis and the tension came down somewhat and the man improved. A similar experience has been reported at the Johns Hopkins Hospital.

Only one other point about the tension with regard to detecting a perforation in typhoid very early. It has been said that the highest typhoid tension is somewhere about 140 and usually much below that. I had a woman with typhoid on the fifth day, without any casts in her urine, with a tension of 152. Another woman on the ninth day, who probably had chronic interstitial nephritis, had a tension of 162. One man had a tension of 162 and another in the third week 165;

so that it would seem that if you are going to be guided by the sphygmomanometer with regard to advising a laparotomy for perforation you must keep track of the individual patient from the beginning of treatment.

Dr. R. C. Cabot: I think as Dr. Vickery does, that we have not proved in any way yet that this instrument is of use in giving us any therapeutic indications. I think we now know that *if* our fingers are of any use to tell us about pulse tension this instrument is of more use. If it was ever of any use to put the fingers on the pulse to find out the tension we have now a much better way of doing the same thing. Another use of the instrument is brought out by the third case of aneurism to which Dr. Vickery referred; comparing digitally both pulses I was convinced that the tension in one was twice as high as in the other. The blood pressure measure showed they were the same. The reason I think was that given by Dr. Vickery, namely, that on one side the artery was so much smaller than on the other. In a small artery I think most of us would be deceived again and again as regards tension when contrasting it with that in a larger artery. If it is of use to know tension this instrument is of value. What I doubt is whether it is of use to know tension, except possibly in kidney disease.

In regard to the cardiac cases which Dr. Vickery has reported I think what was recorded was the blood pressure during the strongest of the varying heart beats. If any wave comes through the cuff to the wrist we say the artery is not obliterated. The strength of different waves in mitral disease is very different, and when we say the blood pressure is 150 what we mean I suppose is that the strongest blood wave in a group occurring within a few seconds brings the blood pressure up to 150. The other waves may be so weak that the average tension is very low and yet our measurements recording only the crest of the highest waves will give a pressure which is very astonishing and quite misleading in view of the manifest phenomena of poor compensation.

TWO CASES OF CRURAL MONOPLEGIA OF TRAUMATIC ORIGIN.

BY J. J. PUTNAM, M.D., BOSTON.

The first patient was an athletic young man, an accomplished boxer, who, about one month ago, received a number of blows about his head during a sparring-match. He does not think there was any particular blow which caused the mischief which resulted, but he was struck a number of times and became very much exhausted from the contest, the more so that he was out of condition. He finally went to his corner in a sort of collapse, and became nearly if not quite unconscious. His friends then took him to the relief station and the next day brought him to this hospital, where he came under the care of Drs. Warren and Greenough. When he appeared at the hospital he did not remember much of anything that occurred the previous evening, but as soon as he improved he recalled some things which he had forgotten which would indicate that the unconsciousness was not so deep as it had appeared. When he came to the hospital his left foot was entirely limp at the ankle, and could not be extended although he could flex it somewhat. Besides that there seemed to be practically nothing the matter except that he was very nervous. It was found that his knee-jerk was exaggerated on the right side, and he had at least a suspicion of an ankle-clonus and also a Babinski reflex which, however, was not obtained every time. Sensibility was not materially affected. He was feeling very uncomfortable about his head and very nervous. After he had been in the hospital some days a plaster was put on to keep the foot in a proper position and he went out. He does not know just how soon his foot began to improve, but certainly within forty-eight hours. About a week later he came to the out-patient department, and then the motions of the foot were almost perfectly good.

The question arises as to whether he had a lesion in the head and what the lesion was. It seemed hardly possible that he could have had a hemorrhage into the substance of the brain or involving the cortex to any great degree without more symptoms, and at the same time the diagnosis of purely hysterical trouble appeared hardly justifiable. He now tells us that he has discovered another symptom, namely, that he bumps into people on the right side, and on examination of his field of vision we find that he has hemianopsia, although not so complete but that he can see vaguely in the right half of the field, especially of the right eye, and that, I think, makes it clear that these symptoms were, so to speak, genuine, and that he did have an affection of the head which resulted from the accident. Then the question arises whether such lesions are not a good deal more common than we suppose, and whether they are as limited as the limited extent of the paralysis would indicate. The lesion or lesions must I believe have gone back as far as the occipital lobe and as far forward as the neighborhood of the Rolandic fissure, and in fact there are perhaps multiple capillary hemorrhages present. He is now practically well except for his hemianopsia, and inasmuch as he sees, although not very distinctly, in the right half of his field, it is to be hoped that the trouble will disappear.

His native tongue is German, and he says he spoke English fluently before the accident but that since then he has not been able to speak so well.

The second patient is a law student who last October was coaching a foot-ball team of young men and was tackling with a number at once when he received a blow on his head from somebody's knee. He came to the ground at the moment and felt his leg limp, but only for a brief time, so that he got up and went on with the game. Two weeks later he was playing basket-ball and was again struck on the head and again felt the leg limp and tingling. After that he received in wrestling and on other occasions blows about the head, and on several such occasions this tingling and weakness came in the leg. In November, after being fatigued through one of these contests, he felt of a sudden his leg getting rigid and a sensation passing up the leg to the arm and the face. He was able to ask his friends to do certain things for him, but at the end of about two minutes he lost consciousness and was unconscious twenty minutes. The same thing happened again about seven weeks ago. Now he has a nearly complete foot similar to that which the last patient had when he first came to the hospital. There is no other sign of cerebral injury, but the paralysis is becoming rather more intense and perhaps more extensive. The knee-jerk is exaggerated and there is a distinct ankle-clonus.

PERINEAL PROSTATECTOMY.

BY F. B. HARRINGTON, M.D., BOSTON.

I SHOW a case of perineal prostatectomy done six weeks ago. It is a conservative prostatectomy in which the ejaculatory ducts have been saved. You will see a small curved scar in the perineum. Two weeks after operation the perineal tube was taken out of the bladder and he then could pass his urine voluntarily and has ever since. He has still a little leakage by the perineum and about an ounce of residual urine. The urine is in good condition. He had a good deal of cystitis when he came in and had spent all his money and time in trying to get relief. He is now a happy man.

Young of Baltimore described this operation in June and his paper is published in the *Journal of the American Medical Association* in October. It is one of the clearest and best descriptions of an operation I ever saw. It does not mean an operation which is to do away with the Bottini. I think the youngest man here can remember when physicians and surgeons practiced and taught that a hernia which was well held by a truss and which gave no trouble should be let alone and operation only done when a truss could not be worn. Now if a patient is in good health we recommend operation as a rule even if the hernia gives little or no trouble. I have always believed that if we ever got a good operation for the prostate we should recommend an operation as soon as a man came to catheter life, not waiting until they came with diseased kidneys and bladders. Such an operation I believe this of Young to be.

Young had operated in June on fifteen men. He said he believed in every one the sexual power had been retained. He was quite certain there had been no injury to the vas or to the seminal vesicles and he does this in this way: An inverted V is made in the perineum down to the urethra having separated it so that the rectum drops away from the prostate; this is done very easily and you have a clear space to operate in. Through the membranous urethra this tractor is put into the bladder and opened. It takes hold on both the lateral lobes and you have a powerful instrument with which you can drag down the prostate getting it well into the perineum. Having brought the prostate into view you make incisions on either side of the urethra. You are guided by this retractor. You make a direct incision along the side of the urethra for a considerable distance down, perhaps one-fourth to one-half inch. You dissect with a blunt dissector the prostate on either side away from the sheath. After you get down towards the bladder you put your finger in. You feel the wings of the instrument. You can very easily go in and shell out the prostate without injuring the urethra which I cannot do by the Alexander operation. You also do not injure the ejaculatory ducts. Dr. Young has rightly designated it conservative prostatectomy. I believe it has a great future.

FINNEY'S OPERATION FOR PYLORIC STENOSIS: SUDDEN DEATH IN STATUS LYMPHATICUS.

BY JAMES G. MUMFORD, M.D., BOSTON.

I PROPOSE to report two cases.

The first case is one of Finney's operation for pyloric stenosis and I am reporting it because I find that it is the first one to have been done in this hospital.

CASE I. The patient was a woman of forty-six, who had suffered all her life from "indigestion." Ten weeks ago she began to have pain about an hour after taking food; the pain was relieved by vomiting. In the course of a few weeks nausea and vomiting increased until at the end of a month she is stated to have vomited all food taken. The pain was in the epigastrium.

She was nourished by enemeta for a time and finally was sent into my wards by her physician, Dr. Winslow, for operation. I found her extremely emaciated and with the symptoms as described. The abdomen was boat shaped, the walls flexed. There was slight gastric dilatation but the gastrectasis was less than one might have expected. The stomach capacity was about fifty-six ounces, and the greater curvature descended only to the umbilicus. There was no ptosis. Free HCl was present, but no lactic acid.

As in so many of these cases, cancer of the pylorus was strongly suspected though no tumor or induration could be determined.

On Jan. 1, I cut down upon the stomach and found it corresponding in size to what we had made out previously. There were adhesions between the stomach, transverse colon and duodenum; the duodenum especially was adherent to the stomach, causing a sharp kink at the pylorus which was thickened by the scar of what was probably an old ulcer. The finger and thumb could not meet through the contracted opening.

Finney's operation of gastroduodenostomy through the pylorus was done. I think it unnecessary to describe this method of operating, as it has been familiar to all readers of medical journals. Suffice it to say that a very free opening was made between the stomach and duodenum, an opening through which one could easily pass three fingers.

The woman recovered promptly; there was little vomiting. On the second day she was taking liquid nourishment and on the seventh day she was eating hearty house diet. She has gained fifteen pounds since the operation and is now perfectly well, reporting that never in her life before has she known what it was to be so free from indigestion. She promised to report here to-night, but I regret to say she has not come in to show herself.

CASE II. This case has two points of interest connected with it. The patient was a young man of twenty-one, with a tumor of the lower jaw which had existed two years. A few days ago I cut down upon it and excised it with about five inches of the jaw, including the symphysis. A few glands in the anterior cervical triangle were removed. The tumor proved to be a round cell sarcoma.

The first point of interest in the case is, that as a preliminary to the operation, I cut down upon and controlled the common carotid on the right side by the use of this little control clamp, devised by Dr. Crile of Cleveland. As you see it is a device resembling a small clothes pin. While putting it on I explained its uses to the students present and warned them that it must be applied with care so as not to

bruise the intima of the vessel and so run the risk of thrombosis and embolism.

The use of the clamp gave me an almost bloodless field to work in, very satisfactory in operations on the face. I have made a practice for two or three years of controling the carotid in these operations and have never met with an accident. The operation in this case was brought to a successful termination and the patient left the table in good condition, with a pulse of 90.

About half an hour afterwards he suddenly died, and naturally my first thought was that he had died of embolism.

Dr. Oscar Richardson made the autopsy and will give you a statement in a few minutes. He found a persistent enlarged thymus gland, characteristic of the status lymphaticus, and with your permission I will read the following paragraph on this subject, written by Dr. Osler:

"What has directed the attention of writers more particularly to this condition is the frequency with which it has been found in cases of unexpected death from very trifling and inadequate causes. A good deal of attention was directed to the subject by the death of the son of Professor Langerhans, of Berlin, immediately after the preventive inoculation with the antitoxin of diphtheria. In another child death occurred under similar circumstances. The condition has also been met with in a number of cases of sudden death under anesthetics, and I know of one instance during anesthesia for adenoid growths. The whole question is one which deserves the most careful study. The anatomical features appear fairly well defined. The clinical features are by no means so clear, nor is it at all certain in what way sudden death is caused in these cases. The students of the question have, however, in the past few years brought forward evidence enough to show that the subjects of this lymphatic constitution have a diminished vital resistance, and are especially prone to fatal collapse under ordinarily very inadequate exciting causes."

Dr. Oscar Richardson: This case which Dr. Mumford reports belongs to a large group of cases which have been recorded from time to time by many different observers. They have all been associated with sudden death without apparent sufficient cause and with certain definite anatomical conditions at autopsy. These conditions are a more or less hypertrophied thymus gland associated with more or less hyperplasia of the lymphatic glands and hypoplasia of the aorta. The hypertrophy of the thymus is the most constant factor in these cases. The condition is known as status lymphaticus or constitutio lymphatica.

On examination of Dr. Mumford's case the body was found to be that of a young man of twenty years of age, fairly well developed and nourished and presenting an operation wound in the region of the right side of the face and neck through which a portion of the jaw had been removed. On section, no evidence of thrombosis was found; the brain was not remarkable and the thoracic and abdominal viscera showed nothing worthy of note, except for the presence of hemorrhagic edema of the lungs, a persistent hypertrophied thymus, a very small aorta and hyperplastic mesenteric and cervical lymphatic glands. These anatomical conditions clearly classify the case as one of constitutio lymphatica.

Various theories have been propounded as to how death is brought about in these cases of constitutio lymphatica but they are generally inadequate. The supposition, however, in regard to certain cases which occur among young children, that death is due to pressure on the trachea and nerves seems reasonable. Some experimental work has been done in regard to the poisonous nature of extracts of the thymus but without solving the question. In a recent paper Blumer calls attention to an hypothesis that the condition known as status lymphaticus is probably associated with, if not due to, a condition of intermittent lymphotoxemia. It is interesting to note in the report of a case of dyspnea in an eight weeks old child, quoted by Blake in the Annals of Surgery, that an operation was performed in which the cervical portion of the thymus was removed and the lower half pulled up and anchored high with stitches. The dyspnea ceased and the child made an uneventful recovery.

ACTION OF RESORCIN.[1]

BY F. C. CLARK, M.D., PROVIDENCE, R. I.

In all the literature thus far published, relative to resorcin, there has been nothing said in regard to its action whether as an internal or an external remedy. Unless an attempt is made in this direction there can be no headway secured in the employment of any new remedy, and medicine will sink into mere empiricism.

I propose to make a few remarks which I hope may be of some service in this connection. Although my experience has been small compared to that of many other physicians, in the use of this remedy, I trust that my efforts may not be for that reason less respected.

It is as an external remedy I shall speak of resorcin, and of its use in eczema. From this I shall deduce a few conclusions which will lead, I trust, to the further investigations of others in wider fields.

Although the number of remedies for eczema rubrum is legion, there has yet been found no specific on which to depend for any absolute cure. However, there are certain remedies upon which we can rely to ameliorate if not shorten the disease, by allaying certain disagreeable features as they occur. In resorcin, I think, may be found a valuable remedy. But whether it cuts the disease short is a matter of opinion.

In the inflammatory stage of eczema accompanied by intolerable itching, burning or smarting, or all three, resorcin is, perhaps, almost infallible. Its action here is anodyne. It almost

[1] So named by Hlasiwetz and Barth (1862), its discoverers, who first obtained it from certain resins. For best accounts of this drug see Squibbs' Ephemeris in course (1888, fol.).

immediately after application relieves either of these three conditions, and the patient is made at once comfortable. It is surprising what benefit may be derived from a comparatively small amount of the drug. Its superiority to diachylon ointment (ung. diachyli) and the various other preparations is most marked. Hence its chief action is to reduce inflammation and soothe irritation. This result has followed so many times in my hands, that I cannot think it is entirely accidental or coincidental.

Thus noting its action, we come to its application. For this purpose two methods may be employed, — in solution or as an ointment. For the first dissolve 20 gr. of resorcin in an ounce of water, thus making a 4% solution. A stronger solution may be employed if found necessary; but this strength has answered thus far in my hands very well.

The application may be made on strips of linen, or lint cut to the desired size saturated with the solution and then laid over the inflamed surface. The slightest covering over this should be laid, just to keep the application in place. A gauze bandage may be sparingly applied when possible, as over a limb or around the neck or body, etc. It is unnecessary, perhaps, to say, that strict cleanliness should be observed in every application. The solution may be used indefinitely; that is until the disease is under control, or harm follows.

I prefer, however, except in some cases, the use of a resorcin ointment. To every ounce of zinc ointment (ung. zinci oxidi benzoati) 20 gr. of resorcin are added. Instead of the zinc ointment cold cream may be used (ung. aquæ rosæ). Sometimes from 5 to 10 gr. of salicylic acid may be added to the resorcin ointment. A good prescription is this:

℞. Resorcin ℈ij
Oxidi salicylici gr. x
Unguenti Zinci oxidi benzoati ad ℥ij

Apply every night or oftener as the condition requires. In preparing this prescription the resorcin and salicylic acid should be dissolved in alcohol to assure perfect union, then the zinc ointment is warmed over a slow fire and the alcoholic solution of the two added, or, if powdered, rubbed together and sifted in; the whole cooled slowly and stirred until sufficiently cold. By this method a more fluid and intimate mixture may be obtained.

The salicylic acid acts, probably, as a mild antiseptic. Cold cream and resorcin answer very well together; but I think greater healing properties may be ascribed to the zinc ointment in combination with the above remedy. Olive oil is also a good menstruum; so is linseed oil or lard, especially when large surfaces are to be treated, having here the advantage of cheapness.

Constitutional treatment, however, is not to be neglected in case it should be required; for resorcin is not a specific. Whether it only possesses palliative powers or is also remedial, in the sense of cutting short the disease, I am unable to say. At least the patient is rendered more comfortable during the inflammatory and irritable stages of the eczema. It is a good remedy, but must not be overrated, which has been the fate of many new remedies when based on empiricism or enterprising advertisements.

The stains on linen and clothing produced by resorcin can be removed with strong soap-suds. Smarting may be remedied by cold cream or vaseline, should it occur.

From the above remarks the following conclusions may, I think, not unreasonably be drawn; that these and similar preparations of resorcin may be employed in the treatment of all inflammatory surfaces, such as erysipelas, erythema, herpes zoster, etc. Of course, the proportions of resorcin and salicylic acid must be varied to suit the case. Even in small quantities salicylic acid is liable to irritate delicate skins. The smarting, however, is usually but slight and of short duration.

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

PROTOZOA IN A CASE OF ALEPPO BOIL.[1]

A CASE of Aleppo boil in a female child of nine, born in Armenia, that presented itself at the Massachusetts General Hospital in July, 1903, afforded Dr. Wright the opportunity for an investigation, the results of which are most important as regards the pathology of this disease. The lesion, which occurred in the skin of the left cheek near the mouth, was excised and from it smear preparations were made and stained in various ways. In these preparations peculiar bodies were seen. They were best demonstrated in preparations fixed in pure methyl alcohol, and afterwards stained with Romanowsky staining fluid for blood films. They were generally round, sharply defined, and exhibited an unstained, or white, central portion, while a large part of their peripheral portions was stained blue. In each of these bodies a larger and a smaller lilac-colored mass could be shown. These bodies were present in very large numbers in the smears, often occurring in aggregations associated with a large nucleus. Microscopic examinations of sections of the material which had been fixed in Zenker's fluid showed a very extensive infiltration of the corium with cells, a type of plasma cells, various kinds of lymphoid cells, and large cells with large nuclei and a considerable amount of cytoplasm in which there were many micro-organisms. Wright regards them as proliferated endothelial cells. The micro-organisms are almost exclusively in these cells, many containing twenty or more. On account of the constant morphology and structure of these bodies, their great numbers, their position in cells, and the different staining of their parts, the belief that they are micro-

[1] By J. H. Wright, M.D. Jour. Med. Research, Nov., 1903. Jour. Cut. Dis., Jan., 1904.

organisms and are the cause of the lesion is justified, and it is evident that they must belong among the protozoa. The writer is, however, unable to give a definite opinion as to their position in classification. He proposes the generic and specific names Helcosoma tropicum.

No pathogenic effect was noted from the inoculation of a rabbit with a part of the material subcutaneously.

Aleppo boil, as is well known, is endemic only in tropical and sub-tropical countries, where in certain localities a large portion of all the inhabitants are affected. It has generally been believed to be of an infectious nature, and capable of transmission from one person to another by inoculation; and there is evidence that it may be carried by mosquitoes and other insects. Many have tried to find the infectious agent, but with no very positive results. Cunningham, in 1885, described a large number of peculiar bodies in a specimen that had been put in alcohol immediately after its removal from Delhi. The writer considers that these bodies were not proved to be of a parasitic nature, although it seems probable that he did see the large cells described above among the various bodies that he regards as parasites.

Riehl, in 1886, described, as the result of his examination of a case, many large epithelioid cells among the infiltrating cells of the lesion which contained in their cytoplasm many bodies which he regarded as micrococci with capsules, frequently more than twenty in a cell. Wright states that in thicker sections the protozoic micro-organisms give to the large cells in which they are contained the appearance of basic staining granules about the size of pus-cocci, each surrounded by a clear space. He does not doubt that the appearances described by Riehl as micrococci with capsules and contained within the cells, represented the protozoa as they appeared under these conditions.

ARSENICAL DERMATOSES.[2]

Rille doubts the well accepted view that herpes zoster may follow arsenical treatment, and also, with more ground, the view that arsenic may give rise to alopecia areata. With regard to the keratoses which follow the use of arsenic, he has never seen them occur in cases of cutaneous affections such as lichen planus, even where large doses of the drug were administered. On the contrary, he cites the case of a young girl who was affected with a general pruritus and lympho-sarcoma. After treatment with Asiatic pills, an intense keratosis of the hands appeared. Having failed to observe this keratosis in cutaneous patients who were affected with psoriasis and lichen planus and treated by arsenic, he is convinced that it is very rare in subjects affected with cutaneous disease, while it is more common in those treated for other affections. It would appear that the writer's experience must have, by simple chance, differed from that of most dermatologists, as the association of zoster and keratosis of the palms of the hands with ingestion of arsenic for cutaneous, as well as for other diseases, must be regarded as an absolutely settled point.

DESQUAMATION OF THE HANDS IN PATCHES, OCCURRING IN SUMMER.[3]

This paper, which is from the Dermatological Clinic of Bordeaux, deals with two forms of estival desquamation of the hands which recur each year.

The first, and more common form, is seen exclusively in warm weather, from June to September. A great many people, of all ages and both sexes, are affected, and the course is the same in all. It has no connection with an habitual hyperidrosis. The lesions are situated on the palms of the hands, and on the palmar aspect of the fingers, seldom on the lateral surfaces, and never on the dorsal surfaces. They appear as small white spots of a rounded form, from the size of a pin's head to that of a large pea. These spots are formed by a layer of exfoliated epidermis of great thinness. They are never associated with any exudation. Beneath the scales the epidermis is slightly redder than normally and absolutely dry. The course of these lesions is very short, lasting scarcely twenty-four to forty-eight hours. They recur, however, as rapidly as they disappear, and the people affected are not free from them during the whole period of summer. They disappear with the first frost, and are never accompanied by any painful symptoms. Of these cases a large number were observed, one of which, that of a student of medicine, is described in detail.

The second form is much less common than the preceding, and the writer has been able to collect but three cases. The lesions are much more extensive, deeper, and more lasting than those just described. Manual labor does not seem to be a factor in their causation. This form also appears only in the warm season, but when once affected, the patient is invariably visited each year. Here, too, the palms of the hands and the palmar aspects of the fingers are the parts affected. The hands are dry, without hyperidrosis. These scaling patches vary in size from a bean to that of a franc piece. They keep on enlarging for two or three weeks, when the epidermis breaks and exfoliates. There is never any redness, infiltration, or induration of the skin, nor are there any subjective sensations except, perhaps, a slight burning. The evolution of a single lesion varies from twenty days to a month. Frequently new lesions appear immediately over the old ones.

In discussing these cases, the writer speaks of the analogy that they bear to dysidrosis, especially to the slight form of this disease which is common in hot weather as small vesicles on the sides of the fingers, which are followed by appearances not unlike those here described; but in these cases there is no preceding vesicle.

The most effective treatment that was tried

[3] Annal de Derm. et de Syph. April, 1903. A. Sarayon.

seemed to be wrapping the hands in compresses wet with a one per cent watery solution of resorcin, and covering with wax paper. If this application is continued through the night, desquamation is furthered and the keratinization is modified.

GRANULOSIS RUBRA NASI (JADASSOHN).[4]

This peculiar disease was first described by Jadassohn in 1901. It is characterized by a local erythematous area on the tip of the nose, covered with small macules and papules, with an oily seborrhea, and also a hyperidrosis of the hands.

Macleod's case concerned a delicate boy of six, who had always been nervous, but free from any especial disease. The lesion on the nose began at the age of six months, when his mother noticed that the nose was always red and covered with perspiration, and also that his hands were moist. The trouble was said to be more pronounced in summer than in winter.

When seen there was a hyperemic patch extending from the tip of the nose up to the bridge, and spreading laterally as far as the middle of the alæ. The patch was symmetrical, not definitely bounded, and covered with punctate beads of perspiration. The most prominent feature of the patch was the presence of a large number of small discrete macules and papules, brownish red in color, varying in size from a pin's point to a pin's head. There was hardly any infiltration, but the papules gave it a granular feeling, which had suggested the name granulosis. There was some passive congestion of the hands, which were moist from hyperidrosis.

Histologically all that was seen was a slight parakeratosis around the sweat pores, but the piece excised was of limited size. Other observers have found the chief pathological changes in the corium, with a dilatation of the blood capillaries and a perivascular infiltration of leucocytes, connective tissue cells, mast cells, and plasma cells. The lumen of the sweat coils was widened and contained a granular débris, while the walls of the coils were thickened. There was little change in the sweat ducts. Jadassohn thought from the histology that it was a chronic inflammation originating in the vessels around the sweat coils. Harrmann was unable to find these changes around the sweat apparatus. Macleod considers that the two cases of Pringle's, which were described as hydrocystoma in 1894, were examples of this affection.

The treatment that was adopted in this case consisted of various pastes containing salicylic acid, and general hygiene. No distinct improvement could be detected at the end of two months. Macleod believes that this is a distinct affection, which is peculiar to young subjects, disappears spontaneously when adult life is reached, begins early in life and affects weakly children who are apt to have a weak circulation and hyperidrosis of the hands and feet. The course of the disease is very chronic, and it is very rebellious to treatment. Macleod thinks that it is probably a simple inflammatory disturbance, secondary to hyperidrosis, and associated with local vasomotor derangement. He considers that it has a close analogy to prickly heat.

[4] J. M. Macleod. British Journal of Derm., June, 1903.

TREATMENT OF LEPROSY.[5]

Brault treated in the hospital at Mustapha thirteen lepers from January, 1902, to October, 1903. Most of the cases represented mixed forms. In one case, it was almost entirely of the tubercular form, and in another entirely of the anesthetic, or nerve, type. On account of this large number of cases, to which were added several others seen outside the hospital, a good opportunity was afforded to try different methods of treatment. Anti-diphtheritic serum was tried in two cases. They received in all six injections, one every second day. An intense fever was excited, and the method had to be abandoned, without any appreciable improvement in their condition.

Chaulmoogra oil, given internally or by injections, is a method of which the advantages did not seem to compensate for its drawbacks. A short time before a patient had died of Bright's disease, who had taken very large doses of this drug, up to 250 drops a day. The author also speaks of a patient in whom the remedy had been used as high as 300 drops a day, who also presented signs of nephritis.

Unna's treatment was tried in the case of a patient who had got to the last stages of the disease and was already cachectic, and who had large ulcerations over the thighs. In this case the ulcerations were healed under ichthyol internally and external applications of the same drug; but the author calls attention to the fact that hygienic measures which were employed at the same time probably had much influence. Later, however, the patient began to lose ground, in spite of a continuance of the treatment. Several cases were treated by injections of calomel and of biniodide, with amelioration in almost all cases. Injections of sublimate proved rather unsatisfactory. On the whole, the writer considers that treatment by mercury is better borne than most of the other general methods. One advantage of this method, he thinks, is its moral effect, in that the patients do not suspect from it the nature of their trouble and are spared extreme mental depression. Various topical applications were tried, such as collodion, with the addition of the biniodide or sublimate, upon tubercles and non-ulcerated lesions, but with only meagre success; and airol and ichthyol proved of distinct value.

In conclusion, the writer considers it indicated above all to ameliorate the life of the lepers by a thorough use of all the measures that are afforded by hygiene. With regard to therapeutics, properly speaking, the writer is rather more reserved because there is so often spontaneous improvement in this disease and because of the danger of injuring the patient by powerful drugs.

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

Stated meeting, Feb. 2, 1904.

Dr. Joseph Fraenkel, President *pro tem.*, in the chair.

A CASE OF HUNTINGTON'S CHOREA (DEGENERATIVE CHOREA) WITH LIMITATION OF THE MOVEMENTS OF THE FACE AND EXTREMITIES OF THE LEFT SIDE.

Presented by Dr. J. Ramsay Hunt: The patient was an Hungarian, thirty-three years old, the youngest of seven children. He had been a resident of the United States for six years. No history of choreiform movements in his antecedents could be elicited. From the patient's sister it was learned that he was extremely dull, even as a child, and lacked interest in his studies. For the past three years he had twitching movements of the left upper extremity, confined chiefly to the fingers and wrist of the left hand. Similar muscle-twitching was also present in the left lower extremity, consisting of slight flexion movements in the ankles and toes. Occasionally, the left quadriceps extensor contracted, elevating the patella.

The face was the seat of irregular grimaces and twitchings, and the latter were also present in the tongue, interfering at times with speech. These movements were at no time violent, and seemed to be increased by voluntary movements of the parts. The left upper extremity was complained of by the patient as feeling cold and heavy, and interfering with finer movements of the hand, such as eating.

Mentally, the patient was dull. He was cranky and irritable at times, careless in his dress, and was unable to obtain any employment. At times, he had mild acute mental symptoms and apparent hallucinations. He had complained of frontal headaches at intervals since the onset of the trouble. Otherwise, the examination proved negative. Muscular power was unimpaired; there was no ataxia; no sensory disturbances. The pupils and all reflexes were normal. He had never had a convulsion.

Dr. Hunt said that the character of the twitchings, although slight and limited to the left side, resembled those observed in Huntington's chorea. The constancy of the symptoms, the pronounced and progressive character of the mental changes even in the absence of heredity pointed very strongly to a degenerative form of chorea. An initial psychosis with secondary motor manifestations would deserve consideration in the differential diagnosis.

A CASE OF MULTIPLE CEREBELLAR TUMORS.

Specimen shown by Dr. B. Sachs: The patient was a boy, seventeen years old, a native of Russia, who was admitted to Mount Sinai Hospital on Nov. 8, 1903. He complained of vague symptoms, and was discharged after a few weeks with the diagnosis of neurasthenia.

He was re-admitted to the hospital on Dec. 19, and stated that for eight weeks previous to Nov. 8 he had suffered a great deal from occipital headache, daily vomiting, difficulty in speech and unsteady gait, associated with dizziness.

When Dr. Sachs first saw the patient, on Dec. 28, he found, in addition to the subjective symptoms above mentioned a very distinct scanning speech similar to that of multiple sclerosis. There were marked ataxic movements of the left upper extremity, a distinct titubating walk, and double optic neuritis. A second examination on Jan. 3, 1904, showed an increase in the ataxic tremor of the left upper extremity, which was also somewhat weaker than the right. The knee-jerks were present, but not exaggerated. There was slight ataxia of the left lower extremity; a marked plantar reflex; no Babinski. The scrotal reflex on the left side was increased; also the abdominal reflex on that side. There was no difference in the facial innervation, but some weakness of the left external rectus. On Jan. 8, Dr. Gruening reported that the optic neuritis was progressing, and that there were hemorrhages in the fundi. Hearing was normal.

On Jan. 15 the patient's skull was trephined for the purpose of relieving pressure and preventing the development of total blindness. The patient died from shock a few hours after the operation.

CEREBRO-SPINAL LUES (SYRINGOMYELIA SYMPTOM COMPLEX).

Presented by Dr. Isador Abrahamson: The patient was a male; thirty-five years old; single; a peddler, and a native of Roumania. When he was eleven years old, after a fright, he became blind in the right eye and the vision of the left eye became impaired. Some improvement in sight occurred within two months.

When he was sixteen years old he contracted a chancre, with the usual secondary symptoms. He was treated for this disease for one year with both external and internal remedies. He was moderately addicted to the use of alcoholic stimulants, and smoked excessively.

This case, which was reported in detail by Dr. Abrahamson, was probably one of cerebro-spinal lues, presenting the syringomyelic symptom complex, or else it was a case of syringomyelia, plus lues, or possibly of luetic origin. Such cases, the speaker thought, were rather uncommon, and were naturally of considerable clinical importance.

Dr. Sachs, in discussing this case, said he had seen some cases which, while luetic, presented the clinical aspect of syringomyelia. He regarded these cases as examples of cerebrospinal lues, not luetic syringomyelia.

FLACCID LUETIC HEMIPLEGIA WITH ATROPHIES.

Presented by Dr. Abrahamson: The patient was a male; twenty-six years old; married; a Russian peddler. He was an excessive smoker and used alcoholic stimulants in moderation. He had lues four years ago. Ten years ago he had an attack of parasitic alopecia, and six years ago he sustained a severe fall. This resulted in a Colles' fracture and he was said to have been unconscious for a long time.

About two months ago he was obliged to remain in bed for three weeks on account of stiffness of the neck, violent neuralgic occipital pains, and headaches, chiefly nocturnal. During the third week of this illness he began to suffer severe right-sided headaches, with vertigo.

Three weeks ago, while in a café, he felt dizzy and staggered as though drunk. He fell to the floor and found that the right side of his body was numb and paralyzed. Speech was also lost. This condition lasted about five minutes, when he apparently again felt normal. A short time afterwards he had a second attack lasting five or six minutes, and in the course of two hours he had four additional similar attacks. From the sixth attack, however, he failed to recover; speech was lost for four days and the paralysis still persisted.

At the present time there was paralysis of the lower two thirds of the right face and of the right upper and lower extremities. There was dropped wrist and

foot of the right side, flaccidity of the right hand and forearm; also the leg and foot. Decided wasting in right posterior forearm musculature; also, but to a lesser degree, in the right leg. The electrical reactions in the posterior forearm were much diminished; myotatic irritability diminished; sensibility intact; heart normal.

Dr. Abrahamson said that in view of the electrical changes, the marked wasting, flaccidity and altered myotatic irritability, all occurring within three weeks after the onset of the attack, he felt justified in calling the case a flaccid hemiplegia with atrophy.

JACKSONIAN EPILEPSY OF LUETIC ORIGIN; IMPROVEMENT UNDER ANTI-LUETIC TREATMENT.

Presented by Dr. Abrahamson: The patient was a male; thirty-nine years old; a shoemaker by occupation and a native of Hungary. He was married and the father of eight children, of whom six were living. His first wife had three miscarriages occurring about the third or fourth month. The patient had typhoid fever in childhood. He was a heavy smoker and a moderate drinker. He positively denied venereal infection.

His present illness dated back to Dec. 15, 1903, when he began to suffer from frequent attacks which were ushered in with a feeling of numbness in the right hand, followed by a drawing in of the thumb, flexion of the fingers and semi-pronation of the hand. The numb sensation spread to the shoulder, then down to the hip and feet. He complained of weakness of the leg and had to sit down to keep from falling. Speech was also temporarily lost. Each of these attacks, which sometimes occurred at hourly intervals, lasted about fifteen minutes, and were followed by some weakness of the right side and slight dizziness. He also complained of left-sided headaches and slight nausea and epigastric distress at the end of the attack. There was also rolling of the eyes during the attack, and rolling of the tongue upon attempting to speak. No frothing; no biting of the tongue; no diplopia. Micturition and defecation were not affected. There was no loss of consciousness.

An examination showed that the right pupil was larger than the left. The pupillary reactions and ocular movements were normal. There was weakness of the entire right half of the body, including the lower two thirds of the face. There was some exaggeration of the deep reflexes on the right side. The special senses were normal. The eyes showed a beginning papillitis.

The patient was put upon inunctions of mercury and large doses of potassium iodide. At first, the weakness on the right side increased, and a right hemianesthesia of somewhat irregular distribution developed. Subsequently, he improved rapidly, and at the present time he had entirely lost his attacks, the right-sided weakness was much less, and only scattered areas of diminished sensibility were present over the right side.

ARTERIO-SCLEROSIS OF SPINAL CORD, WITH HEMORRHAGE.

By Drs. Joseph Collins and Edwin G. Zabriskie: M. H., a fireman, with no particular antecedents, noticed toward the end of 1902 fatigue on exertion, jerking sensations, occasional sharp pains in lower extremities, and a sensation of heaviness, accompanied by difficulty in holding his urine. These symptoms steadily progressed, until he awoke one morning and found himself unable to stand or walk. There was also incontinence of the bowels and bladder.

On examination, it was found that he was unable to flex his thighs slowly, and there was slight atrophy of the left anterior and inner thigh muscles. The reflexes were absent; Babinski's phenomenon present. Power in the upper extremities was fair, but he was easily fatigued. There was slight quantitative diminution of sensation in both lower extremities, and a zone of hyperesthesia as wide as the hand above the trochanters. There was slow speech and mental reflex. Also a moderate degree of general arterio-sclerosis. Death supervened gradually of cardiac weakness.

Autopsy. — Macroscopically, there was arterio-fibrosis everywhere, only slightly marked in the brain and bulb, but very marked throughout the cord. The vessels were distended with blood, and there was some extravasation into the perivascular spaces. The changes consisted in thickening of the media and propria, with loss of muscular tissue. A hemorrhage was found in the ninth dorsal segment of the cord, involving the right posterior and left anterior horns. There was sclerosis of the glia around the margin of the cord and in the lateral pyramidal tracts. Secondary degenerations were found in marginal portions of the right column of Goll, Gowers and the direct cerebellar tracts on both sides above the lesion, and the crossed pyramidal tracts, and columns of Turk below the lesion. There was no definite degeneration of Schultze's tract or the other descending tracts of the posterior columns, excepting in the lower lumbar region, where a small area in the triangle of Gombault and Phillippe was apparent.

Dr. Zabriskie said it was interesting, in view of the difference of opinion as to the origin of the fibres in the descending tracts of the posterior columns, to note that in this case, although the right posterior horn was almost completely destroyed, the comma tract and areas of Flechsig and Phillippe-Gombault were not involved; this would seem to point to the exogenous origin of these fibres.

(To be continued.)

Recent Literature.

International Clinic. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, etc. By leading members of the Medical Profession throughout the World. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia, with the collaboration of twelve other physicians. Vols. III and IV. Thirteenth series. Philadelphia: J. B. Lippincott Company. 1904.

Volume III of the now well known International Clinics contains lectures on the gall bladder and gall ducts, on the treatment of certain common and important diseases, various discussions on topics in general medicine, and several surgical papers of importance.

Among other lectures on a great variety of subjects, the fourth volume contains a discussion of the present state of our knowledge of immunity by Dr. Joseph McFarland.

These clinics are always readable and valuable inasmuch as they are distinctly expressions of personal opinion on topics in which the authors are particularly versed. The form of publication remains unchanged.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 5, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

USE OF PUBLIC INSTITUTIONS FOR CLINICAL INSTRUCTION.

It has been interesting to observe, during the past few years, the gradual disappearance of prejudice against hospitals. Not many years ago, a hospital for general disease, not to mention those concerned with the treatment of the insane, was regarded as a place to be avoided rather than one to be sought by the critically ill. A gradual and natural change of attitude has come about, so that at the present time general hospitals, at least, are overcrowded with applications for admission, and the feeling against them, although at times met, is far less in evidence than it was ten years ago. For somewhat obvious reasons the prejudice against hospitals for the insane still exists, but here, too, it is evident that this feeling is gradually giving place to a more rational attitude. A natural tendency of this disappearance of prejudice has been the somewhat phenomenal expansion of hospital facilities, the foundation of new hospitals, both municipal and suburban, and the general use of such hospitals for the purposes of medical investigation and teaching.

Another curious prejudice, which likewise in great measure is passing, is the feeling that the medical student is in some way a dangerous and unprincipled person. The origin and persistence of this idea is no doubt based upon certain fancied or real attributes of the student of medicine, which the difficulties of acquiring necessary knowledge in years gone by forced upon him, a state of things happily at an end. In the second place the inexperience of the student, and his supposed active participation in the treatment of patients in hospitals, has led to a somewhat natural feeling of distrust on the part of the laity. All this also apparently is at an end for reasons which are too obvious for us to enter into here. The public is gradually, though with some difficulty, being educated to the feeling that the presence of the medical student, and the general medical interest which his presence implies, is a benefit rather than a detriment. In general, it may be safely said that the more examination and the more attention given to a given case the more adequate and satisfactory will its treatment be. This is clearly brought about by the presence of students in the wards of hospitals and institutions.

It should therefore be the aim of all public and semi-public institutions, which have to do with the care of the sick, to encourage the visits of medical students, under proper direction, for the purpose of observation and study of the patients there treated. We have long been impressed with the fact that, although our large municipal hospitals, here and elsewhere, are adequately used for purposes of medical instruction to the unquestioned benefit of the institutions as well as to the students, many other institutions affording excellent opportunities for the study of special cases are wholly neglected. This, we take it, does not arise from a lack of interest on the part of those controlling the institutions, but rather from the lack of initiative on the part of medical schools whose students might profit by the instruction which such institutions may afford. This opinion is reinforced by the fact that, in a recent conversation with one of the trustees of the Massachusetts Hospital for Epileptics, he said that the board of trustees and the management in general would be entirely willing to open the doors of the hospital for purposes of medical instruction to selected groups of students. In a recent report also of the Massachusetts School for Feeble Minded, the superintendent, Dr. Walter E. Fernald, makes the following statement:

One of the functions of a school of this sort is to provide clinical instruction for medical and other students. Graduating classes of medical students from Tufts College Medical School, the Boston University Medical School, and usually from the Harvard University Medical School, visit the school once or more each year, and are each given a clinic, where they are shown groups of cases illustrating the various types of mental defect. Hundreds of physicians now in practice in this and other states have thus been familiarized with this important form of mental disease. Classes from

Wellesley College, Harvard University and the State Normal schools also visit the school, to observe matters of psychological or pedagogical interest. Many teachers and superintendents of schools visit and observe the school classes.

That such a liberal attitude should be of great and distinct advantage to classes of students, and indirectly to the institution, is sufficiently self-evident. These two instances may serve as examples of the feeling which we are sure is widespread among men at the head of various institutions. Unquestionably the student derives a lasting impression from the observation of large groups of cases of similar character which he could hardly attain by the sporadic appearance of such cases at other less special hospitals. It is, therefore, to be regretted that more effort is not made on the part of authorities of medical schools to institute regular instruction at public institutions in the neighborhood of medical centers.

Information of great value to the student could be had in this way in tuberculosis, various forms of mental enfeeblement, epilepsy and its associated conditions, as well as in the great group of the insanities. It is furthermore not to be doubted that if interest were once excited in developing and using such institutions more systematically for medical instruction, opportunities now not thought of would rapidly develop. That sustained objection to the visits of medical students to institutions of this character should longer be made is not to be considered in spite of the fact that we may well expect occasional sporadic objections on the part of persons not thoroughly informed, or influenced by ulterior motives. The education of the public in such matters must be a gradual process, but the time should now be near at hand when it will be clearly recognized by any one of intelligence, who seriously considers the matter, that the greatest possible usefulness of institutions for the sick will be subserved by the publicity given them through visits of outsiders, and especially of those who have a distinct medical interest.

MEDICAL EDUCATION IN AMERICA FROM A BRITISH STANDPOINT.

IT may be remembered that Mr. A. Mosely, being impressed with the capacity of American engineers in South Africa, in 1902 organized a commission to visit the United States for the purpose of finding, if possible, an answer to the question, "How is it that the United States can afford to pay half a dollar in wages where we pay a shilling and yet compete with us in the markets of the world?" In a general way the answer seemed to depend upon the condition of education, using the term in its widest sense. Among other matters to which the commission gave its attention, was the question of medical education, which was under the charge of Dr. J. Rose Bradford of University College, London, and Dr. W. H. Gaskell of Cambridge.

A recent number of the *British Medical Journal* discusses some of the conclusions reached by the investigation of these men and published in full recently in a volume by Mr. Mosely. Dr. Gaskell comments on the uncertainty at present existing in this country regarding the best methods of instruction, and has found it, therefore, more or less difficult to get a definite idea of immediate tendencies. Many of his comments, however, are significant and of much interest to us as expressing the generous but critical attitude of a foreign observer. He finds, for example, that the tendency, which has become established in the universities of the middle west, not to confine physiology and human anatomy to the medical course one of the most hopeful signs for progress in biology. The separation which he deplores has, perhaps, been carried to its extremest limit in the large eastern universities, and we are inclined to think his implied criticism is an eminently just one, and one to which those concerned with the regulation of the curriculum should give renewed attention. Furthermore, he finds that the term physiology is quite differently understood here and in England. In America there are usually three distinct laboratories which concern themselves respectively with histology, including often embryology, physiological chemistry and physiology proper, whereas in England these subjects are usually included under the general head of physiology.

Dr. Gaskell was impressed with the conscientiousness of the teaching in American universities, with the earnestness of the students, as brought about particularly by the so-called concentration system, and also by the great strain thrown upon the teachers by this method. He says on the subject: "To my mind two of the most striking points about the laboratory instruction of all kinds in the States is the energy and activity displayed by the teachers, their earnest endeavor to do their utmost without sparing themselves, and the determination of the students to be taught."

The laboratories in general he found well equipped, and where modern research had in a measure outgrown the facilities originally provided, he notes the erection of new and adequate buildings, speaking particularly of Harvard and the University of Pennsylvania. In consequence of his very careful observations, Dr. Gaskell is led to make the following suggestions, among others, particularly with reference to medical education in his own country: Separate laboratories with separate staffs of teachers should be provided for anatomy, histology, physiology, physiological chemistry, experimental psychology, and perhaps neurology, the extreme concentration method is not recommended; it is preferable to extend a subject, such, for example, as physiology in the broad sense, over two years; histology should be connected with embryology and put into the department of anatomy, but the laboratories of histology and physiological chemistry should be under the control of the professor of physiology, the head of each department being an assistant professor; it is not proven that didactic lectures are in large measure a mistake and that recitations should largely take their place; a system of seminars is to be encouraged; a six or seven years' conjoint course for the academic and medical degree should be encouraged, and preliminary medical subjects should be included among the subjects for the degrees of arts or science.

Prof. Rose Bradford reports on medicine and surgery, after visiting a number of our medical institutions and also several in Canada. The excellence of clinical laboratories connected with hospitals, the utilization of out-patient departments for purposes of teaching, and the general tendency to make the subject taught as objective as possible by means of drawings, lantern slides, etc., all impressed themselves upon his attention. The recitation system also he regards as a method which has a very distinct educational value. His conclusions are systematically given in his own words as follows:

(1) That the enthusiasm of the teachers and of the students was one of the most striking features of his visit.

(2) All the leading universities had exceedingly fine, and in some cases magnificent, laboratories, and the equipment was of a high order of excellence.

(3) In the teaching of the non-clinical subjects the laboratory and practical side was especially developed.

(4) Systematic instruction by lectures seemed not to be in general favour.

(5) Even in the final subjects (medicine, surgery, etc.) the teaching was extraordinarily systematized; but, speaking generally, the students did not have the clinical facilities they obtain in this country (England).

(6) The scientific investigation of disease in clinical laboratories had reached a very high order of development.

(7) The teachers in this country, in such subjects as pathology, might well consider whether some of the methods in vogue, such as the early study of bacteriology and the custom of giving the class unknown organisms and sections to identify, and the careful record of the students' work, are not features thoroughly deserving of imitation.

Evidently the investigation of our methods, which we have very briefly alluded to above, was undertaken in no carping spirit, and so far as we may judge from the report at hand the impression was that the American system, though possibly still in an experimental stage, may offer suggestions of distinct value to the older schools in England. However this may be, we are more and more impressed with the great desirability of a free interchange of ideas on educational matters. It is difficult for us to conceive in this country of a method of education which shall approach in general character that given in the universities of Germany, but we can easily foresee the time in the two great English speaking countries when the best elements of the educational system of each shall be incorporated in the other. Certainly, that system must finally prevail which will at the same time provide the student with the greatest store of useful knowledge and, far more important than this, with the training which will make it possible for him to acquire knowledge independently. In the attempt to teach many the individual must not be forgotten. Certain elements in our developing system of medical education seem destined to bring this to pass in the greatest possible degree.

REPORT OF THE BOSTON INSANE HOSPITAL.

The report of the Boston Insane Hospital for the year ending Jan. 31, 1904, is a brief document, which nevertheless contains certain statements and suggestions of wide interest. Among the suggestions to which we would call attention is the establishment of a colony for certain of the insane of Boston near the city. It is remarked that all the state institutions, excepting Worcester and Medfield, now have colonies, and that were one established for Boston, it would permit a juster classification, and also would be distinctly profitable to the city through the estab-

lishment of a farm capable of supporting both the hospital in the city and the colony. The colony system for the insane, for the feeble minded, and for the epileptic, as well as for any other class of dependents in the community, has always seemed to us a rational means of meeting the problem. Any method by means of which such charges of the state or city may be made in a measure self supporting is certainly to be regarded as a distinctly progressive step.

The report further notes the fact that the trustees of the Boston Insane Hospital will no longer have charge of the non-insane dependents in the Hospital for Epileptics, in the State Hospital for Dipsomaniacs, and in the School for Feeble Minded, who will hereafter be cared for by the Board of Pauper Institutions' trustees. Dr. Edward B. Lane, superintendent of the institution, notes the fact that the past year has been the most active in the history of the hospital, the daily average population being upwards of 550 persons. The per capita cost for the year was $4.68, slightly more than that of the previous year. This institution, like others, suffered on account of the excessive price of coal, which curtailed the expenditure of money for other needed purposes. In general, the year appears to have been a satisfactory one, and with the completion of new buildings, which have been delayed in construction, the institution will no doubt enter upon another year of even greater usefulness.

We observe that during the year Dr. P. C. Knapp resigned from the position of chairman of the Board of Trustees, after a year's service in that capacity. We note also the resignation of Dr. John J. Thomas as pathologist of the consulting staff, and that no successor has as yet been appointed. It is to be hoped that the trustees of the institution may fully realize the importance of pathological study at an institution of this character, and that the work inaugurated by Dr. Thomas may not be long interrupted.

MEDICAL NOTES.

An Influx of Daughters. — All the alumni of the Harvard Medical School who announce the birth of children in the last quarterly of the Association seem to have been blessed with daughters.

National Academy of Sciences. — At a recent meeting of the National Academy of Sciences, among others, the following men were elected to membership: Prof. Paul Ehrlich of Frankfurt and Prof. William T. Councilman of Boston.

Bequest to Tulane Medical College. — The Louisiana State Supreme Court, meeting at New Orleans, has rendered a decision giving the bulk of the estate of the late A. C. Hutchinson, amounting to approximately one million dollars, to the Tulane Medical College.

New York State Cancer Laboratory. — It will be remembered that the announcement was made some weeks ago that the New York legislature had refused to make the annual appropriation of $15,000 for the support of this laboratory. It is now announced that there has been a change of heart, and that the chief opponent of the item has withdrawn his objection, so that the usual amount will be appropriated for the purposes of the laboratory.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, May 4, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 56, scarlatina 13, typhoid fever 11, measles 190, smallpox 0.

Antivivisection Bill Defeated. — The Committee of the Massachusetts legislature, before which the recent bill for the regulation and control of vivisection was held, has given leave to the petitioners to withdraw. This or a similar bill has had the same fate for several preceding years, and should serve as a further protest against the interference of possibly well meaning but misinformed persons.

Possible Abolition of Department of Statistics.— The Boston Board of Aldermen voted, at their meeting on May 2, to abolish the Department of Statistics The matter still requires action on the part of the Common Council, and will then go to the mayor. The discussion at the meeting of the aldermen showed that their action was the result of the most contemptible sort of petty personal politics, and it hardly seems possible that the other branches of the city government can concur in supporting such a policy.

A Memorial to Dr. John Homans. — Friends and associates of the late Dr. John Homans are desirous that some permanent and useful memorial shall be established in grateful recognition of his earnest, fruitful, and long-continued devotion to the cause of surgery.

It is their aim to raise a fund to be placed in charge of the Corporation of Harvard College, the income to be used to promote the acquirement of knowledge in the science and art of surgery in accordance with the recommendation of the Faculty of the Medical Department of the University.

It is hoped that as much as $50,000 may be contributed for the purpose of establishing a John Homans Professorship in the Harvard Medical School, and it is confidently believed that those who remember Dr. Homans' own loyalty and generosity will be glad to contribute towards the raising of this fund. Subscriptions may be sent to Charles C. Jackson, 15 Congress St., Boston.

NEW YORK.

Cottage Colony for Juvenile Asylum. — Seventeen buildings are now in course of erection in the hill country of the Hudson, near Dobbs Ferry, for a cottage colony to accommodate the New York Juvenile Asylum, which for many years has occupied a single large building at Fort Washington, on the Kingsbridge Road, New York City. This institution cares for a large number of the destitute, deserted and delinquent children of the city, and it is believed that the change to the new quarters will result in the physical, mental and moral improvement of the children. During the fifty-two years of its existence it has maintained and educated more than 38,000 children, and in the last annual report of the asylum the directors say: "The ancestry of the congregate school is not to its credit; advanced opinion is unfavorable to dull, forbidding and convent-like walls. Aside from the unedifying environment, the old system is incapable of reproducing the atmosphere of even an average home. It cannot give an adequate amount of individual attention; character development is necessarily neglected, and classification of children under it is a figment of the imagination. Classification is decidedly one of the desiderata of such an institution, and this is possible only where there are many groups, affording opportunity to take into consideration not only character, but stature and educational advancement." The plot of ground purchased at Dobbs Ferry consists of 277 acres, and the new home of the asylum, which will cost the city about $3,000,000, promises to be one of the model institutions of the world. When it is complete there will be about eighty separate and distinct buildings, including, in addition to the living cottages, a chapel, library, infirmary, schools, gymnasiums, workshops and administration buildings. In separate departments the children will be taught printing, shoemaking, tailoring, carpentry, plumbing and other trades, and the farm on which they will work will be a real farm. To meet the requirements of play there will be athletic fields, ample playgrounds and a campus where the boys will be drilled in military tactics. The cottage homes will eventually number about sixty, forty for the boys and twenty for the girls. Not more than twenty boys, nor more than fifteen girls will be allowed under one roof. Each cottage is to be a completed home, having even its own dining room, and each will be in charge of a "guardian" or "house parent" who will exercise as far as possible the functions of a real parent. All this is certainly very different from the manner of caring for the "charity child" in the past, either in this country or in England, and the results ought to be very gratifying.

Miscellany.

SYLLABUS OF SILLIMAN LECTURES AT YALE UNIVERSITY FOR 1904.

The lectures this year were given by Prof. Charles S. Sherrington, M.D., LL.D., F.R.S., of the University of Liverpool, on the subject,

INTEGRATIVE ACTION BY THE NERVOUS SYSTEM,

beginning April 22 and ending May 4.

Lecture I.

Physiological study of the integration of the animal body by the nervous system. Integration of a simple organism by the primitive nerve-net. The reflex unit: receptor, conductor, effector. Intercalation of the synapse into the conductor. The synaptic nervous system set over the nerve-net. Visceral and vascular innervation. Minute and precise use of time achieved by the nervous system: demand for this unequal in different parts of the organism: the synaptic system supplies it best.

Lecture II.

The synaptic system supplies isolated correlation between distant parts. Subdivision of effector organs and segmentation (metamerism). The segmental concept of the nervous system. The segments of a high type of vertebrate as judged by receptor and effector segmental fields. The nervous system of the segment. The integration of the segment as evidenced by nervous reactions. More minute and precise use of space given by isolated correlation: yet the nervous system remains a continuum.

Lecture III.

More varied use of space given by the synaptic system than by the nerve-net. With complexity of the organism increase in number and species

of receptors means correlation to a greater variety of changes in a greater number of environmental points. Reflex arcs and the principle of the common path. Successive use, not simultaneous use of common paths permitted. The proprio-ceptive field. Its quota of receptors. Characters of its reflexes — maintained, secondary. Nervous background and transient reactions. Spinal inhibition of knee-jerk. The common path acts as a whole. Conflicting arcs. Central inhibition and peripheral inhibition compared.

LECTURE IV.

Common paths in relation to private paths. Centrality of the nervous system. The extero-ceptive division of the surface field and its richness in receptors. Category or extero-ceptors. Skin pain: evidence of specific sense apparatus initiating it: characters of the reactions: nociceptive arcs, facile, protective. Nociceptive reactions prepotent in competition for common paths. Weak and strong reflexes. Reactions to which strong affective tone is adjunct are prepotent: such reactions usually consummatory. Physiological incongruity of nerve trunks; yet yield homogeneous results, because common paths inter-related.

LECTURE V.

Seeming inequality of reflex facility of motor mechanisms in one and the same segment. The extensor stroke. Positive stereotropism. Reflex progression of the limb. Apesthesia. Progression under decerebrate rigidity. Transient and maintained reactions. Forms of reflex contractions: brief, rhythmic, cataleptoid, maintained. Features of conduction referable to gray matter: delay, irreciprocity, summation. Conditions determining prepotency over the common path — quality of receptor, intensity of stimulus, duration of reaction. Central fatigue.

LECTURE VI.

The "scratch" reflex: reaction compared with the cardiac; refractory period; intensity; variation of form, two types of movement; the path of the arcs; proprio-spinal aboral tracts; the reflex plurisegmental and its arcs disynaptic with an internuncial path; fatigue and its place of incidence; attempt to obtain central fatigue; mutual reinforcement of allied arcs; the whole common path reacts as a unity; competition of conflicting arcs for the common path; two forms of central inhibition; after effects of inhibition. The common path a passive instrument in the hands of the various arcs. Distinct receptors and conjoined receptors; conflicting and allied arcs. Some psychical aspects of central interference.

LECTURE VII.

Spinal shock. Shivering. Meaning of spinal reflexes. Pseudo-affective reflex, and its spinal path. The relation of visceral reactions to the coarser emotions.

LECTURE VIII.

Nervous integration of the segmental series. Refinements of the receptors in the leading segments. Restriction of distribution a factor toward integration. Distance receptors: their frequency of use; they drive the total animal; they initiate and guide precurrent reactions as contrasted with consummatory; germ of conation attaching to them; derive affective tint from consummatory reactions to which they lead if associative memory attach. The brain developed over the arcs of the distance receptors, *i. e.*, the ganglion of the distance receptors. Relation between locomotion and receptive range. The "head" as physiologically conceived. The head and trunk and internuncial paths. Severity of spinal shock proportionate to the so-called height of the animal's neural development.

LECTURE IX.

Physiological method and the functions of the cerebrum. The "excitable" cortex in dog, monkey and anthropoid ape. Topography of places yielding reactions: strength of stimulus; epileptiform effects, primary and secondary movements: reinforcements, *e. g.*, perineum and trunk, neck and ocular deviation. Narcosis depth. Reciprocal innervation experiments. Silence of the post-central gyrus. Evidence of pyramidal tract. Character of the tract in anthropoids. Contrast in structure between precentral and postcentral cortex — cells, fibres. Degeneration consecutive to amputation, amyotrophy, and tabes dorsalis. Recovery of function after cortical ablation of limited extent. Hierarchy of centers.

LECTURE X.

Confluence of neural paths taken as token of psychical synthesis: tendency to accept also the converse. Convergence of retinal paths toward same region of cortex interpreted as indicating that synthesis of twin retinal impressions to a single sensation is effected by confluence to a single unitary neural mechanism. Binocular flicker. The rotating binocular lantern. Symmetrical flicker; asymmetrical flicker. Some uniocular and binocular comparisons. Binocular fusion in this case a time-combination, not a spatial combination. Cortical localization and composition of a sense-perception. Examination of anthropoid brain for a speech center. Conclusion.

ADVICE FROM A LAYMAN TO MEDICAL UNDERGRADUATES.

IN a recent address made by Maj. H. L. Higginson to the undergraduates of the Harvard Medical School his concluding remarks were as follows:

The world seeks your help in questions of hygiene, and of water supply, drainage and ventilation, because you of necessity study these questions.

See what happens. When our city needed a comprehensive system of water supply, it turned to a great physician who had organized and administered admirably our Massachusetts Board of Health. He has played the principal part in the wonderful Metropolitan system of water-works, as well as the Metropolitan systems of drainage and parks.

New York City searched for a competent man to unite and organize the Lenox, the Astor and the Tilden libraries, and chose Dr. John Billings, a well-known United States Army surgeon.

President McKinley selected an army surgeon who had gone into the fighting line to put Santiago into order after the siege of that city. This doctor (and general) justified the choice so well that he was given charge of all Cuba until it was ready to try self-government. We can safely trust in his good results in the Philippines.

Surely, gentlemen, you get your share of the work and of the honor of the times; and you have deserved it.

Do you believe that my words of advice to my young friends spring from convictions about your profession? A boundless field of knowledge, old and new; great power over mankind through your practice, your sympathy, your devotion; true happiness in seeing intimately the noble, loving side of life; a constant temptation to do good by a word of advice and a smile; the frequent chance to minister to a sore spirit or a weak resolution by firm cheerfulness and hope, — all these are yours, if you will.

But let me insist that you are to expect nothing except from yourselves. The world lies open before you, and invites you to its innermost nooks. Nobody penetrates so far into human life as the physician, if he will; and nobody stays there so surely as he, if he deserves his position. The world gives its rewards for deserts; and if by chance it throws a man a plum, he can only be grateful for the chance shot. See clearly what you wish; and if you fail, do not deceive yourselves about the fault. It rests on your own shoulders.

Banish all thoughts of yourselves, rely on your own powers, and think only of your subject; for your profession is in the making and needs every atom of your wits. Single-hearted, single-minded, devoted to your patient, you will surely win success.

Am I expecting too much of you? You are young gentlemen, carefully nurtured in your homes, and now enjoying the full education and training of a great medical school, conducted by able practitioners and teachers. You are citizens of our great republic, and know your duties. What is more likely to draw forth your best qualities and bring them to their fruition than the expectation of yourselves and of your fellowmen that you will accomplish high and noble results?

NOMENCLATURE FOR PULMONARY TUBERCULOSIS.

A COMMITTEE on nomenclature, consisting of Drs. Bowditch, Stubbert, Baldwin, Knight and Quimby, appointed by the American Climatological Association, suggests the following classification for cases of pulmonary tuberculosis:

Incipient. — Slight physical and subjective signs, with history indicative of pulmonary tuberculosis. Sputa, if present, without bacilli. *First Stage.* — Definite physical signs of localized infiltration; total involvement less than half a lobe, whether at one or more points; cough and expectoration with bacilli; constitutional symptoms slight. (In disseminated cases expectoration and bacilli may be absent with constitutional symptoms more severe.) *Second Stage.* — Infiltration of single or multiple areas approaching or equal in amount to one lobe; or smaller area in stage of softening; cough and expectoration with bacilli; constitutional symptoms, severe. *Third Stage.* — Infiltration in excess of one lobe, or if less in stage of well developed excavation; more severe constitutional symptoms.

The committee also suggests, as a classification of results of treatment in pulmonary tuberculosis, the following:

Progressive. — All essential symptoms and signs continue unabated. *Quiescent.* — Constitutional symptoms slight or entirely absent; physical signs improved or unchanged; cough and expectoration with bacilli still present. *Arrested.* — Absence of all constitutional symptoms; expectoration and bacilli still present; physical signs may or may not persist; foregoing to have existed for at least three months. *Apparently Cured.* — All constitutional symptoms and expectoration with bacilli absent for a period of three months. *Cured.* — All constitutional symptoms and expectoration with bacilli absent for a period of two years under ordinary conditions of life.

Correspondence.

JOHN WESLEY'S LIFE-LONG CAPACITY FOR WORK.

BOSTON, April 26, 1904.

Mr. Editor: The following account of the life and work of John Welsey from Sir Leslie Stephen's "History of English Thought in the Eighteenth Century" is of interest as showing the possibilities of physical and intellectual accomplishment in a lifetime.

"As a mere record of the quantity of work that can be got out of a single human being, endowed with untiring energy, and absolutely devoid of at least the lower forms of selfish indulgence, the account of his labor is encouraging to the strong and calculated to throw the weak into despair.

"For more than fifty years Wesley was the autocratic chief of his society, and not content with administration from a distance, personally inspected, at frequent intervals, every part of the machinery which he had organized. He travelled on his ceaseless round of duty some 4,500 miles annually; he preached two or more sermons a day; and it is calculated that in fifty-two years he travelled 225,000 miles, and preached over 40,000 sermons. The sermons were occasionally delivered to audiences of 20,000 persons, and at the age of eighty-six (1789) he records an address delivered to a congregation of 25,000. Though he doubts whether all could hear, the feat, considered as a mere exhibition of physical energy, is something stupendous. He rose every morning at four, allowing himself only six hours of sleep, though we are told that he possessed the faculty, common to nearly all great workers, of falling asleep at a moment's notice. He often rode seventy miles a day, and generally read as he rode, avoiding stumbling, as he tells us, by riding with a slack rein.

"On his eighty-fifth birthday he ascribes his health to his constant exercise and change of air, to his powers of sleeping, to early rising, and regular preaching during sixty years, at five A.M., and to his having had little pain, sorrow, or anxious care during his life."

Very truly yours,

WM. PEARCE COUES, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 23, 1904.

Deaths reported, 4,196; under five years of age, 1,081; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,005; acute lung diseases 858, consumption 515, scarlet fever 49, whooping cough 10, cerebrospinal meningitis 63, smallpox 10, erysipelas 15, puerperal fever 2, measles 51, typhoid fever 43, diarrheal diseases 127, diphtheria and croup 91, influenza 11.

From whooping-cough, New York 5, Baltimore 3, Springfield 1, Fitchburg 1. From smallpox, Philadelphia 9, Pittsburg 1. From cerebrospinal meningitis, New York 55, Boston 2, Lowell 1, Somerville 2, Brockton 2, Weymouth 1. From erysipelas, New York 8, Chicago, Philadelphia, Pittsburg, Boston, Chicopee, Newburyport and Woburn, 1 each.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending April 9, the death-rate was 18.4. Deaths reported 5,379; acute diseases of the respiratory organs (London) 167, whooping cough 223, diphtheria 57, measles 183, smallpox 9, scarlet fever 35.

The death-rate ranged from 7.0 in Walthamstow to 29.3 in Norwich, London 18.6, West Ham 16.5, Brighton 18.2, Southampton 13.4, Plymouth 19.7, Bristol 19.1, Birmingham 24.8, Leicester 13.7, Nottingham 17.8, Liverpool 19.2, Bolton 21.4, Manchester 21.5, Salford 20.7, Bradford 19.4, Leeds 22.8, Hull 16.6, Cardiff 13.3, Rhondda 18.3, Wigan 15.8, Merthyr Tydfil 17.9, Rochdale 19.5.

METEOROLOGICAL RECORD.

For the week ending April 23, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

RECENT DEATHS.

EDWARD REED WHEELER, M.D., M.M.S.S., of Spencer, died in Winthrop, April 30, 1904.

MILLER COX, M.D., of New York, died on April 24 from pneumonia. He received the degree of B.A. from Union College, Schenectady, and was graduated from the College of Physicians and Surgeons, New York, in 1871. For twenty years he had been a medical inspector in the health department.

SOCIETY NOTICES.

NEW HAMPSHIRE MEDICAL SOCIETY.— The 113th anniversary meeting of the New Hampshire Medical Society will be held at Concord, N. H., Thursday and Friday, May 19 and 20.

G. P. CONOR, M.D., Secretary.

AMERICAN MEDICAL EDITORS' ASSOCIATION.— The annual meeting of the American Medical Editors' Association will be held on June 6 at 2 P.M., Dennis Hotel, Atlantic City, N. J.

AMERICAN PROCTOLOGIC SOCIETY.— The sixth annual meeting will be held at Seaside House, Atlantic City, N. J., June 8 and 9, 1904. The first session will begin at 10 A.M., June 8. The profession is cordially invited to attend all meetings.

A. B. COOKE, M.D., Secretary.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.— The examinations of the State Board of Medical Examiners of New Jersey will be held at Trenton, N. J., June 21 and 22. Application for the regular blanks should be made before June 11.

E. L. B. GODFREY, M.D., Secretary.
Camden, N. J.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY.— A regular meeting of the Society will be held at Hotel Nottingham, Boston, Mass., on Thursday, May 19, 1904, at 7.30 P.M. The meeting will be in charge of the Section on Orthopedic Surgery, Dr. Kelly Sabine, Chairman. Paper I, "Congenital Hip," by Dr. J. D. K. Sabine; II, "A Case of Dupuytren's Contraction Cured without Incision by Brisement Forcé and Absorbents," by Dr. Emma B. Culbertson; III, "Report of a Case," Dr. Clara J. Alexander.

MARION NUTE, Secretary *pro tem.*
32 Mill St., Dorchester.

THE HYSTERO-NEUROSES AND THEIR RELATION TO THE PHYSICAL EXAMINATION OF ALL WOMEN PATIENTS.*

BY DANIEL H. CRAIG, M.D., BOSTON, MASS.,

Surgeon to Out-Patients, Free Hospital for Women; instructor in Clinical Gynecology, Tufts College Medical School; instructor Boston Polyclinic, etc., etc.

THE relationship between the hystero-neuroses and the physical examination of all women patients may not at once be clear, but I feel sure that you will be convinced that such a relationship does in reality exist. Physical examination occupies the same position relative to the hystero-neuroses that judge and jury occupy to the accused, or suspected, criminal. It is through their good offices that he must be acquitted or sentenced, and I feel certain that errors of judgment would be scarcely less frequent under the deplorable reign of lynch law than they are in cases of the hystero-neuroses when not tried and proved by physical examination. The ideas which I wish to express, although in this instance confined to the hystero-neuroses, apply with equal force to every form of reflex symptom, and I have chosen the hystero-neuroses only because I naturally know more of the evil effects accruing from the overestimation and underestimation of their importance than I do of any other.

First let us understand just what is meant by the hystero-neuroses. Engelmann [1] defines them as, "Those phenomena which simulate a morbid condition in an organ which is in an anatomically healthy state, and which are due, not to structural changes in the organ in which they appear, but to morbid or physiological changes in the uterus or ovaries." To uterus and ovaries I would like to add kidneys, although of course such an addition would necessitate a designation of broader scope than hystero-neuroses; but in women the urinary organs are so anatomically distinct from those of the male that they come logically within the most strictly limited province of the gynecologist.

The hystero-neuroses have been comprehended from time immemorial both by the medical profession and the laity, especially the neuroses incident to pregnancy; but in recent times they have been more commonly realized to be either understood or misunderstood by the profession ever since Emmet so forcibly called attention to them in 1867 and the succeeding years in connection with his operation for trachelorrhaphy. That they have been grossly misinterpreted is easily demonstrable. Examples are constantly appearing both at my office and at my outpatient clinic at the Free Hospital for Women; but as these latter are charity patients who have not, perhaps, as a whole, been able to command the services of the highest type of medical adviser, I have undertaken to see how frequently the hystero-neuroses have been misinterpreted amongst private, well-to-do patients. To this end I examined my current volume of case records with this investigation in view. I confined the examination to the current volume that I might not be open to the criticism of antedating, in the least, present progressive methods of research. The cases recorded are 194. Of these I find that the hystero-neuroses had been undeniably and unmistakably misinterpreted in 26 cases, or nearly 14%. This percentage is quite high enough to justify such a study, but when to this is added the fact that a certain number of these 194 cases had not consulted a general clinician, perhaps for years, that the cases were frankly gynecological from the outset, that their first resort was to me, and that of the above 26 cases in which errors had been made practically all had consulted *several* physicians, it is easily seen that the actual percentage is considerably higher; unfortunately, my records do not show exactly how much higher, as it is at all times difficult to obtain such facts, except from naturally loquacious patients, without arousing suspicions, often very unjust, of their own physician's thoroughness.

The hystero-neuroses have been quite abundantly exploited by our most able gynecologists, and it is not my intention to ply you with a repetition of these facts and I do not feel that there are any new ones to add. In fact, I think possibly they have already been overstated, and I am certain that a careful following of the methods which I adopted three years ago will considerably lessen the number of cases in which the diagnosis of an hystero-neurosis will be made. They have been woefully overestimated by some enthusiasts and equally erroneously understated by others.

This subject seems a fitting one for this occasion in that it has been very wisely said that the neuroses constitute the link which binds the specialist to general medicine. Virchow said, many years ago, that no man can be a thorough specialist who is not a good physician, and this grows more manifestly the fact each year as more elaborate and perfect means of investigation demonstrate the complex interdependence of the various bodily structures, for the human body is a mechanism possessed of marvelous powers of autonomous compensation whereby the function of any overworked or diseased organ is taken up either by other organs or by sound portions of the partially diseased organ. It is a thorough comprehension of these compensatory processes which distinguishes the wise physician from his less discriminating confrere.

The more thorough the physical examination of all women patients the less opportunity there will be for over- or underestimating the hystero-neuroses. Probably those gynecologists who in the eighth and ninth decades of the century but just ended were urging the importance of the hystero-neuroses little thought that need would ever arise for cautioning the profession against

*Read, by invitation, before the Massachusetts Medical Society, Middlesex (East) District, March 16, 1904.

[1] System of Gynecology, Mann, p. 151 et seq.

the exaggeration of these conditions. But I am so impressed with this necessity that I have formulated the rule for my students, "*Never accept any symptom as an hystero-neurosis until every other possible cause has been rationally ruled out.*" I might stop right here for such causes cannot be rationally ruled out except after painstaking physical examination.

Why is the thorough physical examination of patients, not only women but men as well, so neglected? Some will give one answer, some others, but there should be no laudable reply. In the minds of the laity it is not the greater diagnostic or therapeutic acumen that distinguishes the specialist, but the greater thoroughness of his methods of investigation. It is usually for diagnosis rather than treatment, except in the case of major surgery, that the patient seeks, or is sent to, the specialist. And just here permit me to say that I am by no means attempting to contrast the specialist with the general clinician, because to do so would as often be disastrous to the one as to the other. As compared with the really industrious, studious, general clinician every specialist is a man of small attainments, and his sole right to existence lies in his possession of knowledge which the circumstances of a busy and varied practice make it well-nigh impossible for his confrére to obtain. My personal experience leads me to believe that the gynecologist errs through overestimation of the hystero-neuroses nearly as often as the general clinician does through underestimation. However, that this overestimation is not characteristic of all gynecologists is readily demonstrable from the writing of a few, as, for instance, Ford[2] who, incited by this overenthusiasm, goes so far as to deny all reflex action to lacerations of the cervix uteri. A more temperate statement is nearer the truth, and the truth, the whole truth, and nothing but the truth is what science demands.

The gynecologist, like every other specialist, unless he carefully guards against it, is all too prone to come, in time, to consider the female pelvis or, of course, the respective organs over which the other specialists preside, as the abiding place of all the evils to which female flesh is heir. I know no remedy which will so speedily dispel this fantasy as the routine, thorough, physical examination of all women patients.

But to return to the reasons for the neglect of physical examination. The incompetent neglects physical examination because he fears, first, that he will know no more at the end than at the beginning, and, second, that the patient may attribute his long search for causes to a limited diagnostic knowledge. To such I say: Begin such routine examination at once in all patients, and this practice alone will inevitably make competent diagnosticians of them in a few weeks or months. It will be found a veritable postgraduate course. The busy man will reply that it consumes too much time. This is not true. The patient has a right to demand so much of the physician's time as is essential to diagnosis. At my out-patient clinic it is the rule to treat, in from two and one-half to three hours, from 20 to 36, or even more, patients, of whom from 3 to 7 are new ones, with the aid of one assistant. In each new patient the full physical examination obtains, and I am sure the time consumed is not excessive. Another says patients object to the exposure. Not if they are made to understand the all-importance of learning accurately every available fact in their case. The man who is content to prescribe for his patient after merely listening to the patient's recital of her symptoms is not in the true sense a member of the fraternity devoted to medical *science*. His methods are strictly empirical. But he, in thus following the example of the charlatan, handicaps his professional brethren, for patients come to assume that a doctor must be able by merely looking at their faces and listening to their voices to make the most difficult diagnoses. Believe me, for I speak from experience, nothing so much pleases a patient, after it is all over, as a comprehensive examination.

Nor am I pleading that a pelvic examination of every woman be made. No, indeed. I have said, Accept no symptom as an hystero-neurosis until every other cause has been rationally excluded. And what does this preclude? First, it precludes the necessity of doing what my experience leads me to believe a majority of the general clinicians avoid. That is, a thorough study of etiology, pathogenesis and pathology. It is my belief that most busy physicians on meeting a puzzling case turn to their libraries and open the appropriate book to the desired subject. They then turn the leaves hastily until they reach the symptomatology, diagnosis, prognosis and treatment. These they read with deep interest, but how will a doctor permanently cure without removing the cause, and how, except by fortunate accident and with the aid of long-suffering nature, will he remove a cause without a thorough knowledge of it? In short, the laudable tendency of modern medicine to eradicate causes renders it incumbent upon the physician to read the very portions of his literature which the above example slighted. A thorough knowledge of etiology and pathogenesis becomes the keynote of success. If then a thorough search might be invariably made for extrapelvic causes of symptoms which might or might not be hystero-neuroses, all necessity for intrapelvic examination may often be proved wanting, and in doubtful cases, especially in single women, the therapeutic test may often seem justifiable before proceeding to pelvic exploration.

If, however, there is any form of neurosis in which great allowance is due the errors of estimation it is the hystero-neurosis, because there exists good and sufficient reason wherefore the general clinician is less proficient in gynecological diagnosis, at least in its refinements, than is the case concerning other organs. This arises from the difficulty naturally encountered in

[2] W. E. Ford, Trans. Am. Gyn. Soc., Vol. xx, 1895.

supplying large numbers of demonstrating cases to the student during his preliminary studies, and also from the fact that in practice a pelvic examination is to be avoided whenever not positively indicated, and particularly in the young unmarried. But it is just here that the knowledge of the hystero-neuroses comes in play. A thorough comprehension of this subject and a realization that pelvic lesions may cause distant neuroses with pelvic symptoms so slight as to have been overlooked by the patient will, after a thorough examination of the seat of the reflex symptoms without any discovery of a cause, lead to such a pelvic examination with the happiest results.

It seems almost unnecessary to even name one of the many instances in which the hystero-neuroses have been made a diagnostic scapegoat. You have each and every one seen such. I refer to symptoms anywhere from head to foot which, with or without a semblance of reason, have been attributed to the menopause. So firmly have women become impressed by these gross exaggerations that many a perfectly healthy woman looks forward for years with apprehension to the dreaded ' change of life " only to learn by experience what doctors should long ago have learned by observation, that a woman with healthy pelvic organs has nothing to fear from the menopause. When hystero-neuroses or local pelvic symptoms arise at the inception of the menopause they are as much an indication for investigation and treatment as they are at any period of a woman's existence. And if this rule might be invariably followed, just try to realize the cases of cervical carcinoma which would be recognized in the early stages when radical operation has most to offer.

Thus far I have spoken only of the advantage to the patient in the thorough investigation of the causes of disease but the patient is by no means the only gainer. Insufficient physical examination very frequently leads to a three-fold error: first, an incorrect, or at least inexact, diagnosis; second, an incorrect therapy; and third, an erroneous prognosis; and the patient, and her friends, will readily forgive, if they ever suspect, the first two, but will inevitably discover and possibly grudgingly forgive but never forget the third. The prognosis is the one element in every case which the layman can judge critically and justly if very often harshly. Therefore, if the penalty for an error must be paid it often falls to the lot of the patient to pay the first installment but the doctor usually pays in the end and frequently the lion's share.

One last, by no means negligible, advantage to be gained by the comprehensive physical examination of all patients is the discovery that the patient may be suffering from two or more distinct pathogenies in no way related to each other directly nor reflexly except in so far as both disturb general metabolism. This constitutes the class of cases in which the general clinician, the family physician, and the specialist reach their highest degree of efficiency through intelligent co-operation, each coincidently attending to those factors within his legitimate scope.

Permit me to outline what, in the foregoing, I have meant by a thorough physical examination. Three years ago I adopted the rule to which I have since strictly adhered, that every new patient be examined as to the condition of all viscera, those of special sense alone excepted, these being considered beyond the limits of the average gynecologist. The first step is a routine anamnesis. And when I say routine I do not allude to the filling in of spaces left in a printed form. Nothing could be worse. A short experience with such history blanks is all that is necessary to convince anyone that no one blank will accurately adjust itself to all cases any more than will one prescription. This recording of histories is too frequently neglected by general clinicians. It often serves as the opening wedge to discover facts which would otherwise remain hidden either through the patient's underestimation of their importance or her idea that they can have no connection with symptoms in remote organs and hence their concealment through false modesty. It is always possible, by beginning at the beginning and inquiring in the most commonplace way as to the age at which menstruation began, to get a full menstrual and pelvic history without in the least offending the delicacy of the most scrupulous.

The history completed, the patient's heart and lungs are examined by auscultation and percussion. Realizing the intimate relationship existent between respiratory and intrapelvic lesions, catarrhal conditions of the upper air passages should be looked for. The abdomen next receives attention, the liver and spleen being percussed out and palpated if possible. Robson's and Boas's points are palpated for evidences of gallstones. The kidneys are next investigated as to palpability, mobility or enlargement and the course of the ureters followed down to the pelvic brim. The position and size of the stomach, colon and small intestine are next determined by auscultatory percussion, and the colon and iliac regions are palpated for evidences of appendicitis, ovarian tenderness or colonic fecal impaction. The hypogastrium is palpated for uterine or bladder enlargement or tenderness. The history will always determine the regions which must have careful examinations and those in which we merely wish to be assured that all is really normal. And no man of discernment requires to follow this routine long to learn how inadequate to complete and accurate diagnosis the patient's statement of symptoms is.

The abdominal viscera well understood the pelvis is investigated. This with the general clinician will not, of course, follow in every case as it does with the gynecologist, but should follow, in all except the young unmarried, in all cases in which symptoms exist which are known to result from hystero-neuroses, even occasionally, when every known extrapelvic cause has been exhausted without satisfaction.

With the supersensitive patient nothing so

greatly facilitates the pelvic explorations as nitrous oxide. It is easily given at the office and produces a transient but quite sufficient relaxation with no disagreeable after effects beyond a possible momentary dizziness.

The thighs and legs, containing no important viscera, are examined only when the seat of special symptoms.

The following are a few cases selected as types either of belittling or exaggeration, or both in the same case, of the hystero-neuroses taken from the twenty-six cases above mentioned.

CASE I. Mrs. H. F. M., age thirty, married seven years, never pregnant, housewife. Family and past histories entirely irrelevant. First catamenia at twelve, always regular and painless, of five to seven days' duration and requiring from five to seven napkins. Last catamenia one week ago exactly on time. Present illness: Two years ago, while travelling in Mexico contracted dysentery (?) and was ill several weeks. Extreme rectal tenesmus resulting in frequent, prolonged and violent straining. During this straining on one or two occasions felt as though something gave way in the pelvis. Never wholly recovered from this attack and has been constantly under medical attendance ever since. Has been under the care of three general clinicians and one who, while stopping at the same summer hotel, proclaimed himself a specialist in gastro-intestinal diseases. Since the abatement of the dysentery (?) she has had a great variety of gastro-intestinal symptoms but no marked diarrhea; on the contrary she has been generally inclined to constipation. No one of the four doctors had ever even suggested to Mrs. M. that she loosen her clothing for examination. There were absolutely no pelvic symptoms, not even a noticeable leucorrhea.

The physical examination showed a catarrhal nasopharyngitis for which she was advised to consult a competent specialist with the offer of assistance in selecting one if necessary. The heart and lungs were entirely normal. Examination of the abdominal viscera revealed nothing abnormal beyond the fact of a moderate distention of the intestine with gas. Both kidneys were easily palpable but not pathologic. The abdominal examination failing completely to show adequate cause for the gastro-intestinal symptoms and realizing the effects that the violent straining of two years before might have had on the pelvic organs a pelvic examination was made and a readily replaceable, considerably enlarged uterus was found retroverted to the third degree. Both tubes and ovaries normal. The uterus was replaced with immediate relief of all gastro-intestinal symptoms, and as no form of packing nor support was well tolerated, Alexander's operation was done two months later. At the present time, ten and one-half months after the operation, this patient remains entirely well and is again travelling abroad.

In this case I am certain that had any one of my four predecessors made a thorough physical examination he would at once have been impressed with the disparity between the symptoms and the absolute normality of the stomach as to position, size and tenderness. This case clearly indicates a lack of appreciation of the hystero-neuroses and by way of contrast permit me to cite one in which they were as grossly overestimated.

CASE II. Miss E. T., age forty-three, single, no occupation. Family history excellent, also past history. Had never had any acute serious illness. Had vulvo-vaginitis as a child but recovered promptly and completely but as a result had ever since been warned by her mother to expect all sorts of pelvic troubles. First catamenia at fourteen, always regular and never painful after the first year. Duration four to six days using two napkins a day. Last catamenia four months ago and had been gradually growing less. One year ago, after a comparatively mild attack of la grippe, became weak and anemic and began to have considerable leucorrhea which has persisted up to the present. During all this year catamenia gradually growing less, and six months ago began having backache, usually in lumbar region. For past two months has had pains, at times quite severe, in the epigastric region and extreme fatigue amounting almost to inability of locomotion. Four months ago consulted her physician who heard her recital of symptoms, and without further examination prescribed for supposed reflex neurosis arising from the supposed effects of the menopause and assured her that there was not the least occasion for alarm. As this treatment, however, yielded no results he advised her to consult me with the idea of having a curetting done.

Physical examination showed heart, lungs and abdomen absolutely normal beyond a questionable hepatic enlargement. Examination of the pelvis showed the leucorrhea to be thin and milky and coming almost, if not quite, entirely from the vaginal walls. The uterus was small suggesting the beginning of postclimacteric atrophy, was freely movable and no pelvic abnormality could be detected. The spine was slightly rigid, a little tender in the lumbar region, and the patella reflex was abolished. Delay was advised and a note sent to her doctor and the woman taken to a prominent neurologist who confirmed the diagnosis of tabes dorsalis.

The subsequent history of this patient is unknown to me, but it is evident that the menopause occurred, as it should have done in a normal pelvis, absolutely without symptoms and that the leucorrhea was the direct result not of a local lesion but of general debility and anemia. The fact of greatest interest in this case, however, is that special knowledge was not in the least demanded to exclude the pelvic origin of the symptoms, and there is not a doubt that the physician from whom she came was entirely competent to make the correct diagnosis as well as any specialist, had he followed the rule of investigating the causes of symptoms.

I wish to cite just one further case in which the question of the hystero-neuroses was by no means as simple, for it is quite possible to find many cases in which certain extra-pelvic symptoms are of undoubted reflex origin while coexistent symptoms have definite local pathologic basis.

CASE III. Mrs. N. M. T., age thirty-five, married four years, never pregnant; father and mother living and well. Past history good. Present illness began four years ago. Has had more or less leucorrhea all her life. First catamenia when eighteen, and was then operated upon for imperforate hymen. Irregular from the first. Never knows when to expect flow. Last menstruation two weeks ago. Always painful. Moderate pain in left iliac and sacral regions all the time, but decidedly aggravated at the menstrual epoch. Dura-

tion of flow from four to eight days, requiring four or five napkins a day. No clots and no odor.

Two years ago began having what her physician termed "nervous indigestion." A few months later began suffering severely, at times, with a pain of variable character but always located exactly at the vertex. Often felt as though head was opening and shutting and she feared impending insanity. One year ago resorted, on her own responsibility, to a well-known specialist in gastro-intestinal diseases. Was told after a thorough examination of her abdomen, and nothing more, that she had a gastro-ptosis and entero-ptosis. Gastric lavage was advised and practiced with marked relief of the gastro-intestinal symptoms, but the headache, leucorrhea, sacral and left iliac pain, which she was assured were the result of debility owing to malassimilation, remained uninfluenced. Not feeling satisfied herself that these were entirely nutritional symptoms she, once more on her own authority, sought a gynecologist. After taking her history he assured her that all her troubles were probably reflexes from the pelvis and proceeded to a pelvic examination and made no further investigation. Under his treatment she made some pelvic and head improvement, but the gastro-intestinal symptoms recurred. It was at this point, that through the advice of her neighbor, she came to my office.

The result of the physical examination was as follows: Heart and lungs normal. Abdominal examination shows a normal or but very slightly enlarged stomach considerably ptosed while the transverse colon was considerably below the umbilicus and was V-shaped and much dilated with considerable fecal impaction at the sigmoid flexure. The pelvic examination showed a large uterus with a very short portio vaginalis which is moderately antereflexed. Left ovary the size of a pullet's egg, prolapsed and firmly adherent. A peculiar band, resembling the cicatrix of a vaginal laceration, in the upper left portion of the vagina. On operation, six weeks later, the left ovary, completely degenerated, was removed and the omentum was found rolled up, and thus much shortened, and adherent directly across the pelvis so that the traction thus caused was producing the gastro- and coloptosis mechanically. Before her discharge from the hospital the stomach and colon were very nearly in their normal position, and when last heard from, a year and a half after the operation, she was well and attending to her household duties.

This case has been cited because it is one in which a particularly good history was obtainable. She was a self-reliant, assertive woman who stated facts clearly and without questionings, and above all because it demonstrates the shortcomings of the family physician in failing to make any physical examination at all, and each of the specialists, in confining his examination to those organs within the limits of his own particular specialty.

Illustrative cases might be cited in great abundance, but I think the above are quite sufficient as exemplifying my meaning.

TUBERCULAR MENINGITIS IN ADULTS.*

BY HENRY JACKSON, M.D., BOSTON,
Visiting Physician, Boston City Hospital.

Various diseases of the brain and the meninges are among the most serious diseases with which we have to deal, serious because of the importance of the vital organs attacked, and in many instances presenting indefinite symptoms that make the diagnosis difficult. There are a few symptoms that offer us great assistance in arriving at the diagnosis of some intracranial disease, and it is the experience of most clinicians that the physician must be satisfied if he is able to make a diagnosis as to the organic processes present, even though he cannot accurately define the exact pathological condition which has caused the organic process believed to exist in the individual case.

Trauma, syphilitic disease, cerebro-spinal meningitis, meningitis secondary to various pathological processes, as the diplococcus of pneumonia, and septic organisms and tubercular meningitis — all give rise to intracranial diseases that have many points of resemblance in their symptomatology though their etiology is so different. Add to these diseases the effect of mechanical processes which cause symptoms suggestive of meningitis, and we find ourselves brought face to face with a most difficult problem in the differential diagnosis of a supposed case of meningeal disease. Examples of mechanical processes which simulate intracranial disease are found in edema, due to chronic alcohol, the so-called "wet brain" of the drunkard, and internal hydrocephalus, dependent upon closure of the canal between the third and fourth ventricles by the organic remnants of a previous meningitis that has run its course. The enumeration of these various diseases does not represent a theoretical consideration of any and all processes that may give rise to symptoms suggestive of meningitis, but is a review of conditions that in some cases must be considered *seriatim*, while in all cases many of the conditions must be eliminated to enable us to arrive at a fairly probable diagnosis.

In meningitis we have many symptoms common in several diseases, as fever, headache, general malaise, and often leucocytosis. We find fever in cases of simple trauma, often of a high grade, and on the other hand, the temperature may be quite low in tubercular meningitis, and other forms of meningitis of an inflammatory origin.

Headache is usually present, but often it is not severe, and in many cases the sensorium is so dulled that at all events there is no expression of pain in the head though it may be present.

Leucocytosis is a symptom of importance, chiefly because we must not place too much reliance upon it in making our diagnosis. We often find a leucocytosis of moderate degree in trauma or cerebral hemorrhage, and it may be absent in local suppurative processes. In acute cerebro-spinal meningitis a high white count is the rule, a symptom that usually is of importance in the differential diagnosis of tubercular meningitis, but I have seen a high white count in tubercular meningitis, and thereby been led to make an incorrect diagnosis. It seems probable that the white count in meningitis is independent of

* Read at the meeting of the Boston Society for Medical Improvement, January, 1904.

acute inflammatory processes, as leucocytosis may be found in cerebral hemorrhage as we find fever without the demonstration of any acute septic process.

The most important evidence to be drawn from the presence of leucocytosis in a doubtful case is that thereby we may with much assurance eliminate typhoid fever, a disease that must be considered in most cases. My personal experience is that I have never seen leucocytosis in a case of uncomplicated typhoid fever. I am aware that such cases have been observed, though very rarely.

Delirium, fever, stupor, or maniacal symptoms may be present in meningitis in common with other diseases, hence arises the difficulty of diagnosis in doubtful cases. As meningitis may be due to so many causes, it is fair to assume that we must always be on our guard to eliminate this serious disease in cases where such a diagnosis is possible.

We have two classes of symptoms directly dependent upon the organic changes in the brain or meninges on which to base our diagnosis, namely, disturbance of the pulse rate and paralyses of various muscles, especially of the eye and face. In the pulse we have a sign of the greatest possible value which may not be disregarded if present. In the early stages of meningitis, or in cases with moderate effusion within the head, we find a slow pulse as the result of irritation of the vagus, while in the later stages we have an exceedingly rapid pulse from paralysis of the same nerve.

Looking at this matter from a practical standpoint, a slow pulse, or a relatively slow pulse, in a very sick person should always arouse the suspicion that there is some factor which is causing an abnormal reduction in the rate of the pulse. The pulse of typhoid fever is slow in comparison with other diseases that have a similarly high fever, but this rule does not apply in cases of fever in which the individuals are so sick as to suggest the probability, or even the possibility, of meningitis. I have seen in consultation three cases, all with a slow pulse, yet evidently very sick; the slow pulse was in each case a source of relief to the attendant physician, whereas to my mind the slow pulse was one of the chief causes for alarm. Two of the cases were tubercular meningitis, and one evidently cerebral, though the diagnosis was obscure. All died within a few days of the time that I first saw them, and in all an exceedingly rapid pulse preceded death. If the pulse be not only slow but irregular, or intermittent, it furnishes still greater cause for alarm.

On the other hand, a pulse of normal rate, or one with a rapidity such as might be expected from the general condition of the patient, is a strong presumptive proof that the case is not cerebral in origin. Therefore, taking these two factors into consideration, it may be stated with much confidence that in the pulse we have a strong bit of evidence for or against the existence of meningitis in an individual case.

The existence of paralysis of one or more muscles of the eyes, or of one of the muscles of the face, is of the greatest value. The paralysis may be so slight that doubt arises whether the slight deviation may not be natural to the individual. As a rule one or more muscles are affected; rarely is the lesion sufficiently great to produce absolute paralysis of any of the larger muscles of the extremities. Especial attention should be paid to the existence of paralysis, as it is a sign easily overlooked when the patient is very sick. Twice I have seen cases in which a facial paralysis was not recognized, as in the ordinary motions of the face it was not recognizable, though pressure on the point of exit of the supra-orbital nerve made it apparent.

It is not rare in hospital practice to meet with cases of tubercular meningitis in adults, and, as in my experience these cases are essentially different from the disease as seen in children, it seems worth while to review the recent cases in the Boston City Hospital with the addition of one seen in private consultation.

I have notes of eighteen cases collected in the last few years at the City Hospital. Seven cases were between eighteen and twenty-five years, eight between twenty-five and thirty, and three between forty and fifty years of age. In hospital practice the previous history of a patient is apt to be rather unreliable, though perhaps not more so than the history of our private patients, especially when we consider the accurate data usually gathered by our house officers. In one case no history was obtainable; in three cases there was a history of a subacute disease two years before coming to the hospital which certainly suggests the possibility of a preceding subacute tubercular process, namely, in one case pleurisy, in one case a slight cough which lasted a long time and kept the patient in bed, and in the third case some disease that kept the patient in bed several weeks, though he recovered subsequently.

Fourteen of the hospital cases gave no history of a disease preceding their present attack on entering the hospital. The case seen in private practice had not been sick for over seventeen years, during which time his wife could give us accurate information. Therefore, it is evident that in making the diagnosis of tubercular meningitis the lack of the evidence of a pre-existent tubercular trouble is no strong argument against the probability that the individual has tubercular meningitis.

The history, however, does not agree with the post-mortem examination, as in only two cases did the pathologist fail to find the evidence of an old healed tubercular process. On the other hand, no one of the cases showed extensive tubercular disease susceptible of diagnosis by our recognized methods of clinical examination.

Therefore, as in the case of the history of their preceding illnesses, the general examination failed to suggest a probable tubercular trouble, except possibly in two instances: one patient was admitted for acute pleurisy of the usual type, and

did not develop cerebral symptoms until four weeks after entrance to the hospital; the other had a chronic tubercular hip joint disease, which had existed since childhood and was said to have resulted from an early infantile paralysis. This latter case might probably have been diagnosed as tubercular, though it was not.

The period of sickness before entrance to the hospital was varied, but, as a rule, much shorter than the incubation period as seen in children. One case was admitted as a sunstroke case, with the history of an acute attack of unconsciousness. One case had complained of sore throat for two days; one had been sick for two weeks; three for a week; seven for ten days; in one no history. In fifteen cases, therefore, the disease was abrupt in its onset, or preceded by symptoms of short duration. One patient had been sick with vomiting and diarrhea for four weeks; this attack had followed, and was supposed to be due to, the eating of uncooked ham. In three cases only was there a history of symptoms extending over a period of several weeks, and in these three cases there was a general, acute, miliary tuberculosis in addition to the tubercular meningitis. The prodromal symptoms in all were indefinite, symptoms suggestive of many acute febrile diseases, rather than pointing towards a definite cerebral trouble. Four only of the cases laid especial stress on headache and vomiting, though headache was present to a certain extent in other cases. Three were delirious, and in one the mental symptoms were so marked that some form of insanity was considered possible. In the other cases the symptoms were described as weakness, malaise, fever and cough, or stomach trouble, as in two instances.

A good idea is obtained of the general impression that the cases made when first seen by the fact that in most of the cases the blood was examined by the Widal test. The course of the disease as it progressed in the hospital was that of some cerebral trouble. One third of the cases presented the type described as typhoidal delirium; two thirds presented varying grades of stupor and delirium. A small number were noisy and delirious. Headache was often complained of when the question was raised, but in only one case was severe headache an important and prominent symptom, that is to say, the disease in adults is not usually marked by the same headache, photophobia, cerebral cries, and extreme restlessness that make up the picture of the disease as usually seen in children.

In two cases there were convulsions. So far, then, we may say that the cases present nothing in their previous history suggestive of tubercular trouble, nothing in the history of the prodromal period that may establish the proof of a cerebral disease, whereas the course of the disease itself offers pretty strong proof that we have to deal with some acute cerebral trouble.

Taking up the physical signs, in all the cases but one, the pulse was slow in the first part of the acute stage. The pulse rate was usually from 60 to 70, until the last few days of the disease, and occasionally the pulse was as low as 50. In the last two or three days of life the pulse rate was 130 to 150, even rising in a few cases to 180, the average 140. Comparing the slow pulse rate just given with the picture of the general condition described, as stupor, delirium or noisy maniacal conditions, and the marked discrepancy between the pulse and the general condition, offers us practically proof that the pulse rate is dependent upon cerebral trouble. The temperature was unimportant, rarely over 102.5°, usually from 100 to 101°, and in one case normal or under after the second day.

The white count in nine cases showed on the average a much smaller number than in acute cerebro-spinal meningitis. In one case 23,000, in another 17,400 white cells were counted, in the other cases the count was at or below 12 000.

(1)	12,500	(6)	12,000
(2)	17,400		7,200
(3)	10,000	(7)	7,500
(4)	12,000	(8)	6,500
	10,000	(9)	9,400
(5)	12,800		
	23,200		

The small leucocytosis favors the diagnosis of tubercular meningitis as against acute cerebro-spinal meningitis.

Lumbar puncture was done in eight cases; in all the fluid spurted out showing that it was under pressure; in each case the fluid showed no growth, except in two cases the albus as a contamination from the skin; the fluid was almost clear, with a few flocculi. In one case the bacilli of tuberculosis were found on microscopic examination.

The lumbar puncture in these cases is, therefore, very different in its results from acute cerebro-spinal meningitis. In the latter we find pus or semi-purulent contents, and organisms are easily obtained by culture. Examination of the fundus oculi gave little information; in only one case was neuritis found. Retinal tubercles are certainly rarely found. In four cases the fundus is distinctly described as normal.

Paralysis. — In three cases no paralyses were noted, but these cases were very sick and death ensued shortly after entrance to the hospital in two. In one case extensive and marked paralyses were present, namely, a dilatation of the left pupil, and a complete left hemiplegia, face, arm and leg.

In two cases there was very slight facial paralysis in addition to strabismus.

In twelve cases paralysis was found limited to one or more of the muscles of the eye. We may then say that the rule is to find paralysis limited to the eye muscles. In this regard there is no difference from cerebro-spinal meningitis, but the paralysis found in syphilis, cerebral edema and trauma is usually more extensive.

Other signs of cerebral trouble were found, but less frequent and less marked than in cerebro-spinal meningitis, namely, retraction of the head, Kernig's phenomenon, and opisthotonos, the last mentioned sign being found only once.

After the onset of acute symptoms three died in less than two weeks, and several died in less than one week, two cases lived for three weeks.

Autopsies. — The post-mortem findings corresponded very accurately with the clinical examination as to the lungs, in no case was there found a lesion that was sufficiently marked to give rise to signs during life.

In sixteen of the eighteen cases small areas of chronic tuberculosis were found; small areas in the lungs in nine cases; caseous bronchial lymph glands in seven cases; chronic tuberculous hip in one case.

Acute miliary tuberculosis was found in the lungs in seven cases, and general acute miliary tuberculosis in five cases.

The cord was involved in a large number of the cases, as well as the meninges of the brain, namely, in eight cases. It seems to me that the involvement of the cord is not usually considered as so common. The meninges of the brain were involved alone in ten cases.

In the case with left hemiplegia there was marked flattening of the convolutions, the result of increase of the subdural fluid.

I give the history of two cases.

CASE I. Woman, twenty-one years of age. Previous history, always well. Present illness: For one week a cold with a little cough; for three days had been weak and sick. She entered the hospital on Aug. 25.

Physical examination on entrance as follows: Sordes, typhoidal appearance; pupils not abnormal; lungs not abnormal. Aug. 27, head retracted, tache cérébrale. Aug. 29, less stupor, convergent strabismus of right eye. Aug. 31, fundus normal, W. N. B., probably tubercular meningitis. Sept. 1, ptosis of left eyelid. Sept. 7, gradual failure and death.

Pulse slow to Sept. 1, later rapid. Temperature 101–102°.

Autopsy. — Area size of an almond of caseous tuberculosis at one apex. Tubercular cerebro-spinal meningitis.

CASE II. Man, forty-two years of age. For seventeen years he had had no serious illness. He went to Europe in the spring, as he was not very well. Arrived at home June 10; June 17 felt poorly; tongue coated, no fever, pulse not quick. For ten days he was cared for by his wife. Suddenly, on June 27, delirium came on, and a nurse was called. For next five days pulse 60–70, low, irregular fever, delirium. During the night of July 1 and 2 he became much worse, respiration was stertorous; at that time pulse 80. He waved the right hand constantly, and could wave the left a little; moderate Kernig; no knee-jerk; pupils both rather large.

Paralysis left side of face, left arm and left leg. Heart negative; lungs negative; Widal negative. In a few days the pulse became very rapid and death.

Autopsy. — Tuberculous meningitis, with exudate the most prominent feature, most marked at the base; marked flattening of convolutions from increase of subdural fluid. Spinal cord negative; thoracic organs not abnormal, except a few miliary tubercles at one lobe. Lymph nodes, mesenteric, bronchial, aortic and cervical showed no evidence of tuberculosis.

This case I report in detail as careful search was made for evidence of a chronic tubercular process, which might be the starting point of the acute tuberculosis. No such lesion was found.

CLAUDIUS' IODIZED CATGUT.

BY HORACE BINNEY, M.D., BOSTON.

THE sterilization of catgut sutures and ligatures by immersion in an aqueous solution of iodine was first brought before the public by Claudius of Copenhagen in the "Deutsche Zeitschrift fur Chirurgie" for 1902.[1] A second article by him appeared in the same publication, in the following year.[2] In this country, attention was first called to this new method of sterilization by Dr. Nicholas Senn.[3] The most recent discussion of the subject is an article by Martina of Gratz.[4]

The improvement during the past few years in the preparation of sterile catgut has shown itself in the comparative rarity, at the present time, of abscess following aseptic operations. The number of surgeons must, however, be small whose experience does not include cases of abscess where the catgut used seems alone to blame. It is also a well-known fact that cultures taken from many of the commercial preparations of catgut sutures have not infrequently shown the material to be infected.

An example of such bacteriological tests is the work of Dr. Jouett, for Dr. Hildreth of Cambridge, Mass., done during the past year. A résumé of his experiments with catgut, prepared by a number of different firms, is, through the courtesy of Dr. Hildreth, here given:

Number of specimens examined	18
Positive growth obtained in	9
In infected specimens growth appeared in .	24–48 hrs.
Number of cases in which a coccus was found	6
Number in which a bacillus was found . . .	3

The precise character of the organisms was not investigated and the question as to their pathogenicity is unsettled.

Another example of less significance than the above is an investigation by the writer of a small amount of catgut on which suspicion fell. Out of ten samples of chromicized gut, positive growths was obtained in three cases, appearing in from two to seven days. The bacteria found were cultivated on the ordinary liquid and solid media and in one case showed characteristics of the *Bacillus mesentericus vulgatus;* in a second, those of the Hay bacillus. In the third case a spore-bearing bacillus was found which was not identified. The first two are known to be non-pathogenic spore-bearers, and among the most resistant to sterilization of all bacteria. That the third (unidentified) was non-pathogenic was inferred from its failure to grow on blood serum.

What conclusion may be drawn from these experiments? Of course, the question of technique and possible contamination of the catgut and cultures during the course of tests at once arises. But, allowing that such accidents did occur, it is unlikely that in experiments carefully conducted the percentage of positive growth would be as high as 50% in the one case and 30% in the other. Moreover, the variety of the organisms found argues against contamination, during

[1] Vol. lxiv, p. 489.

[3] Journal of the American Medical Assn., xl, p. 817, 1903.
[4] Deut. Zeit. f. Chir., lxx, p. 141, 1903.

the test, in all cases. We may, therefore, conclude that certain commercial preparations of catgut are not invariably sterile and are, therefore, a source of danger in operations. While the non-pathogenic character of the organisms in three of the above cases suggests an absence of danger to the patient, we cannot accept this, for the presence of such bacteria in a wound undoubtedly favors the growth of any other bacteria which are present in, or accidentally enter into, the tissues during operation.

The above experiments emphasize the need of a method of preparing absolutely sterile catgut — one that can be always trusted.

In general, it may be said that the simpler the method of preparation of sterile catgut, the better the results, because the risk of accidents is less and, needless to say, the cheaper the product. The efforts of most manufacturers to supply an absolutely sterile article have elaborated rather than simplified the methods of preparation.

One of the newer methods for sterilization is the cumol method.[5] In this the gut, arranged in a convenient form, is put through a process of drying, is treated with cumol and again dried at high temperatures, the whole process requiring more or less constant attention for at least five hours. Gut prepared in this way has been shown to be absolutely sterile, but the method, besides being complicated, is expensive, the apparatus costing at least $40.00. The other methods in common use are less expensive, but it is a well known fact that they are more or less complicated; hence the need of a simpler method. This need seems to have been largely filled by Claudius' iodized catgut.

A synopsis of the method is as follows: Raw catgut wound on glass spools is placed directly into the following solution: Iodine, 1 part; potassium, 1 part; water, 100 parts.[6] The bottle is labeled and dated. Claudius states that after eight days the gut is ready for use and may be kept in the same solution and bottle. Through the action of the iodine solution the gut becomes deep black in color, completely sterile, antiseptic, pliable, and easy to tie. Immediately before using, Claudius recommends rinsing the gut in a 3% aqueous solution of carbolic acid or in any sterile fluid, to remove the surplus of iodine solution. The antiseptic action of the latter solution is demonstrated by Claudius by numerous tests in which he found that staphylococci were killed after three minutes' exposure to the solution, anthrax spores after twenty hours. Careful experiments with gut which had soaked for eight days in the solution showed it to be invariably sterile.

Dr. Senn[7] has used catgut prepared by this method with results so far entirely satisfactory, but I have not learned of his yet having published a detailed report of his personal experience with it.

[5] Miller: "The Sterilization of Catgut." Johns Hopkins Medical Bulletin, September 1900, p. 225.

[6] KI is dissolved in a small amount of water, to which the pulverized iodine is added then diluted with water to the above strength.

[7] Journal American Medical Association. (*Loc. cit.*)

The writer, desiring to test sterilization by iodine of a raw commercial gut, which is extensively used by eastern surgeons, made the following experiment. Raw gut was cut into pieces about six inches in length, soaked in the iodine solution for one week and then placed in bouillon tubes. In eleven cases the gut was soaked in two changes of sterile salt solution twenty-four hours each, to remove the iodine. In three cases this was omitted. In every case there was no growth of bacteria at the end of ten days. Control cultures to determine the presence of bacteria or spores in the raw gut were not found practicable because of the difficulty of completely removing the antiseptic agent used to kill surface bacteria, without recontamination. In the attempts made a trace of the antiseptic was invariably carried in the gut when planted in the culture medium, sufficient to inhibit all growth.

In order to determine the penetrating power of the iodine and thus prove that bacteria or spores in the substance of the gut, as well as on the surface, were destroyed, the following method was employed. Raw gut was macerated thoroughly in water, placed in bouillon cultures of the *Bacillus mesentericus vulgatus* for ten days and, at intervals of three or four days, was thoroughly triturated with a glass rod. The gut, impregnated with bacteria and spores, was then transferred to the iodine solution and soaked for one week. It was then removed and soaked in sterile water for two or three days, to remove the iodine, after which it was planted in bouillon. At the end of sixteen days, in every case there was no growth, proving the effective sterilization of the gut by the iodine solution.

In a similar way Martina tested gut which had been soaked in bouillon cultures of anthrax bacilli. The gut was dried, placed in the solution of iodine and potassium iodide for varying lengths of time, and washed and transferred to culture media; specimens exposed to the I. K. I. solution for forty minutes or longer gave negative results in agar, gelatine and bouillon. He further demonstrated the antiseptic property of iodized gut by placing pieces which had been drawn repeatedly through the unsterilized hands in various culture media. In no case did any growth of bacteria appear. The same test with cumol and sublimate-alcohol catgut gave positive results. He also placed pieces of the iodized gut in culture media in which various kinds of bacteria were then planted. The presence of the iodine in every case inhibited the growth of bacteria for a considerable distance around the gut, showing that the iodine was to a certain extent diffused into the surrounding medium.

Owing to the volatile nature of the iodine, the solution tends to become weaker the longer it is kept. Martina used solutions which were three weeks or more old. He states that the probable limit at which the solution can be safely used is three months. The writer in most of the cases referred to above used solutions from two to four weeks old. It is probable that if the solu-

tion is kept in a tightly corked bottle, and does not become transparent, it may be safely used until the end of four months.

Durability. — From experiments with rabbits and a few clinical tests it was found that the iodized gut corresponded closely with plain catgut in the time required for absorption. Claudius found it was absorbed more slowly than carbol-alcohol catgut when used as a skin suture, requiring twelve to sixteen days. Martina made extensive experiments with rabbits and found the gut entirely free from iodine, much swollen and quite fragile after ten days. He concluded that in cases where a great strain was to be put upon the sutures, the iodized gut was not applicable, since its strength after eight days was not sufficient. In hernia operations he does not advocate its use for the suture of the fascia. Other surgeons, whom Claudius quotes, have had no unfavorable results from its use in similar cases. Martina is also opposed to its use in suture of tendons. In such tissues, of slow healing properties, any rapidly absorbable suture would naturally be unsafe, if the parts were under any especial tension. The cases in which the iodized gut prepared by the writer was employed are but nine in number, in eight of which the catgut was used on the fascia in closing the laparotomy wound, and in every case, the wound healed in a satisfactory manner. No tests were made as to the absorbability of catgut sterilized by iodine after being previously chromicized, nor has it been used clinically. From a few experiments it appears, however, that this method of sterilizing chromicized catgut is an effective one.

Antiseptic Action in the Tissues. — Martina showed experimentally that the antiseptic property of the gut lasts about forty-eight hours, and it is probable that this holds true for sutures placed in human tissues. Thus, any bacteria which might adhere to the sutures during handling, and become introduced into the tissues, must be destroyed by the action of the iodine. This is, doubtless, the strongest reason for the good results obtained from the use of iodized catgut.

The absorption of iodine from the suture naturally suggests the possibility of toxic effect. The quantity of iodine absorbed from the sutures, even in a case where a large number of ties are used, such as a dissection of the breast and axilla, has never been found large enough to cause any poisoning. Its only action appears to be local as shown by slight reddening of the skin, which according to Martina lasts for four days, when the gut is used as a skin suture.

Strength. — Claudius found that iodized gut after soaking for one week in the solution was stronger than ordinary catgut prepared by other methods, and that the strength was retained until the end of six months. Gut which had been soaked longer became brittle and therefore unsafe. He also considered the strength of the gut to be increased by washing in a three per cent carbolic solution immediately before use. With this observation, Martina does not agree, nor do the writer's experiments bear it out. Martina prefers an iodine solution of one half the usual strength to the carbolic solution, for the purpose of rinsing the gut. The writer found that gut kept in watery solutions was inferior in strength to gut which had been transferred to an alcoholic solution previous to use. The question of preserving the catgut in an alcoholic solution naturally arose, and various antiseptic substances dissolved in alcohol were tried. Corrosive alcohol was found satisfactory as far as preservation of the strength was concerned, but iodine is rapidly absorbed from the gut by this solution, and it therefore becomes a plain catgut, and antiseptic action in the tissues is lost. An alcoholic solution of biniodide of mercury was tried and found to be highly satisfactory, since there is but little tendency for the iodine to be absorbed out of the catgut. The best results were obtained by rinsing the catgut (after its soaking for one week in the iodine solution) in 95% alcohol, to remove the superfluous water, then placing the gut in a solution of biniodide of mercury, one part; 95% alcohol, one thousand parts; glycerine, twenty parts. Gut preserved in this solution retains the iodine well, and is stronger than that preserved in watery solutions. The fluid, being antiseptic, permits any catgut not used during the operation to be returned to the bottle without resterilization. This, of course, applies only to clean operations. Any handling of suture material with dirty hands or gloves would, of course, endanger the sterility of the gut. Gut soiled in this way may, however, be safely used after resterilizing in the iodine solution.

The longer the gut has been kept in the solution of mercuric biniodide the stronger it appears to become, and for this reason the gut which has been but recently sterilized may be found of insufficient strength. If, however, the spools are allowed to stand in the air before using, for fifteen minutes or more, the gut becomes very strong and of a convenient consistency for tying. It was found advisable in every case to remove the suture material from the solution at the beginning of the operation. It was then unwound from the spools and cut into convenient lengths, laid on the instrument table and covered by a sterile towel. The above procedure gave most satisfactory results.

The preserving solution of biniodide of mercury is stable and has no unfavorable action on the catgut, which may therefore be used safely after keeping for a long time. In several cases gut which had stood for two months was used and found thoroughly satisfactory. It can probably be safely used after a much longer period.

Clinical Results. — The detailed reports of a large number of cases in which iodized catgut has been used by foreign surgeons with the best results may be found in the articles above referred to. A single instance of its successful use, mentioned in the second article by Claudius, was in the practice of Dr. Schon, who used the

iodized catgut in seventeen dissections of the breast and axilla with a perfect healing in every case. This operation is, as he states, probably the best test of catgut, owing to the large number of ligatures employed, and the comparatively poor circulation in the tissues about many of the ties.

The catgut prepared by the writer was employed in the following cases, which were operated upon at the Baptist Hospital, Brookline, by Dr. Hugh Cabot. Catgut of size No. 1 was used throughout: Interval appendix, 3 cases; interval appendix with myomectomy, 1 case; amputation of the breast for sarcoma, 1 case; gastro-enterostomy, 1 case; ovarian cyst, 1 case; varicose veins of leg, 1 case; cholecystectomy, 1 case. These cases were operated upon during the last eight months, and in every one the healing of the wound was satisfactory. Up to the present time the result, so far as suture material is concerned, is perfect.

Cost. — Finally, a word is to be said as to the cost of this method of sterilization. All of the ingredients of the solutions are inexpensive, and the solutions can be safely prepared by any apothecary, or, if necessary, by the surgeon himself. The exact cost has not been figured nor the relative cost compared with other preparations, but it is certainly very much less. The fact that gut which is not used during operation may be returned to the stock bottle is alone a source of considerable economy.

CONCLUSIONS.

Catgut prepared by Claudius' method is superior to other catgut in that: (1) It is invariably sterile. (2) It is readily absorbed in the tissues. (3) The ease and simplicity of its preparation enables the surgeon to prepare his own sutures with a minimum of trouble. (4) It is comparatively cheap.

CONCERNING THE DANGER OF INFECTION TO THE ATTENDANTS OF TUBERCULAR PATIENTS.

BY LOUIS FAUGERES BISHOP, A.M., M.D., NEW YORK,

Physician to Lincoln Hospital, New York (including the Phyllis Pavilion for Consumptives).

THERE is one point that I would like to take up, and that is the danger of contagion of pulmonary tuberculosis.

It is not very long ago since pulmonary tuberculosis was not considered an infectious disease; in fact, it was not thought that one person could get it from another. The opinion was held that it arose from within the body, and that if people suffered it was a matter of fate. The cause of it was not understood. This belief persisted for a good many thousands of years and the general opinion was that consumption was not an infectious disease.

We do not know the cause of scarlet fever or measles as well as we know that of tuberculosis, and yet there never was a time when it was doubted that scarlet fever and measles were contagious, the reason being that there was the evidence that when people came into contact with these diseases they contracted them. It has, however, been observed all these years that people lived in the house with consumptives and were intimately associated with them and yet did not uniformly get the disease, hence the belief arose that it not was a communicable disease.

When consumption was found to be a germ disease like typhoid fever and others we jumped to the conclusion that it was of necessity contagious. This is, however, not strictly true. If any of us have charge of a case of measles and we have not previously had the disease, we are liable to get it, but we can take care of many cases of consumption and be exposed to infection and yet not get it. With measles we would not escape once in a thousand times; that is, everyone is liable to measles unless he has had it and is protected against the disease, while with tuberculosis it is not necessary to have it and we are not uniformly liable to get it. This is founded upon the fact that no one enjoys immunity against the poison of measles, whereas most people enjoy an immunity which protects them in the case of slight infection with tuberculosis; that is, most people are in the same position toward tuberculosis as if it were a disease that protected against itself and they had had an attack. All of us in the city take in the germs of tuberculosis every little while. If the dust that flies about the streets on a windy day be analyzed the germs of tuberculosis will be found; indeed, there will be fewer tubercle bacilli found in the tubercular ward of a hospital than in the air of a dusty street, because in the tubercular wards there are no carpets or dust to carry the germs, while in a crowded street all conditions are favorable. So, even though we all of us at some time inhale the germs of tuberculosis we do not get tuberculosis because we enjoy a natural immunity against it. The tubercle bacilli can be introduced into the human body but there will, ordinarily, be no ill effect. There is one exception, and that is in the case of a very severe infection if the person is inoculated with the germs of tuberculosis repeatedly and the natural immunity temporarily broken down, but even then if the individual is not susceptible he will throw it off.

The germs of consumption are so widely distributed that a large number of people once in a while are so badly infected that the disease takes a start. They are sick for a little while but the condition is not recognized and the lesions heal and they get well. The only way we know that this happens is because the lungs of those dying of other diseases are examined and those who make a great many post-mortem examinations find that a large number of persons have at some time or other had a slight degree of pulmonary tuberculosis and have recovered without ever knowing that they had it.

I scarcely consider it fair, therefore, that tuberculosis should be put in the same category with

other contagious diseases, because it is only contagious in the sense that it may be transmitted from one to another, but is not contagious in the sense that the average person is liable to catch it. It is only contagious to those who are susceptible to it. This is a very important point, because in it lies the principle of the only treatment known for tuberculosis, and that is to restore to the individual the natural immunity which he enjoyed before he became infected and this is best accomplished by measures directed to the system in general.

There is no specific remedy for tuberculosis, and I am not sure that there ever will be, but some day it is possible that we may learn some better way of restoring this individual immunity. It has been found by experience that if a person not too far advanced in tuberculosis can be put in the open air and kept there day and night in any climate, that this treatment with proper feeding has a strong tendency to restore the natural immunity, and the result is that the lesion heals in most people who are infected slightly and in some who are quite severely infected. The whole thing comes down to a matter of susceptibility; if we are susceptible to tuberculosis we can hardly escape, while if we are not susceptible we can scarcely get it if we try.

As far as danger in taking care of tuberculous patients is concerned, this is practically nil. I think that if anyone working among tuberculous patients who uses ordinary care gets the disease he would have acquired it under other conditions.

Clinical Department.

LOCAL CONDITIONS IN THE RESPIRATORY TRACT MODIFIED BY GENERAL FUNCTIONAL OR ORGANIC DISEASE.

BY FRANCIS P. EMERSON, M.D., BOSTON.

LOCAL measures have been carried so far and have accomplished so much for the relief and cure of chronic catarrhal conditions of the respiratory tract that one does not need to urge their importance nor to reaffirm belief in such rational methods. It is not to detract from these brilliant results that I try to emphasize some general principles that seem in danger of being overlooked. We have all reached the point where it is admitted that no examination of the respiratory organs is complete that does not include the air tract as a whole, but does this mean the search for mechanical obstructions or the sequelæ of acute inflammatory processes only? Drainage can be established and obstructive lesions overcome to the temporary gratification of our patient, but is there not a local function to be preserved and also a relationship between it and general functional and organic disease? The term "specialist" can only be used relatively, because the result of minute investigation of any organ in its physiological and pathological aspect is to lead us to the broader consideration of the modifying influence upon it, of habits, environment, climate, seasons, occupation, heredity, age, etc., as well as its relation to other organs. This would seem to be a self-evident truth did not the question come up for discussion at a recent meeting of a national laryngological society as to whether the rhinologist was ever justified in prescribing even a laxative without the consent of the general practitioner. Every man who operates in the nose often must have noted the difference in reaction between the patient who leads an active out-of-door life and the one of sedentary habits. In the same way the man or woman with chronic constipation, indigestion, rheumatism, or gout will show an individual reaction that is not represented by the amount of trauma or the virulence of an infective organism. Normal excrementitious products may be retained within the body so that there results an incomplete chemical metabolism, or we may have an acid intoxication or the formation of leucomaines. The retention of such by-products may cause a chronic pharyngitis, an enlarged inferior turbinate or be one of the causes of a general arterio-sclerosis indicated locally by prominent tortuous vessels at the base of the tongue. Alcohol and chronic secretory disturbances of the stomach may for a long time produce local throat trouble, preceding marked symptoms in other organs.

"Taking cold" may result from reduced immunity due to over function of the larynx or from excessive heat or debauch so that pathogenic organisms of the throat become active, as well as from the lighting up of a subacute rhinitis from the chilling of the surface of the body. The prephthisical anemia of the larynx is an early local manifestation of a general trouble which all recognize.

A violent epistaxis may be the only symptom of a serious organic kidney or cardiac disease. Instances might be multiplied, but the object of this paper is not to exhaustively point out all the local conditions that simply indicate a general disorder or are associated with it, but to emphasize the importance of studying the patient as a whole so that when the local condition has been remedied general medicinal measures may be carried out in conjunction with the family physician to prevent a recurrence. Even chronic follicular pharyngitis is probably the sequel of changes resulting from hypertrophic disease in childhood and associated with the so-called lymphatic tendency. The chronic form we often hear spoken of by the older practitioners as throats of debility. Here the general lymphatic tendency needs to be studied on broad lines as well as local measures instituted.

CASE I. Miss M. S., single, school teacher, age twenty-five. Referred to me in 1901 for hay fever. Nervous temperament. Was anemic two years. Digestion good. No especial sickness but is always nervously exhausted, especially at the end of her school year. Nose always troubled her but two years ago had sore throat and has been worse since. Hay fever comes on in June and lasts until September then skips one month and returns to last all winter. A large horizontal

ridge was removed from the left naris and the naso-pharynx treated. Freedom from hay fever one year when she returned as bad as before. Adrenalin was prescribed and a specimen of urine requested which on two analyses gave specific gravity 1008. Quantity 2 qts. Urea 1%. Albumen and sugar absent. Her symptoms immediately subsided under adrenalin and she was referred back to her physician with the analyses and suggestions as to her general condition. Whether she remains well or not, the importance of a stable nervous system from a good physique is conceded as probably one of the factors in the triad which go to make up the symptom-complex which we call hay fever.

Case II. Mr. A., school teacher, American, forty-seven years, 150 lbs.

Family History. — Father died seventy, grippe. Mother died eighty, always well. Two brothers and one sister. One brother and sister have rheumatism.

Past History. — Patient had inflammation of the bladder six years ago of three weeks' duration. Grip ten years ago. Indigestion or so-called bilious attacks frequently. As a boy had sick headaches. Left wrist has pained him since fall of 1903. Throat sore and pharynx red, horizontal ridge through left inferior meatus. Septum to left and at upper third is in contact with the middle turbinate. Naso-pharyngitis and laryngitis. Larynx malformed from early struma. Uvula large and glistening. Croupy cough and embarrassed breathing as through a sieve. Tongue heavily coated and bowels inactive. Much prostration. He remained under my care through the winter, and, after the acute symptoms subsided, attended to his usual duties but having constant subacute exacerbations until summer when he went as usual to the seashore working about his summer place but failing to be benefited as usual. As the season was very wet I suggested that he go back into the mountains which he did but returned in the fall in poor condition. The ridge in the left nose had been removed but no attempt was made to set up his septum owing to his bad general condition. His bowels had been regulated and beside the local measures he had been given tonics with poor results. At this time examination of the urine gave specifiic gravity 1024, strongly acid. He was given lithia grs. v T. I. D., advised to box twice weekly with sufficient clothing to make him perspire followed by a cool sponge bath, sleep in a cool room and take a cold bath daily. The diet was regulated, the ingestion of water increased and the temperature of the house lowered to 64°-68°.

Nov. 28. — Urine 2 qts., specific gravity 1017. Urea 1.13%. No albumen, although he still has his deviated septum he is doing his work easier than usual and has been free from any but a slight cold for the last three severe winter months and keeps improving. It is still necessary to use an alkaline nasal wash twice daily and probably will be until the nasal condition is corrected, but his improved general condition has modified the activity of the local process and makes it easier to control.

Since writing the above his left middle turbinate commenced to show myxomatous tissue along its anterior border, and later a fully developed polypus necessitated its removal. This was apparently an ethmoiditis from grippe.

Case III. Mr. L. S., referred by Dr. —— in November, 1903; merchant, American, fifty-four years, weight 185. Smoked excessively since eighteen years of age until one year ago. Throat trouble fifteen years. Uses no stimulants. No catarrh. Is large meat eater three times daily and drinks three glasses water per meal. Never sick except typhoid fever at fifteen years. Throat begins to trouble him in the fall and lasts through the winter. Painful and accompanied by a hacking cough.

Family History. — Father died seventy-three, chronic rheumatism. Mother died sixty-one, apoplexy. One brother well. Three sisters well.

Examination. — Chronic pharyngitis. Large amount lymphoid tissue at the base of his tongue and prominent blood-vessels. Upper naso-pharynx negative.

Urine. — Specific gravity 1024. No albumen. Urea 1.77%. Uric acid marked.

Beside local treatment the nitrogenous food was restricted and he was given Carlsbad Sprudel, one teaspoonful in a glass of water on rising, with an occasional dose of calomel and citrate of lithia grs. v T. I. D. He continued to improve steadily and at the end of two weeks volunteered the information that he was getting over the feeling of exhaustion at night that had troubled him so that he felt like lying down as soon as he returned from business and that his throat was entirely free from pain. Here the pharyngitis seemed to be worse in the fall from the diminished action of the skin and the increase of nitrogenous food.

Case IV. Mr. K., referred to me in 1899 by Dr. ——; Irish American, merchant, forty years. Has smoked 3 to 5 cigars daily. No stimulants.

Past History. — Tonsilitis, quinsy. Bronchitis frequently. Grippe, pneumonia, typhoid at twelve years. Bowels inactive.

Family History. — Father died sixty, stoppage of bowels. Mother died sixty-four, grippe and meningitis. Three brothers well. One sister well.

Examination. — Right naris. A horizontal ridge running well back on to the vomer. Right middle turbinate shows dried secretion on its anterior border and is close to the septum. Right sphenoid carious. Ridge was removed and local treatment instituted for several weeks. The following winter he had some bronchitis and went south. 1901 and 1902 his history was one of continued bronchitis and naso-pharyngitis until April, 1903, when after a change of flannels he took cold and examination showed so much puffiness over the left arytenoid with a general dark red appearance of the whole mucous membrane that I sent him home and saw him again in the evening when the edema had extended to the other side, and during the night the larynx was scarified twice to relieve his respiration. He recovered very slowly and on coming to the office a careful examination showed the nose and upper pharynx not inflamed, but as the sphenoid was bare the anterior wall was broken down to relieve the dropping posteriorly. A previous examination of the urine had given a specific gravity of 1031. Quantity, one and a half pints. A few crystals uric acid. No albumen. His physician had been aware of his condition but as the patient was a man with large business interests he could not be prevailed upon to follow directions for physical exercise until his last attack which so frightened him that he commenced systematic horseback riding, cool bathing, long walks, etc. General medication was directed toward his concentrated urine with noticeable effect upon his larynx which improved at once in becoming less sensitive to changes of temperature and more free from unpleasant sensations which had annoyed him since his acute attack. The throat here strongly suggested an incompetent kidney.

Case V. Mr. K., referred by Dr. —— in April, 1901; American, teacher, forty-six years. Has always had a persistent cough following every cold.

Examination. — Slight cartilaginous ridge well for-

ward in both nares. Naso-pharyngitis. Tonsils enlarged. Adenoid tissue at the vault and in Rosenmuller's fossæ. Lymphoid tissue extends laterally from base of tongue up to epiglottis and is continuous with that at base of tonsils. Glandular tissue at base of tongue very prominent which accounts for his long continued coughs. Chronic indigestion. The enlarged glands at the base of the tongue were cauterized and the lymphatic tissue in the vault and fossæ removed as well as that lower down about the epiglottis. He continued in good condition until February, 1903, when he reappeared with a painful pharynx, without any naso-pharyngitis above. He was referred back to his family physician with suggestions in regard to his digestion. A test meal showed chronic secretory trouble which was corrected with benefit to his throat.

The above five cases show that judicious local treatment was necessary to their restoration, yet they also illustrate the point that one must have a broad outlook as these conditions represent no one disorder but chronic functional or organic disturbances of metabolism which aggravate and tend to recurrent exacerbations of the local disease.

GERMAN MEASLES.

BY F. H. MONTGOMERY, M.D., DANVILLE, KENTUCKY.

THE Clinical Department of THE JOURNAL of April 14 contains an article entitled "Concerning German Measles" by Dr. Chas. W. Townsend, which I have read with much interest and which induces me to submit to you the following clinical experiences:

CASE I. A young lady, sixteen years of age, developed a rash the thirtieth day of January. There were no prodromes, a rise of less than one degree of temperature, only slight malaise and some enlargement and tenderness of the posterior-cervical glands. The eruption lasted two days. On Feb. 13 I was again called to see her when she gave a history of having felt badly for three or four days with marked catarrhal symptoms and considerable cough. Temperature 101. She had a typical eruption of rubeola over face, chest and back. This persisted four or five days and disappeared leaving her in good condition. She had no sore throat in either attack.

CASE II. A child two years of age. After three or four days of catarrhal symptoms this child, on Jan. 23, developed an attack of broncho-pneumonia of the congestive type and had several convulsions. Both lungs became filled with liquid rales, the patient became somewhat cyanosed and fell into a condition of semi-coma. Temperature at this time was 105½ (taken in the groin). He rallied from this condition and during the following night broke out with a typical rash of rubeola. This patient was seriously ill for three weeks, the pneumonia producing grave anxiety for a fortnight after the disappearance of the rash. On March 6, after having been out of bed for some ten days, he developed a rash with more of the characteristics of scarlatina than that of the former attack. He had no prodromes, his temperature did not reach 100 F., he had no sore throat and the rash disappeared in less than two days. The post-cervical glands were enlarged and tender.

CASES III, IV AND V. All were members of the same family. I attended them during well marked, uncomplicated attacks of rubeola from Jan. 23 to Feb. 3. On March 21 one of them developed a rash similar to that described above, having had no prodromes, and was followed in a few days by its development in the other two. The source of infection in these cases was undoubtedly case No. II, as they were next-door neighbors and playmates.

CASE VI. A girl of about twelve years of age on Feb. 12 developed a rash, having had no prodromes. Temperature 99½, post-cervical glands enlarged and tender. No catarrhal symptoms. On Feb. 27, after the usual prodromes, this patient developed a well marked attack of rubeola. An interesting point in this case is that I attended her during a well marked attack of scarlatina in the spring of 1898, when the symptoms were all so characteristic and the source of infection so well known that there was no chance for error.

CASES VII AND VIII. Two children of the same family, cousins of case VI and exposed to her on Feb. 12 and 13. On Feb. 24 one of these, without prodromes, developed a rash attended by slight temperature and enlargement of the post-cervical glands. On Feb. 28 the other child developed a similar condition, and a few days later their mother (who had had rubeola) went through the same character of sickness. This family moved to a neighboring state, but just prior to their removal these children were exposed to case IX during his attack of rubeola, and I have recently learned that they both developed this disease in about ten days after exposure.

CASE IX. Cousin to VII and VIII and visiting in the same family. Was exposed to VII and VIII and to their mother during their attacks of illness. On March 16, without prodromes, developed a rash accompanied by slight temperature and enlargement and tenderness of the post-cervical glands. He had absolutely no sore throat. On March 6 played with a child who had the cough and catarrhal prodromes of rubeola, and on the twenty-third was thoroughly broken out with the typical rash of this disease.

During the period covered by these cases there was no scarlatina reported to the authorities of this town, and I could hear of none, but there was an epidemic of rubeola and I am confident of Rotheln.

The following points in this series of cases are interesting:

(1) The occurrence of two attacks of eruptive disease in each of these nine cases within the duration of a few weeks.

(2) The fact that one of these attacks could be absolutely diagnosed as rubeola.

(3) The fact that the other attack did not have the initial chill or vomiting of scarlatina, did not have any sore throat, and did not desquamate, and the period of incubation where it could be determined was too long for scarlatina — being from twelve to twenty days.

(4) That case VI had previously had an attack of scarlatina contracted from a known source and followed by marked desquamation.

In conclusion I would say that I attended during this period a number of other cases of typical rubeola and also a number of cases of this very mild eruptive disease as they were both epidemic in this community, but report only those cases that had an attack of each.

Medical Progress.

THE PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., AND HAYWARD W. CUSHING, M.D.

A METHOD OF ANESTHESIA DURING OPERATION ON THE FACE.

L. Ombredanne[1] recommends the following method, the advantages of which are that the inconvenience to the operator of the usual apparatus and the danger of wound infection from the same are avoided. The apparatus consists of a can-like receptacle, containing a sponge fitted with a movable perforated cover and a tubelike "nose," to which is fitted a flexible rubber tube, which connects the apparatus with a metal tube, which perforates a piece of soft rubber which is placed between the patient's teeth and lips. When used, the sponge in the "can" is saturated with ether, the patient's nostrils "tamponned," the soft rubber mouthpiece placed in the proper position in the patient's mouth and the ether vapor is inhaled. By lifting the lid of the "can," the desirable portion of air can be mingled with the ether inhaled by the patient. The method is another modification of the practice of inhaling ether without an apparatus which, more or less, covers the face and is held in position by the hand of an anesthetizer. This particular device would not seem to have all the advantages of the method described in a recent report of the Boston City Hospital.[2]

IGNITION OF ETHER VAPOR IN PRESENCE OF A CLOSED ELECTRIC LIGHT.

D. Murray makes a short but interesting report of a case where an explosion occurred under the condition above stated. The etherizer was testing the corneal reflex. The patient was lying prone and the head was turned around so as to bring it directly under an electric lamp. At this instant the ether vapor ignited and the patient was slightly burned. The lamp is described as a "closed" light.[3]

In this connection the cause of a recently noted gasolene explosion is of interest. The patient was cleansing an article of clothing with gasolene in a wash basin on a cold day. Another person touched the victim of the explosion with her hand. The contact produced an electric spark and an explosion of the gasolene vapor followed, resulting in severe burns and a fire in the house. Although no similar accident with ether is on record as far as we remember, still the above incident suggests it as a possibility.

PROGNOSIS IN FRACTURES OF BASE OF THE SKULL.

Graf[4] has compiled and studied the records of the König clinic at the Charite Hospital in Berlin from 1896 to 1902. He has arranged statistically, and according to their relative frequency of recurrence, the different clinical results of cases of fracture of the base of the skull (not only the immediate but also the final condition of the patients).

He collected 90 cases (77 men, 13 women). The most frequent cause of the injury was a fall from a greater or less height (63 cases). The immediate mortality was 21 deaths in 24 hours. On second to third day, 4; 6 on sixth to eighteenth day, 3 of meningitis. The most frequent symptom of the fracture was hemorrhage from the nose, ear and mouth. One ear, 64 times, both ears, 13. Nose and mouth, 39 times. Escape of cerebro-spinal fluid from one ear, only six times. From the nose once. Subconjunctival hemorrhage, 25 times. Postorbital, twice. Of paralysis of cranial nerves, the facial was most frequently noted, 24 cases. This was generally due to hemorrhagic pressure which recurred after absorption of the clot. There was loss of consciousness in 74 cases. In 28 this was of short duration. In 40 cases from several to twenty-four hours; of these latter 21 ended fatally. The pulse was slow and strong in 16. Aphasia in 3. Convulsions in 3.

In 48 patients in whom the after history was learned, the most frequent condition was headache (34). This followed in 8 cases a blow on the head. In 16 patients this was constant and incapacitated the individual for hard work. Twenty-seven complained of vertigo, which was caused in 10 patients by backward motions of the head. Ear noises occurred 16 times. Weakness of memory, 17. Diminished intelligence in 11. Dementia in 2. Abnormal irritability, 15 times. The hearing power was found to be normal in 12 out of 39 patients tested. Four had middle ear catarrh and 20 impaired hearing, due to interference of the sound conducting apparatus. Short clinical histories of the special cases are appended.

TUMORS OF THE RETROCAROTID GLAND.

P. Reclus and M. Chevassu[5] have recently made a contribution to the literature of this subject. The etiology of these tumors is not understood, but they occur in early life; in the few cases reported the affection having been seen between the seventh and thirty-third year. They seem to be made up in most cases, as in that described by the authors, of blood vessels and numerous cells of undetermined origin, the whole enclosed in a capsule. Of slow growth, the patient becomes aware of the existence of the tumor by chance, or after it has gained sufficient size to cause some discomfort; slight pain in its neighborhood in some cases, first calling attention to it. With the head slightly extended, the outline of the tumor may be readily recognized and at the same time it may be seen to pulsate; these pulsations being synchronous with the radial pulse. The tumor occupies the carotid region, embracing the division of the common carotid and the bifurcation of its two initial branches. Its size is said to vary between that of a pigeon's and hen's egg; it is generally soft and elastic, quite mobile transversely, but slightly so vertically and

[1] Gaz. des hôpitaux, 1903, no. 109.
[2] Thirteenth series, 1902, p. 118.

[5] Revue de Chirurgie, September, 1903.

it may be made to disappear under pressure; though upon withdrawal of pressure it regains its former size within two or three successive pulsations. Auscultation over the tumor may reveal a systolic murmur. The pulsation seen is the most striking symptom, this being synchronous with the radial pulse, non-expansile and disappearing upon compression of the common carotid. The authors state that a positive diagnosis of tumor of the retrocarotid gland may be made in the presence of a single, soft, pulsating, non-expansile tumor of slow development in the carotid region at the level and above the thyroid cartilage. Treatment is surgical, consisting in extirpation of the tumor.

ESOPHAGEAL DIVERTICULA.

In a comprehensive article, G. Riebold [6] states that traction diverticula are very frequent in adults (3.5 % of all autopsies on adults and none in children under fifteen years). Their location is usually the anterior or lateral (more often the right than the left) wall at the level of the trachea; in four cases they were seated 5 to 6 cm. (2½ inches) higher, in one case 10 cm. (5 inches) lower, and in another the posterior wall was involved. In the majority of cases only one is found, but at one autopsy there were as many as nine. They all stand in intimate relation with indurated chalicotic or anthracotic lymph-nodes. The form most frequently encountered is that of a funnel 3 to 6 mm. ($\frac{1}{10}$ to $\frac{1}{8}$ inches) deep, but a large number of variations may be described. The shape of the opening is not constant and the longest diameter is usually directed obliquely upward. All the layers of the esophagus may participate, but usually the mucous membrane is defective. The clinical importance of these diverticula lies in the possibility of perforation and infection of the surrounding tissues. The stagnating food may set up an inflammation and progressive ulceration, or else the gland will suppurate and discharge into the esophagus. The result is an enlargement of the original diverticulum, or a purulent mediastinitis or perforation of the pus into the trachea, bronchi, lung, pleura, pericardium, or vessels. Carcinoma or tuberculosis are very apt to develop upon the scar tissue of an old diverticulum. The diagnosis during life has never been made. The fact that a glandular inflammation is apt to spread toward the esophagus and draw out its walls is best explained by an obstruction of lymph-channels which permits a retrograde transport of germs. Similar diverticula of the trachea and bronchi have also been described, but here the cartilaginous rings offer a much greater resistance than the soft walls of the esophagus. In the second group, the diverticula by traction and pressure, part of the wall of a traction diverticulum is bulged out, or else the entire pouch has yielded and it would be hard to distinguish it from a pressure diverticulum, were it not for the remains of glands and chronic inflammation in the neighborhood, and perhaps the deposit of coal in the walls. This group is rare, and position and etiology are the same as in the preceding group. Lastly, the pure pressure diverticula claim attention, especially since their causation has been a mooted point. It is probable that the pressure of a morsel passing down the esophagus or forced expiratory acts bulge out a posterior pharyngeal wall weakened congenitally or by trauma. The muscle fibers of the inferior constrictor will yield so that a hernia of the mucous membrane can readily take place. After the bag has attained a certain size, the pressure of the contained food will enlarge it more and more. The diagnosis is fairly certain and treatment is also satisfactory; formerly one fourth of the cases died of starvation or aspiration pneumonia, with pulmonary gangrene, but now a large number are amenable to operation, Lower down in the esophagus, especially on its anterior and lateral wall, above physiological stenoses, similar pathological lesions are sometimes seen, and it is likely that here, also, a congenital weakness is at fault.

DERMOID CYSTS AND TERATOMAS OF THE ANTERIOR MEDIASTINUM.

Dangschat, [7] an assistant in Garre's clinic in Konigsberg, gives practically all the information obtainable on this subject up to date. He reports two cases operated on in the Konigsberg clinic and has collected from the literature forty-four similar cases. Only two of these are from American journals, one reported in 1879, and three others are mentioned from English sources.

Various theories have been advanced to account for the origin of these tumors. The theory of origin by direct embryonic inclusion, by development from the thyroid or thymus or from the gill-slits, Dangschat rejects. The symptoms generally appear at about the time of puberty. The growth usually continues for several years and is much slower than that of sarcoma and carcinoma. Difficulty in breathing is the most important symptom of these dermoids, and with it there is often considerable pain. In a considerable proportion of cases there was cough and expectoration and in a few cases spitting of blood. As the growth increases in size, the prominence of the chest wall is noticeable. Earlier in the disease the picture may resemble that of tuberculosis of the lungs, but at a later stage the diagnosis would lie between pleurisy with effusion, aneurism, echinococcus and actinomycosis. The finding of hairs in the sputum furnishes positive diagnostic proof. In many other cases puncture with an aspirating needle would clear up the diagnosis.

When the history leads to a probable diagnosis of dermoid cyst, operation should be undertaken. Aneurismal bruit and symptoms of inflammation in actinomycosis would probably leave little doubt as to the differential diagnosis from these conditions. The prognosis is absolutely unfavorable unless a timely diagnosis is made and suitable operation undertaken. The operation in most cases necessitates resection of several

[7] Beitrage zur klin. Chirurgie, 1903, xxxviii, p. 692.

ribs, or of the sternum, and evacuation of the cyst and suture of the remaining cyst wall into the opening. The cavity then is scraped with a curette, or treated with caustic, and left to close by granulation. In three of the cases out of forty-four, death followed the operation, in one case from hemorrhage, in the second from infection, and in the third from an unknown cause. The remaining patients were either cured or improved. In several of the cases reported, cavities of very large size resulted from the operation. These can hardly be expected to close without further treatment. He suggests that in such cases these cavities may be obliterated sometimes, either partially or entirely, by turning in large skin flaps from the surrounding parts after the wound was well covered by healthy granulations, or, failing in this, the Thiersch method of skin grafting might be employed.

SPEAR WOUND OF THE HEART.

A most interesting example of this condition is described by T. McArdle[8] where a barbed spear was embedded in the chest, passing through the wall of the left ventricle, but without entering the cardiac cavity, and the patient made a good recovery after operation. The patient was a Soudanese and the spear entered near the lower angle of the left scapula, passed through the chest and projected at a point midway between the left nipple and the midsternal line, about one inch above the nipple. Operation was done. A part of the sixth rib was resected and the spear was found to have penetrated the margin of the left ventricle. This fleshy fragment was divided, the spear withdrawn and the external wound sutured. Restoration of pulse and respiration followed and the man made an interrupted recovery. Interesting points are the slight general influence produced by operative interference with the cardiac muscle, the profound disturbance caused by the change in cardiac position, as shown by the apparent fatal syncope which followed traction on the spear while it was still fixed in the wall of the heart and the peculiar modification of the cardiac sounds produced by the presence of a foreign body in the cardiac wall.

RESUSCITATION BY MASSAGE OF HEART AN HOUR AFTER DEATH.

Dr. Paul Sick[9] reports that a lad of fifteen was being operated on Dec. 13, 1902, at the Kiel clinic, on account of tuberculous peritonitis, when heart action and respiration ceased. Artificial respiration and König-Maas massage of the heart restored the respiration for a single minute or two, but it then subsided again and after thirty minutes the youth was still cyanosed, pulseless, no respiration, the entire body growing colder and colder. The heart was then exposed by a Rotter incision and, forty-five minutes after the first signs of disturbance, massage was applied directly to the heart, supplemented by warm compresses. After fifteen minutes the heart gave signs of life and in fifteen more minutes was beating regularly. Respiration was resumed, the pupils contracted to normal, the color returned and the pulse became good, although rather frequent. The pericardium was then sutured and the thorax flap replaced and sutured over the tampon. Two hours later the youth had regained consciousness and complained of thirst and dyspnea; respiration 60, pulse 144. Under camphor and saline infusion the condition remained about the same for twenty-four hours. The speech was indistinct, hurried but intelligible. Then symptoms of collapse were observed, the dyspnea increased and death ensued after three hours of coma. Signs of slight fibrinous pericarditis were found at the autopsy and of old pleuritis, fresh recent tumefaction of spleen and liver, with tuberculosis of peritoneum and mesentery in an advanced stage. Sick remarks that the resuscitation might have been permanent in a subject less severely undermined. The action of the chloroform on the heart had evidently been magnified by the shock and the altered conditions in the circulation entailed by the laparotomy and evacuation of the ascites.

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

STATED meeting, Feb. 2, 1904.

DR. JOSEPH FRAENKEL, President *pro tem.*, in the chair.

(Concluded from No. 18, page 488.)

REPORT OF TWO CASES OF TUMOR OF THE PONTO-MEDULLO-CEREBELLAR SPACE (ACOUSTIC NEUROMA) WITH OPERATION.

By DRS. J. FRAENKEL AND J. RAMSAY HUNT.

CASE I. Reported by DR. FRAENKEL; operation by DR. CHARLES A. ELSBERG: The patient was a man, forty-eight years old, a theatrical manager, who entered the Montefiore Home on July 1, 1903. One brother was an imbecile; otherwise his family history was negative. His previous personal history was also without bearing on the present condition. He denied excesses and venereal infection.

About five years ago the patient first noticed that his hearing on the right side was impaired, so that he had to use his left ear when at the telephone. A year later his gait became staggering and uncertain, and he could not co-ordinate his lower extremities at all times. The right lower extremity was the first to be affected. The patient did not notice that he swayed to one side more than the other. Three years ago his gait frequently was like that of a drunken man, and two years ago a transient diplopia was noticed. About the same time the lower extremities became marked spastic, his sight became impaired, his speech became stammering, and he noticed that he was tremulous when writing or performing any other intentional function with the upper extremities. During the last year, occasional insufficiency of the sphincters was noticed and he was unable to walk without assistance. At no time was there any pain, paresthesia or girdle sensation.

An objective examination showed static and locomotor ataxia. Romberg's symptom was present. The patient falls and inclines to the left side. There is slight mental hebetude and occasional emotional explosiveness. There was motor weakness of all four extremities, particularly on the left side; a tactiform unsteadiness of both upper extremities, particularly of the right; loss of position sense in right-sided upper extremity; exaggeration of reflexes, particularly on the left side; Babinsky present on both sides, more marked on the left; marked nystagmus; scanning speech; considerable choked disk, with retinal hemorrhages; deafness of the left ear.

Six weeks before the operation, a paralysis of all branches of the seventh nerve set in, with marked changes of the electrical reactions.

The operation for the removal of the tumor was performed by Dr. Elsberg. The patient unfortunately died from what appeared to be an acute uremia thirty-six hours after the preparatory operation.

DR. CHARLES A. ELSBERG, who did the operation in this case, said that the opening in the skull was made in a rather unusual situation. In most of the operations for a tumor in the posterior fossa, the cerebellum was exposed by the so-called occipital craniotomy, in which the opening was made in the occipital bone somewhere between the median line and the posterior margin of the mastoid, and below the level of the lateral sinus. For tumors situated in front of the cerebellum, as was the tumor in this case, and for tumors in the anterior and lateral parts of the cerebellum there were several objections to this method of exposure:

(1) It was not the shortest route from the surface of the skull.

(2) The manipulations in the removal of the tumor must be done by the sense of touch alone.

(3) Even with the most gentle manipulations the cerebellum was apt to be contused and its tissues lacerated.

(4) In the digital examination of the anterior parts of the cerebellum from the under surface of the organ, the finger must come in frequent contact with the medulla and perhaps the pons, and the great danger from even slight injury to these structures was well known.

Dr. Elsberg said he investigated this subject for the purpose of finding, if possible, a method by which the disadvantages above mentioned would be avoided.

Actual measurements on a number of skulls showed that the shortest distance from the surface of the skull to the anterior edge of the lateral lobe of the cerebellum on the same side was measured on a line which ran along the posterior surface of the petrous portion of the temporal bone, and reached the surface of the mastoid 1 to 2 cm. behind the external auditory meatus. The distance from the outer surface of the occipital bone, below the level of the lateral sinus, to the anterior edge of the cerebellum diminished steadily as the measurements were made more and more distant from the median line. These facts showed that the shortest route to the ponto-medullary space on the same side would be through an opening made in the mastoid process.

If, in the cadaver, an opening was made in the mastoid region and the dura incised, the lateral edge of the lateral lobe of the cerebellum fell away from the posterior surface of the petrous portion of the temporal bone, so that fully one half of that part of the bone could be seen. With only very slight retraction, the lateral lobe could be drawn sufficiently towards the median line so that the auditory and facial nerves could be plainly seen in their course from the ponto-medullary cerebellar space to the internal auditory meatus, and even the ninth, tenth and eleventh cranial nerves could be seen in part of their course in the posterior fossa. The auditory nerve could be cut close to its origin with a fine scissors without touching the pons or medulla. Dr. Elsberg said he had performed the operation on the dead body a number of times and was convinced of its feasibility. In the living body, where the cerebellum was filled with blood, the same conditions would be found, although to a somewhat lesser degree. This had been demonstrated by Krause, of Berlin, in a somewhat similar operation devised by him in a case in which he cut the auditory nerve in the posterior fossa for the relief of a persistent tinnitus aurium.

As was well known, considerable of the lateral parts of the cerebellum could be cut away without causing a permanent disturbance in the functions of this part of the brain. Therefore, this was the part of the cerebellum that could be handled with the greatest safety, and at the same time, could be most easily retracted. From these facts it followed that the approach to the anterior edge of the cerebellum along its outer edge was not only the easiest, but also the route by which the organ was least apt to be injured during the manipulations.

An examination into the anatomical relations of the parts in the posterior fossa would soon make it clear that when the ponto-medullary cerebellar space was approached from the mastoid region along the outer edge of the lateral lobe of the cerebellum, neither finger nor instrument need come in intimate contact with the pons or medulla until the space itself had been reached. It was probable that the correct way to remove tumors from this region was to expose the structures on the central side of the tumor, if possible, and first divide these, and then to work outwards all of the time, away from the pons and medulla. Hence, with this lateral method, the danger of wounding these important structures was reduced to a minimum.

Dr. Elsberg thought it was advisable, in almost all of these cases, to operate in two stages. On Jan. 21, 1904, under chloroform anesthesia, the bone was exposed by a flap of the soft parts, including the periosteum over the mastoid and outer parts of the occipital regions. An opening was then made with the cranial drill, chisel and rongeur, measuring 5 by 8 cm., and extending from above the superior curved line of the occipital bone to within 1½ cm. of the margin of the foramen magnum, and from within 1 cm. of the external auditory meatus to 3 cm. from the median line. In the upper part of the wound the occipital lobe, covered by its dura, was visible, and in the lower part, the right lobe of the cerebellum, covered by its dura. The greater part of the lateral sinus of the right side was thus exposed. The wound was then closed, the flap being sutured back into place, and a voluminous dry dressing was applied.

The patient was considerably shocked at the end of the operation, but he reacted well to stimulation. His condition remained fairly good until the second day, when his kidneys ceased to act and he passed into a uremic condition and died in forty-eight hours.

The skin-flap was turned back about two hours after death and the dura incised. With the head turned to the side, the tumor could be plainly seen at a depth of from 3 to 4 cm. and when the finger was introduced it was found that the tumor could be peeled out with the greatest ease. It seemed probable that had the patient survived the first operation, the removal of the tumor could have been accomplished at

the second operation in a short time and with very little difficulty.

After the patient's death it was learned that he had had an attack of acute nephritis, with general edema, some years before, and although the urine had been carefully examined prior to the operation and had showed no evidence of renal disease, it was just to suppose that long-standing kidney trouble was the probable cause of the acute suppression of urine after the operation.

CASE II. Reported by DR. HUNT; operation by DR. GEORGE WOOLSEY: This patient was a Jewish peddler, forty-two years old. Six years ago he began to suffer from an annoying tinnitus in the left ear, followed by some impairment of hearing. During the past four years he had had occasional occipital headaches, with vertigo. These symptoms gradually increased in severity and were accompanied by cloudiness of vision. For the past six months there has been an unsteadiness of gait.

When he first came under Dr. Hunt's observation, the watch tick was not perceptible with the left ear, and the tuning fork was very faint to aerial and bone conduction on that side. There was paresis of the left seventh nerve, more apparent in its upper branch, with slight quantitative electrical changes. There was paresthesia in the sensory distribution of the left fifth nerve, with objective sensory disturbances. The pupils were unequal, the left being wider than the right. Reactions were present. There was amblyopia and choked discs, and a slow nystagmus in extreme positions. There was hemiasynergia and hemiataxia of the left side. In falling, the patient favored the left, and progression was decidedly to that side. The nuclear reflexes were active, the knee-jerks exaggerated, the left more so than the right. There was no ankle-clonus. The skin reflexes were present; no Babinsky.

The diagnosis of a neurofibroma of the left acoustic nerve was made, and operation was advised. From the known pathological character and relation of the surrounding structures of this variety of tumor in general, it was possible not only to localize the growth, but to state in general terms its situation in the ponto-cerebellar space outside of the brain substance, its possible size and consistency, and its enucleability. Its attachments to the surrounding structures consist only of the leptomeninges, blood vessels and adhesions, and when these are divided it would be possible to lift the growth out of its socket in the brain with ease.

With these data at his disposal, Dr. Woolsey decided on entering the occipital bone on its postero-inferior surface, to the left of the median line and below the lateral sinus. The index finger was inserted through the trephine opening and beneath the left cerebellar hemisphere, coming in contact immediately with the nodular surface of the growth, which was broken up by gentle manipulation and removed in fragments.

There was a tendency for the cerebellar hemisphere to rise into the trephine opening, and this, with the digital manipulation, caused some laceration of its substance, with oozing.

Following the removal of the growth, the respirations of the patient became irregular and shallow, with occasional alarmingly long intervals. The pulse was rapid. The operation, which was done under ether, had required nearly two hours. At 5 P.M., three hours after the operation, the patient's temperature was 102; pulse, 112; respirations, 26. The breathing had improved in character, and the patient seemed to be reacting. Slight clonic twitchings of the left side of the face were noticeable. Death occurred at 1 A.M., apparently of respiratory and cardiac failure, just twelve hours after the completion of the operation.

Permission was obtained to remove the brain only. The outer surface of the dura was dotted here and there with little tufts and excrescences, which proved to be attached to the brain cortex, and when torn away, they left minute depressions, with a punched-out border. Examination of the base showed that the tumor had been almost completely removed, only two small fragments remaining, together with a small blood-clot, scarcely larger than the little finger-nail. The inferior surface of the cerebellum was lacerated, but there was no external evidence of injury to the pons and medulla. The general ventricular cavity of the brain was dilated, showing that there had been a not inconsiderable internal hydrocephalus. Upon splitting the worm of the cerebellum, Dr. Hunt said he was surprised to find a firm, rounded projection from the left side of the floor of the fourth ventricle, corresponding to the site of the tumor. Microscopic sections through the brain proved this to be an extensive edema and hemorrhagic infiltration of the left peduncle of the pons, evidently arising from the region of the lacerated cerebellum, and gradually encroaching on the vital centers of the medulla. This internal pons hemorrhage was probably the immediate cause of death.

DR. GEORGE WOOLSEY said he was much interested in the class of tumors described in the cases reported by Drs. Fraenkel and Hunt, for they were so definitely localizable and could be so readily enucleated that they were very suitable for surgical treatment if they could be successfully exposed. He believed that this could be done. In the case he had operated on several months ago, which was referred to him at Bellevue Hospital by Dr. Hunt, he knew of no previous experience to serve as a guide in the operation. The tumor was approached from behind and the side by removing a large area of bone, comprising all that part of the occipital bone below the superior curved line and to the left of the median line. The opening left only a narrow bridge of bone between it and the foramen magnum and extended forward into the mastoid until the bone became very thick.

Passing the finger beneath the cerebellum, the tumor was felt and removed piecemeal. This necessitated introducing the finger a number of times, and there was some laceration of the lateral lobe of the cerebellum which did not seem of any moment. The tumor was larger than he expected to find it. In another case he would try to pass a forceps along the finger, seize the tumor, enucleate it with the finger and remove it entire.

The plan of operating in two stages, recommended by Horsley and employed by Dr. Elsberg, he thought was most excellent where the exposure was prolonged and much blood was lost. He thought Dr. Elsberg's method of approach had much to commend it, although it was not so much nearer the site of the tumor than the opening he had made as might be inferred. It had the objection that the bone was very thick, so that too much time and perhaps blood was lost in getting through it. In operations on brain tumors it was important not to take too much time in the exposure alone. This objection was obviated by operating in two stages. Dr. Woolsey said the entire operation in his case took no longer, if as long, as the exposure in Dr. Elsberg's case.

After the operation, his patient seemed in good condition and appeared to suffer but little from shock, but symptoms of the latter appeared several hours later, and he failed to rally. On the whole, in another similar

case, he would be inclined to operate in two stages and by the lateral approach suggested by Dr. Elsberg.

DR. GEORGE E. BREWER said that he had been interested in the subject of cerebral tumors for many years. He had twice explored the posterior fossa, in the first instance finding a subcortical cerebellar growth of tuberculous origin, which was successfully removed, the patient making an excellent operative recovery. He died some months later, however, from general tuberculosis.

In the second case the patient succumbed after an extensive bone removal, undertaken simply to relieve pressure. A number of anatomical investigations carried on in the dissecting room of the College of Physicians and Surgeons led the speaker to advocate the plan of opening the skull by removing, practically, all of the bone below the superior curved line to within half an inch of the foramen magnum below, and from the median line to a point half an inch behind the mastoid. By opening the dura, the finger could be easily passed behind the lateral lobe and reach the situation of these tumors at a depth of less than an inch and one half from the surface of the wound. Of course, adequate exposure to remove such a growth would necessitate the destruction of a portion of the lateral lobe; this, however, could be done without serious trouble to the patient, as had been demonstrated in his first case.

It was Dr. Brewer's opinion that speed of operation was perhaps the most important factor necessary to success, as these patients almost invariably died if the operation was at all protracted. He was in favor of doing the operation, when practicable, in two stages. The first operation should consist of the removal of the bone only, which to a certain extent relieved the pressure, and at a subsequent period the dura should be incised and the tumor removed. He thought the primary operation should be done in from twenty to thirty minutes.

DR. HUNT, in closing, referred to a previous communication, published in conjunction with Dr. Fraenkel, in which five cases of tumor of the ponto-cerebellar space were recorded. In that paper, especial stress was laid on the certainty of localization and the enucleability of this group of tumors, and their surgical importance.

In both of the cases under discussion, in which operation was attempted, the diagnosis of an acoustic neuroma was made, and the operative procedure was modified to meet the known anatomical peculiarities of this type of tumor. In Case I the patient succumbed thirty-six hours after performing the first stage of the operation, apparently from shock, although a renal complication could not be excluded. In Case II death was due to laceration of the cerebellum, with resulting effusion of blood into the tissues of the medulla and pons. Both of the operations were prolonged and tedious, and considerable trauma was inflicted in removing the thick occipital bone, and enlarging the trephine opening. It seemed of paramount importance, in exposing tumors in this locality, that the operation be done expeditiously and with great gentleness, as any concussion must be especially effective in this region. The division of the operative procedure into two stages was also to be recommended.

THE ZOOLOGICAL SOCIETY of Philadelphia, according to the *Medical News*, is to make experiments looking toward the prevention of tuberculosis in animals, this disease being one of the most frequent causes of death. An unused house in the garden is to be converted into a hospital where all new specimens will be received and examined.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

MEETING JANUARY, 1904, DR. W. T. COUNCILMAN IN THE CHAIR.

DR. HENRY JACKSON read a paper on

TUBERCULAR MENINGITIS IN ADULTS.[1]

DR. W. N. BULLARD said that he desired to express his full agreement with the writer in regard to the symptoms in the tubercular meningitis of adults. Up to the time of the appearance of the ocular or facial palsies the condition suggests that found in an advanced stage of typhoid fever, but without the special signs of typhoid (rose spots, etc.). Where the paralyses exist it is evident that the affection is of intracranial origin, but even at this stage it is distinguished from the other intracranial affections by its lack of destinctive symptoms. Contrary to what might be expected the deep reflexes are normal. It is not by any means an uncommon affection and in any case of obscure acute or subacute intracranial disease the possibility of its existence should be considered.

DR. P. C. KNAPP had also found that the clinical picture of tubercular meningitis in the adult differed from that usually seen in childhood. There was another form of tubercular meningitis often observed in the adult, which must be so regarded pathologically, although clinically it was quite distinct. In many cases of so-called solitary tubercle of the brain in the neighborhood of the meninges there is often a patch of chronic tubercular meningitis, with perhaps a few miliary tubercles scattered about in the meninges in the vicinity. In such cases the symptoms are those of a cerebral tumor rather than of meningitis.

DR. E. E. JACK desired to say a word from the standpoint of the eye. He had examined quite a number of cases of tubercular meningitis, but had never found tubercles in the choroid. He had, however, seen them in general miliary tuberculosis and it is his impression that they are almost limited to that disease.

DR. J. L. MORSE: While the type of tubercular meningitis in infancy and childhood, as a rule, corresponds to the picture drawn by Dr. Jackson and by most textbooks, it is not very uncommon, especially in infants, to have the disease resemble the adult type as described by Dr. Jackson. I can remember distinctly a number of cases in infants, proved either by autopsy or by lumbar puncture, in which there were not only no marked nervous symptoms, but in which there was no bulging of the fontanelle, no Kernig's sign and no exaggeration of the reflexes. Dr. Jackson spoke of the aid given by lumbar puncture in the differential diagnosis between tubercular and cerebro-spinal meningitis. I cannot agree entirely with his statements. While, of course, in a general way, the fluid from tubercular meningitis is only slightly turbid, it may be decidedly purulent, and while in cerebro-spinal meningitis the fluid is usually decidedly turbid or purulent, it may, especially in long cases, be almost clear. Tubercle bacilli are, of course, rarely found in the fluid of tubercular meningitis, but absence of bacteria does not, however, by any means, rule out cerebro-spinal meningitis, for while the meningococcus is usually present early in the disease it is usually absent later. Dr. Jackson did not speak of the characteristics of the cells in cerebro-spinal fluid in the two diseases. To my mind, the sort of cell is of great importance in diagnosis, as the amount of mononuclear cells predominate greatly in tubercular meningitis, while polynuclear cells predominate in cerebro-spinal meningitis.

Recent Literature.

Students-Aid to the Muscular Attachments. Graphic Scheme. Part I. The Upper Extremity. By Errett E. McLellon.

This chart is designed to show graphically the origin and insertion of muscles of the upper extremities of the body. To accomplish this end a diagram of the skeleton is reproduced with the various muscles represented diagrammatically, simply as lines. The chart itself is liberally supplied with explanatory text, and in addition there is a considerable amount of information on general anatomical points. The front of the body is represented on one side of the chart and the back on the other. Anything which helps to fix muscular attachments is certainly of value, and this should accomplish, in a measure this result.

Elements of Surgical Diagnosis. By A. Pearce Gould, M.S. (Lond.), F.R.C.S. (Eng.), Surgeon to the Middlesex Hospital, Member of the Council of the Royal College of Surgeons of England and of the Examining Board for England, Member of the Senate of the University of London. Third edition. Revised and enlarged. Chicago: W. T. Keener & Co. 1903.

We welcome an old friend in this little red-covered book on the elements of surgical diagnosis. We have long wondered why Mr. Gould did not bring the book out again with the additions of modern surgery. This he has done and in a very satisfactory manner. We are very sure that it is a book which will serve a most useful purpose and will be greatly valued by students, physicians and surgeons.

Hypnotism: Its History, Practice and Theory. By J. Milne Bramwell, M.C., C.M. London: Grant Richards. 1903.

Dr. Bramwell has produced a practical book on the theory and practice of hypnotism. He calls attention to the fact that, although many books on the subject have been published in foreign languages, few have as yet appeared in English. He therefore discusses the topic from a general point of view as well as from the standpoint of wide personal experience extending over twelve years. The general aim has been to draw attention particularly to those points which may be of practical value to those desiring to practice hypnotism as a means of treatment. Theories are discussed, but not at great length, and the pitfalls of hypnotic practice are dwelt upon in considerable detail. The value of the book lies largely in its appeal to personal experience. Many cases are reported of the most varied affections with the outcome of suggestive treatment. The discussion is judicial and the book is certainly worthy of warm recommendation to physicians in general, as well as to those concerned particularly in the use of hypnotism as a therapeutic aid. The book is admirably printed and attractively bound. It contains no illustrations. An excellent systematic bibliography is appended which should prove of value to students of the general subject.

The Blues (splanchnic neurasthenia); Causes and Cure. By Albert Abrams, A.M., M.D. 12mo. pp. 240. With 27 illustrations. E. B. Treat & Co.: New York. 1904.

The writer calls attention to a special form of neurasthenia, characterized by paroxysms of depression, popularly called the "blues," which he terms splanchnic neurasthenia. This he believes to be due to a congestion of the intra-abdominal veins, and the chief abdominal symptoms are abdominal sensitiveness, tenderness and enlargement of the liver and intestinal flatulence. This form of neurasthenia can be cured by relieving this congestion by various physical methods, such as abdominal massage, exercises to strengthen the abdominal muscles, respiratory exercises, electricity (especially the sinusoidal current) to the abdomen, abdominal supporters and cold douches to the abdomen. The author's theories are interesting and they may prove of some assistance in the treatment of certain cases of neurasthenia.

Scheme for the Differential Testing of Nerves and Muscles for use in Diagnosis. By J. Montgomery Mosher, A.M., M.D. 8vo. pp. 58. With two cuts, five charts and six plates. Brandon Printing Company: Albany. 1903.

This little volume gives the essential rules for testing the electrical reactions of nerves and muscles, a specimen chart for electro-diagnosis, and a description in the text of the anatomical position of the various motor points of the nerves and muscles, with a series of new plates of the motor points drawn from original investigations. These plates are superior to those in ordinary use, being larger and clearer and more helpful to the student by the use of color, the motor points of the muscles supplied by a given nerve being of the same color as the motor point of the nerve. The volume will be useful to all who use electricity for diagnosis.

The Practical Medicine Series of Year Books. Vol. III, which is one of a series of twelve, issued once a month. Gustavus P. Head, M.D., Editor. 12mo. pp. 322. Casey A. Wood, M.D., The Eye; Albert H. Andrews, M.D., The Ear; T. Melville Hardis, A.M., M.D., The Nose and Throat. Chicago: The Year Book Publishers. 1903.

The selections from current literature in this little volume are well chosen and instructive. They are evidently intended for the use of the general practitioner who does work in these specialties and has not time to follow the literature of the subjects through the thousands of pages which appear in the ophthalmic and aural journals yearly. The printing and paper are good and the volume of handy size.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 12, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston weekly, by the undersigned.

SUBSCRIPTION TERMS: $5.00 *per year, in advance, postage paid, for the United States, Canada and Mexico;* $6.50 *per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE MINIMUM PROTEID REQUIREMENT OF THE HEALTHY MAN.

AMONG the many interesting papers presented at the April meeting at Washington of the National Academy of Sciences none attracted greater attention than the " preliminary report " by Professor Chittenden of Yale on the results of his investigation into the minimum proteid requirement of the healthy man. This investigation has been going on for the past six months in the laboratory of the Sheffield Scientific School, the experiments being made upon twenty-seven men of whom six were professors and instructors in Yale University, thirteen were soldiers detailed, as volunteers for the service, from the United States Hospital Corps, and eight were Yale students selected on account of their proficiency in athletic exercises. The object of the research was to determine whether the commonly accepted dietary standards represent the actual needs of the human organism or merely indicate what men are in the habit of eating.

Prof. Carl von Voit of Munich, whose studies have usually been regarded as furnishing trustworthy information on this point, placed the proteid requirement of the average human being at 118 gm. daily, corresponding to the excretion in the form of urea of 16 gm. of nitrogen, but of late years evidence has accumulated that certain individuals and even certain races of men could lead healthy and active lives with a daily consumption of proteid food far less than that indicated in Voit's standard tables.

Thus Kumagawa [1] has shown that Japanese dietaries containing relatively small amounts of proteids suffice to maintain the health and strength of that oriental race, and Sivén [2] has demonstrated the possibility in his own case of living for several weeks with a daily average nitrogen excretion of only 4.52 gm.

Under these circumstances Professor Chittenden's attention was naturally attracted by the claim made by Mr. Horace Fletcher [3] that great economy of food can be effected by careful attention to mastication and insalivation, and when, through Mr. Fletcher's appeal to the Secretary of War, the soldiers were detailed for the purpose, the investigation began in earnest, the expenses being borne by certain research endowments aided by a liberal contribution from Mr. Fletcher himself. No publication of results has as yet been made by Professor Chittenden, and we must therefore limit ourselves to a statement of the main facts as reported to the National Academy.

In brief it may be said that an amount of proteid food from one third to one half of that required by the Voit standard has been found amply sufficient to provide for the support of the body even in the case of those who indulged in athletic exercises. In fact, the testimony of the athletes themselves with regard to the feeling of vigor which they experience, their capacity for work and the absence of muscular soreness after violent athletic contests is one of the most convincing arguments in favor of a reduction of proteids in the diet. Professor Chittenden's personal experience is also extremely interesting, for his own proteid metabolism was for six months measured by the daily excretion through the kidneys of 5.82 gm. of nitrogen. During this time he enjoyed excellent health and performed an unusual amount of intellectual work. In reply to a question on the subject he stated to the Academy that nothing would induce him to return to his former dietary habits.

The important points in this investigation are the large number of persons concerned, the care with which the research has been conducted in its minutest details, and the length of time over which it has extended. The amount of work involved in the daily analysis of the excreta of twenty-seven persons for six months is not easily appreciated except by those who have undertaken similar investigations. Other observers have shown the possibility of reducing proteid metabolism to a fraction of its customary amount,

[3] The A B–Z of Nutrition. New York: Frederick A. Stokes Co. 1903. The New Glutton or Epicure. New York: Frederick A. Stokes Co. 1903.

but it has remained for Professor Chittenden to demonstrate that such a reduction, maintained for six months, is consistent with the preservation of a high degree of health and vigor. It is to be observed that these results have been reached without the employment of any special methods of eating. Thus, while Mr. Fletcher's main contention as to the possibility of effecting a great economy in nutrition is amply confirmed, the investigation is not conclusive as to the importance of thorough mastication and insalivation. Mr. Fletcher has, however, shown in the volumes above referred to that many persons have found that attention to these processes has been of great assistance in the improvement of their nutrition.

The immediate lesson to be drawn from Professor Chittenden's work seems to be that the optimum of proteid metabolism probably lies nearer to the minimum than to the maximum of nitrogen equilibrium and that the feeling of gastric distention, which is apt to be accepted as a sign that the appetite is appeased, is, perhaps, not a wholly trustworthy indication of the satisfaction of the body's need of nutriment.

LEPROSY IN MASSACHUSETTS.

The occurrence of leprosy in any New England state is so rare as to attract public attention whenever a case is reported. During the past month, a Portuguese, a native of the Cape Verde Islands, living at Harwich, Mass., was found to be suffering with leprosy. According to the reports of the public press the people of this town appear to have been greatly alarmed at the discovery of a leper among them, and yet, if the experience of the past hundred years or more with reference to the existence of leprosy in this country may be taken as worth anything, the actual danger to a community from the existence of a case of leprosy is not so great as that which may at any time be due to the existence of a case of tuberculosis, or of typhoid fever. The spread of these diseases from the sick to the well through neglect of proper precautions has been a matter of common occurrence. But, notwithstanding the arrival of very many lepers in the United States during the years before the enforcement of acts restricting immigration, there is scarcely any record of its spread to other persons, and instances of its occurrence among the descendants of such lepers in this country are also quite as rare. Why then so much apprehension about a disease of such rare occurrence, and of actually less danger to the community than other diseases of every-day prevalence? Much is undoubtedly due to the great importance attached to the disease in the accounts given in the Mosaic books of the Old Testament. The identity of that disease with the leprosy of to-day does not appear to be a settled question.

Of the half-dozen or more cases, which have been reported in Massachusetts in the past twenty years, none have given rise to any spread of the disease. These few cases have, with one exception, been foreign born, and were natives of countries where leprosy is more or less prevalent. The exceptional case was that of a native of Massachusetts who contracted the disease after a residence of many years in the Hawaiian Islands, and after intimate association with the natives. He returned to his home in 1882, and died there in March, 1883.

In this country the states where the greatest numbers exist are California and Minnesota, but in these states the disease is limited, in the first instance to the Chinese and in the other to the Norwegian immigrants, and has in no instance attacked other people. Many cases have also occurred in Louisiana. In the little settlement at Tracadie, New Brunswick, where it has existed for a century, the disease has not spread to other towns.

The experience of Minnesota in regard to this disease, is instructive, as it covers a period of about fifty years, since immigrants from Norway began making that state their home. In Norway, as in many other countries, the disease is decreasing. An enumeration made about forty years ago showed 2,800 lepers in that country, but at present there are but little more than 1,000.

The number reported in Minnesota in the past twenty years or more has been 112. "In that state all lepers are registered and kept under observation, and all suspected cases are carefully examined. No further isolation than the use of their own beds and utensils is required, and this their own good sense, and that of their relatives, as a rule secures. Of the twenty-one lepers now known to be living in Minnesota, all are Scandinavians, and in none is the disease known to have been caused by exposure to infection in this country, but in nearly every one there is a history of exposure in Norway or Sweden." (15th Report of State Board of Health of Minnesota. Appendix 18.)

In 1888 Dr. G. A. Hansen of Norway, the discoverer of the *Bacillus leprœ* came to this country to study the disease among these immigrants

and their descendants, and gives the following interesting results of his observations: "Of about 160 lepers who have immigrated to Wisconsin, Iowa and Minnesota, thirteen are alive, whom I have seen myself, and perhaps three or four more. All the others are dead. Of all the descendants of lepers (and that includes the great-grandchildren of some of them), not a single one has become leprous. This is, in short, the result of my observation."

In consequence of the difference of opinion which prevails as to the methods by which leprosy is spread, there are also differences of opinion as to the best methods of prevention. The English Leprosy Commission considered compulsory isolation as unnecessary, while the Berlin Conference were of a contrary opinion. Notwithstanding the fact that compulsory isolation has not been practiced in Norway, the disease has by intelligent management diminished very much in that country. Hansen believed that its spread could be checked by scrupulous cleanliness, on the part of the patient. Since the number of lepers existing in any one state is comparatively small, the plan of providing a hospital or asylum by the General Government, in which such unfortunate persons may be placed, affords a practicable solution of the problem. This plan was advocated by Dr. J. C. White in an able paper in the *American Journal of Medical Sciences* (October, 1882). He stated that: "such measures should be undertaken by the national government, and should be made applicable to all parts of the country alike."

THE PATENT MEDICINE CURSE.

UNDER the foregoing title, Mr. Edward Bok has performed a useful service, by publishing, in the *Ladies' Home Journal*, a portion of the report of the Massachusetts State Board of Health upon the percentage of alcohol in patent medicines, together with some very timely and useful advice to the public upon the insidious and harmful character of many of these preparations. It is a very encouraging sign that several public journals of high standing have, within a comparatively recent period, taken a bold stand against the mercenary overtures of the patent medicine trust, and have in some instances excluded advertisements of such concoctions altogether from their columns.

Among the worst offenders in this direction are the so-called religious weekly papers. After publishing a list containing many of the tonics, bitters and other alcoholic remedies so frequently advertised in the columns of these journals, Mr. Bok goes on to say: "A pretty consistent picture do the two portions of the average religious paper present — advocating with one hand alcoholic prohibition, or temperance, and receiving, with the other hand, money for advertising — and thereby recommending to their readers — preparations filled ten times over with more alcohol than the beer which fills them with so much horror in the editorial columns! There are no papers published that are so flagrantly guilty of admitting to their columns the advertisements, not only of alcohol-filled medicines, but preparations and cure-alls of the most flagrantly obscene nature, as the so-called religious papers of this country."

Unfortunately, the original sources of much of the reliable information on this subject, the analyses of expert chemists, scattered through the pages of several reports of the State Board of Health in different years, do not reach the general public. The editions are limited by statute, and hence cannot accomplish the results that are secured by publication with judicious comments in the columns of a public journal having a very wide circulation.

Public interest in this question is shown by the fact that bills were introduced in the legislatures of three different states during the past winter, providing that the ingredients of proprietary medicines "shall be stated on packages or other receptacles thereof prepared for sale." (House Document 939, Mass. Legislature, 1904.) Further than this, a reputable drug journal[1] has, in its March and April issues, published editorials decidedly in favor of such legislation. The following extract from the March number of this paper strikes at the root of the evil:

> The fact that no such bill has ever passed and become a law in any state speaks badly for the intelligence or else the morality of the average legislator. From the standpoint of public policy nothing can be urged against a measure of this kind, while a multitude of sound reasons can be given why such a law should exist in every state. That a measure which asks for justice to the purchaser, health to the community, enlightenment to ignorance and an end to base fraud and robbery, should annually knock at the doors of legislative halls for admission, always to meet with denial, would seem to indicate that "something is rotten in Denmark." That the day is coming when a law of this kind must pass, seems certain to those who believe in the inherent righteousness of things, and the constant trend of society toward higher ethical

[1] The Druggist's Circular, March and April, 1904.

planes. The conviction has been growing for years that in many of the proprietary medicines in which so many people indulge, resides the first insidious introduction to alcohol and narcotics that later develops into soul-destroying habits.

Nearly a half century ago, the genial poet-physician said: "I firmly believe that if the whole materia medica, as now used, could be sunk to the bottom of the sea, it would be all the better for mankind and all the worse for the fishes." To this sweeping statement, however, Dr. Holmes made certain exceptions, and we half suspect from a later passage in the same address that he had in mind the great army of patent medicines which even then were legion.

"Somebody buys all the quack medicines that build palaces for the mushroom, say rather toadstool, millionaires. Who is it? These people have a constituency of millions. The popular belief is all but universal that sick persons should feed on noxious substances." Later on he aims the following Horatian shaft at the same industry:

Hardest of all when art has done her best,
To feed the cuckoo brooding in her nest,
The shrewd adventurer, fresh from parts unknown,
Kills off the patients Science thought her own;
Towns from a nostrum vendor get their name,
Fences and walls the cure-all drug proclaim.
Plasters and pads the willing world beguile,
Fair Lydia greets us with astringent smile.
Munchausen's fellow-countryman unlocks
His new Pandora's globule-holding box,
And as King George inquired with puzzled grin,
"How — how the devil got the apple in?"
So we ask how, — with wonder opening eyes, —
Such pigmy pills can hold such giant lies!

The fictitious value which can be created by means of liberal advertising is fully illustrated in the case of patent and proprietary medicines. Upon this point the *Druggist's Circular* says: "Aside from these positive dangers lies the fact that many of these preparations are pure and simple frauds upon the community. Their intrinsic worth is trifling compared with what is charged for them,[2] and where they benefit once, they injure a dozen times. Their dupes, while running after imaginary health, are sinking themselves deeper into the toils of chronic and sometimes of acute disease."

[2] An illustration of this fact is shown in the case of a certain proprietary medicine recently brought out in a western city, in which the only ingredients are water and sulphur, the sulphur being so combined as to produce its most destructive agents, sulphurous and sulphuric acids ruinous to the teeth of those who swallow the compound. This article, which sells for one dollar per pint bottle, can be made for two cents a gallon.

When the community at large are informed that hair dyes marked "harmless" owe their activity to one of the most insidious of all poisons, sugar of lead, face bleaches also marked "harmless" are composed of the most violent poisons; asthma and catarrh cures contain considerable quantities of cocaine; "spring medicines" owe their action, not to inert sarsaparilla, but to an agent which cannot be taken by the quart with impunity, and many temperance tonics are popular only because of the alcohol they contain, and this information is conveyed by an honest label affixed to each package, the health of the community will be improved in no small degree.

Even the life insurance companies have taken up the subject, and applicants for insurance in some companies are now asked, "What patent medicines or cures have you taken in the past five years?" One writer says, "A man who will swallow a patent medicine for his blood will swallow a yellow journal editorial for his mental ballast, and he who will bolt department-store pills for his liver is not a fit subject for life insurance."

MEDICAL NOTES.

Appointment of Dr. Charles R. Bardeen. — It is announced that Dr. Charles R. Bardeen, at present associate professor of anatomy in the Johns Hopkins Medical School, is to take the chair of anatomy at the University of Wisconsin.

State Requirements for Medical Practice. — The Illinois State Board of Health has done a service in gathering together in brief the requirements for medical practice in the various states of the Union. The aim of the compiler has been to give the essential facts to physicians who are desirous of ascertaining how they can qualify in particular states. No attempt has been made to enter into further detail regarding laws, regulations, fees for examination, time and place of examination, etc. The pamphlet, which is printed by the American Medical Association Press, should certainly prove of much practical value.

Sanitary Conditions in the Philippines. — According to the monthly report of the Board of Health of the Philippine Islands and the City of Manila for December, 1903, evidence of continued improvement in sanitary matters is apparent. During the month in question two new free dispensaries were opened, with the hope

that they might become more popular than they have hitherto been with that class of the population for whom they are especially designed. Hitherto they have been regarded with considerable distrust.

A course of instruction for provincial health officers was also put into operation in Manila during the month. The course extends over a period of four weeks, is wholly practical, and is designed to give general instruction in sanitary work as needed by the various provincial boards of health. The course will be continued until all presidents of provincial boards of health have had an opportunity of taking it. Plague and malaria are reported to be under control, and smallpox plays a very small part in the mortality.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, May 4, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 44, scarlatina 18, typhoid fever 19, measles 179, smallpox 0.

DEPARTMENT OF STATISTICS. — The Boston Common Council has refused to concur with the recent action of the Board of Aldermen in voting to abolish the Boston department of statistics.

A LEPER IN HARWICH, MASS. — A case of leprosy in a Portuguese has been discovered in Harwich, Mass. He is at present living alone in an isolated situation and is prevented by the authorities from leaving the premises. His food is supplied by the town.

AMERICAN SOCIAL SCIENCE ASSOCIATION. — This Association holds its annual meeting in Boston, May 11, 12, 13 and 14. Dr. S. H. Durgin is chairman and Dr. H. W. Hill, secretary of the Department of Health which meets Friday, May 13, in Huntington Hall of the Institute of Technology.

ALCOHOL AS A STIMULANT. — Further interesting information regarding the action of alcohol as a stimulant was afforded by the so-called Marathon race recently held in Boston. The race involves a run of twenty-five miles. One of the contestants, a youth of eighteen, began to take raw brandy near the beginning of the race. He had four or more drinks in all, although he had never taken liquor before. The result was a condition of extreme exhaustion at the end of the race, with poor pulse, low temperature and mental dulness. It was the opinion of the physicians in attendance that alcohol taken as a stimulant in such tests of strength and endurance acts rather as a poison than as a stimulant.

A DINNER TO DR. C. S. SHERRINGTON. — Dr. C. S. Sherrington, who has this year delivered the Silliman lectures at Yale University, was tendered a dinner by Prof. R. H. Chittenden, at which a company of twenty men from various cities, particularly known for their work in physiology and allied sciences, were present. Among the non-medical guests was Mr. Horace Fletcher whose work on nutrition has of late excited wide attention.

BOSTON MORTALITY STATISTICS. — The number of deaths reported to the Board of Health for the week ending May 7 was 239, as against 210 the corresponding week last year, showing an increase of 29 deaths, and making the death rate for the week 20.66. The number of cases and deaths from infectious diseases included diphtheria, 52 cases and 3 deaths; typhoid fever, 17 cases, 1 death; measles, 192 cases, 3 deaths; tuberculosis, 44 cases, 31 deaths. The deaths from pneumonia were 32.

NEW YORK.

CELEBRATION OF ONE HUNDRED AND FIFTIETH ANNIVERSARY OF KING'S COLLEGE. — In the latter part of October next Columbia is to have a four days' celebration of the one hundred and fiftieth anniversary of the foundation of King's College, by which name the institution was known up to the time of the Revolution.

RESIGNATIONS. — On May 4, Dr. William T. Bull formally severed his connection with the Medical Department of Columbia University, and as a token of their regard the classes of 1904 and 1905 presented to him a silver loving cup, appropriately inscribed. Dr. Robert W. Taylor, Clinical Professor of Genito-Urinary Diseases, has now tendered his resignation.

FORDHAM HOSPITAL. — Plans for the new buildings of the Fordham Hospital, in the Borough of the Bronx, to be erected by the city, have just been filed at the Building Department. The proposed structures include the main hospital building, 305 by 43 feet and five stories in height, a four-story power house, which will also contain a laundry and quarters for employees, a two-story brick stable and dead-house, and a five-story, nurses' home. The estimated cost is $560,315, of which $339,000 is for the hospital proper.

Prevalence of Cerebro-Spinal Meningitis. — During the past month there has been a very serious increase in the prevalence of cerebro-spinal meningitis. In the week ending April 9, 24 deaths were reported from it; in the week ending April 16, 26 deaths; in the week ending April 23, 55 deaths; and in the week ending April 30, 70 deaths. The disease is represented as of a malignant type, a large proportion of the cases terminating fatally in a very brief time. This appears to be especially the case in a certain section of Harlem, in the neighborhood of 106th Street and Madison Avenue, where nine children have died within ten days, and where a feeling akin to panic prevails among the people. No such severe visitation of cerebro-spinal fever, it is stated at the Health Department, has occurred in New York within thirty years.

Investigation of Oysters. — To determine whether the oysters which supply the New York market are exposed to contamination a series of investigations was sometime ago undertaken by Dr. Walter Bensel, assistant sanitary superintendent of the health department. They were very carefully made and extended along the shores of Long Island, on the west side of Staten Island, along the New Jersey coast, and up the Sound as far as New Haven. The conclusions reached by Dr. Bensel are, briefly, as follows: (1) That the beds from which oysters are taken for consumption in the city often lie in grossly polluted waters; (2) That the process of "freshening," "fattening," or "drinking," often performed as it is in small streams badly contaminated with sewage, is a most dangerous practice and should be discontinued.

Increase of Tuition Fee at Columbia. — As a result of the recent increase of the tuition fee from $200 to $250 a year, ninety-eight of the students at the school have decided not to return next season, but to go to other institutions. When the announcement of this increase was made a few weeks ago the students held a meeting of protest, the result of which was that a petition was sent to each member of the board of trustees, urging that it was a manifest injustice that those who had entered with the understanding that the fee was to be $200 a year should be subjected to the increase. At their meeting of May 2 the trustees decided not to make any concession, and at the next meeting of the students, on May 5, ninety-eight of them announced their intention to pursue their medical studies elsewhere.

Continuance of High Death-Rate. — The unusually high death-rate continues, and during the past month it even advanced one point. The Health Department reports show that during April the mortality in the city represented an annual death-rate of 24.82, as against 23.80 in March and 18.98 in April, 1903. The corrected death-rate for the month, excluding non-residents and infants under one week old, was 23.76. The maximum mortality of the year was reached during the week ending April 9, when the death-rate ran up to 25.76. In the corresponding week of last year it was more than 6½ points lower, 19.05. Among the diseases which showed an augmented fatality were the following: The weekly average of deaths from diphtheria and croup increased from 40.8 in March to 60.25 in April; of deaths from scarlet fever, from 26.2 to 29; from measles, from 29 to 41.5; from broncho-pneumonia, from 114 to 132.25; from pulmonary tuberculosis, from 195.6 to 202.75; from Bright's disease and nephritis, from 130.6 to 135½; from organic heart diseases, from 106.4 to 114; from diarrheal diseases, from 41.6 to 49.25; and from diarrheals under two years of age, from 32.4 to 36. Among the few diseases showing a decline in mortality were the following: The weekly average of deaths from pneumonia decreased from 296 in March to 244.75 in April; of deaths from influenza, from 28.2 to 22; from typhoid fever, from 9.4 to 6.25; and from cancer, from 51 to 48¼. No death from smallpox was reported; the last fatal case of that disease occurring in the week ending March 19.

Obituary.

RESOLUTIONS ON THE DEATH OF DR. CHARLOTTE BLAKE BROWN.

It is with deep regret that we learn of the death of Dr. Charlotte Blake Brown of San Francisco, at the early age of fifty-six years.

Her pioneer work on the Pacific slope and her warm interest in all medical women won the esteem and admiration of a wide circle of friends.

It is therefore resolved, That the New England Hospital Medical Society deplores the loss of her great services to her sex and to the profession.

Resolved, That a copy of this expression of appreciation be published in the Boston Medical and Surgical Journal and also be sent to her family.

Emma L. Call, M.D.,
Mary F. Hobart, M.D.,
Emma B. Culbertson, M.D.,
Committee.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 30, 1904.

Deaths reported, 1,694; under five years of age, 414; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 398; acute lung diseases 264, consumption 201, scarlet fever 17, whooping cough 6, cerebrospinal meningitis 3, smallpox 8, erysipelas 8, puerperal fever 4, measles 13, typhoid fever 61, diarrheal diseases 49, diphtheria and croup 23, influenza 5.

From whooping-cough, Baltimore 1, Pittsburg, 2, Springfield 2, Fitchburg 1. From smallpox, Philadelphia 8. From cerebrospinal meningitis, Philadelphia, Worcester and Chelsea 1 each. From erysipelas, Philadelphia, Baltimore, Providence and Taunton 1 each, Boston 4. From typhoid fever, Philadelphia 45, Baltimore 3, Pittsburg 7, Providence 1, Boston 3, Fall River 1, Brockton 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending April 16, the death-rate was 17.6. Deaths reported 5,142; acute diseases of the respiratory organs (London) 156, whooping cough 216, diphtheria 41, measles 191, smallpox 6, scarlet fever 21.

The death-rate ranged from 8.2 in Reading to 25.2 in Halifax London 16.7, West Ham 14.6, Brighton 21.9, Southampton 9.7, Plymouth 18.8, Bristol 16.1, Birmingham 22.1, Leicester 17.7, Nottingham 19.7, Liverpool 20.0, Bolton 13.1, Manchester 21.5, Salford 21.4, Bradford 21.9, Leeds 19.6, Hull 17.7, Cardiff 18.3, Rhondda 18.8, Wigan 23.2, Merthyr Tydfil 18.6, Walthamston 10.3, Norwich 23.9

METEOROLOGICAL RECORD.

For the week ending April 30, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

RECENT DEATHS.

EDWARD LIVINGSTON TRUDEAU, Jr., M.D., of New York, son of Dr. E. L. Trudeau of Saranac Lake, N. Y., died from pneumonia, after a brief illness, on May 4. He was thirty-one years of age, and was born at Saranac Lake. He was graduated from Yale in 1896, and from the medical department of Columbia University in 1900. Later, he spent two years as an interne at the Presbyterian Hospital, New York, and in the autumn of 1903 commenced private practice. In December last he was married to Miss Hazel Martyn of Chicago.

AUGUST F. W. REIMAR, M.D., of College Point, Borough of Queens, New York City, died suddenly on April 29, from cardiac disease. He was a native of Germany, and sixty-six years of age. He was graduated from Augusta University, Goettingen, in 1860, and came to the United States in 1864.

SOCIETY NOTICES.

AMERICAN GYNECOLOGICAL SOCIETY.— The twenty-ninth annual meeting will take place in Boston, May 24, 25 and 26, 1904. The sessions will be held in the Boston Medical Library, No. 8, The Fenway. The profession is cordially invited to attend.

J. RIDDLE GOFFE, M.D., Secretary.

AMERICAN UROLOGICAL ASSOCIATION.— The annual meeting of the American Urological Association will be held at Atlantic City, June 8 and 9, 1904.

FERD. C. VALENTINE, M.D., Secretary.

THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION.— This Association will hold its sixtieth annual meeting at the Planters' Hotel, St. Louis, May 30, 31, June 1, 2, 3, 1904.

C. B. BURR, M.D., Secretary.

AMERICAN LARYNGOLOGICAL ASSOCIATION.— The twenty-sixth annual meeting of the American Laryngological Association will take place at Atlantic City, N. J., June 2, 3 and 4, 1904. The sessions will be held at the Hotel Chelsea.

JAMES E. NEWCOMB, M.D., Secretary.

BOOKS AND PAMPHLETS RECEIVED.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and Other Topics of Interest to Students and Practitioners. By leading members of the Medical Profession throughout the World. Edited by A. O. J. Kelley, A.M., M.D. Vol. I. Fourteenth Series, 1904. Philadelphia: J. B. Lippincott Co. 1904.

Seventh Annual Report of the Trustees of the Boston Insane Hospital. For the year ending January 31, 1904.

Exposé de M. de Piza, Délégué du Brésil, sur la Fièvre Jaune. Paris, 1904.

The Practical Medicine Series of Year Books. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Issued Monthly. Under the General Editorial Charge of Gustavus P. Head, M.D. Vol. IV. March, 1904. Chicago: The Year Book Publishers.

Original Articles.

ENTEROSTOMY IN PERITONITIS.

BY ROBERT B. GREENOUGH, M.D., BOSTON,

Surgeon to Out-Patients, Massachusetts General Hospital; Assistant in Surgery, Harvard Medical School.

THE value of direct drainage of the intestine by enterostomy, in cases of acute intestinal obstruction, is so well recognized as to need no further argument in its support. It is almost universally employed in the graver cases of mechanical obstruction or ' ileus," and the technique and indications for the operation have been thoroughly established. (Kocher,[10] Treves.[28])

The value of enterostomy in that form of intestinal obstruction which occurs in diffuse peritonitis, the so-called " dynamic obstruction " or " paralytic ileus" has not been so fully recognized. A number of writers have called attention to the advantages of the operation in this condition, but the varying technique of the application of the fistula, and the different arguments advanced in its support, appear to justify a brief review of the subject and the report of a series of forty-one cases of diffuse peritonitis from the Massachusetts General Hospital in which the operation has been done. The writer would here express his thanks to the surgeons of the hospital for the permission to report their cases.

In 1891, Mr. F. T. Paul[23] of Liverpool described a glass tube which he used in the operation of inguinal colostomy, and in 1892 he published a further communication in which he reported the use of this tube in cases of acute mechanical obstruction and peritonitis and in resection of the colon. The device was accepted in England and is in use in that country at the present time. In 1895, a similar device was described by Dr. S. J. Mixter[20] of Boston and its value in the paralytic obstruction of acute general peritonitis reported. The Mixter tube and the Paul tube are to all intents and purposes the same, and although the priority of description belongs undoubtedly to Mr. Paul, to Dr. Mixter belongs the credit of its successful application in the treatment of paralytic obstruction and its introduction in this community, where it is commonly known as the Mixter tube.

In 1893, Henrotin[9] observed the beneficial effect of a spontaneous fecal fistula in a case of diffuse peritonitis and applied the principle successfully in a later operation for the same condition. Had a[7] in 1894, Mixter[20] in 1895, Porter[25] in 1897, Pond[24] in 1898 and van Arsdale[29] in 1899 bore witness to the efficacy of the operation in paralytic obstruction and reported cases. During this time puncture or aspiration of the distended bowel at operation with immediate closure of the wound was extensively employed in cases of diffuse peritonitis. McCosh,[18] however, observed that the relief to distention obtained by this maneuvre was confined to a distance within twelve inches of the puncture, and in general the temporary and incomplete relief obtained by this method, and the inability to apply the procedure in the after treatment of the case, have led to its rejection in favor of the more lasting effects of enterostomy. In 1897 McCosh[18] advised the injection of magnesium sulphate solution directly into the small intestine at the time of operation, and reported a number of successful cases. This procedure again approaches that of enterostomy and has obtained a number of adherents. It is directed against the symptom of paralysis of peristalsis and has been combined with multiple puncture of the bowel and closure of the wounds. Its advantages and disadvantages will be discussed in connection with the causes of distention.

Lennander[14] in his valuable article on peritonitis published in 1901 discusses the value of puncture of the intestine and enterostomy and decides strongly in favor of the latter in the graver cases of diffuse infection. He opens the cecum in preference to the ileum, on account of the danger of irritation and digestion of the wound and the development of an artificial anus. The cecum is attached to the parietal peritoneum and a catheter is introduced and held in place by a purse-string suture. He considers the operation indicated when distention is present or when its advent is to be feared from the extent of the peritoneal infection. When enterostomy is not performed at the primary operation Lennander advises the fixation of the cecum in the wound for secondary enterostomy if occasion should arise.

At the German Surgical Congress in 1902, Heidenhain[8] presented an elaborate paper on enterostomy in peritonitis and reported several cases. He considers that the obstruction in peritonitis is chiefly due to paralysis of peristalsis, but that this paralysis is to a great extent local in character and confined to one or more adjacent coils of bowel. The cause of the paralysis he attributes chiefly to infiltration of the bowel wall and to toxemia, although he admits the significance of adhesions and mechanical obstruction. For these reasons Heidenhain performs enterostomy of the ileum above the affected portion of the bowel and does not advise the operation when there is a diffuse infection of the peritoneal cavity. At the same meeting Doyen[3] of Paris presented a communication upon enterostomy of the jejunum in peritonitis, an operation against which a number of arguments can be advanced, based chiefly upon the need of an immediate secondary operation for closure of the fistula in order to prevent digestion of the wound and death from starvation.

In 1903, papers by Finney and Pancoast,[5] Follis,[6] Lund[15] and Escher[4] appeared on the subject of enterostomy in peritonitis and other conditions, and a number of methods of operation were described. Finney and Escher attached the opening in the bowel to the parietal peritoneum by suture and protected the abdominal cavity with gauze, while Follis placed gauze between the bowel and the parietal peritoneum and sutured through the gauze. Follis

made use of the operation chiefly for mechanical obstruction and opened the ileum. Finney also opened the ileum for the relief of distention either of mechanical or paralytic origin and for the introduction of nourishment. Escher advises enterostomy especially in typhoid perforation, in order to save the time required to close the perforation and to ensure drainage of the intestine. Lund [15] considers especially cases of distention due to mechanical obstruction rather than paralysis, and occurring in local rather than diffuse infections of the peritoneum. He advises secondary enterostomy of the ileum as the operation to be preferred. For this purpose the ileum is sutured to the parietal peritoneum and a catheter introduced for drainage. The fistula is then to be closed by excision and suture at a later operation. He reports in detail five cases of enterostomy of which four recovered, and refers briefly to five other unsuccessful cases which are not reported.

Statistics of results in diffuse peritonitis which are based upon selected cases can be of little value. So many factors enter into the question of the ultimate result of the disease that it is impossible to find two cases exactly alike. The duration of the disease and, what is of far more importance, the extent of diffusion which has occurred during that time, the source of the infection and its virulence, the presence or absence of gross or readily diffusible irritants accompanying the infection, the resistance of the patient and the previous condition of the peritoneum, all play an important part in the patient's chances of recovery. The operation itself, the duration of anesthesia, the extent of manipulation and exposure of the abdominal contents and the efficiency and rapidity of the surgeon are of great significance. Finally, the conduct of the after-treatment of the case, the judicious use of lavage of the stomach and bowel, the administration of fluids, of stimulants and of nourishment, the employment of subcutaneous and intravenous infusion, and the care of the abdominal wounds and drainage wicks or tubes, — all are important elements in the results of treatment of this grave disease.

The classifications of the different forms of peritonitis are often inadequate in clinical application. The three forms of diffuse peritonitis described by Mikulicz [12]; diffuse septic, gangreno-purulent and fibrino-purulent peritonitis, can in many cases be differentiated with certainty only at the autopsy table. For clinical purposes the main fact is the determination of whether the peritonitis is a local process or whether it is diffuse and spreading. The appearance of the exudate and of the peritoneum, the extent and rapidity of diffusion and the constitutional reaction of the patient then determine the gravity of the condition. In this connection the correct interpretation of the appearances of the peritoneum of the general cavity in the presence of a local process is of great importance. In certain cases of local peritonitis of a virulent type a degree of inflammatory reaction occurs in the general peritoneal cavity which is due more to chemical and toxic causes than to actual bacterial infection. This condition produces a moderate injection of the peritoneum and a serous exudate containing leucocytes. It has been called "peritonism" by many writers (Burkhardt,[2] Weber [30]) and it subsides promptly on evacuation of the local abscess without requiring irrigation or drainage for its relief. While undoubtedly predisposing to a more severe form of actual peritonitis on the introduction of bacteria, peritonism itself is of minor significance and should be distinguished from actual peritonitis. Without the proof of cultures or cover-glass examination therefore, the lesser degrees of peritoneal inflammation cannot always be accepted as demanding more than local treatment.

The actual causes of death in diffuse peritonitis are variable. Patients may die in the first twenty-four hours after operation from the severity of the disease and the added shock of operation. A certain number of cases will die within forty-eight hours from the commencement of the disease itself with septic intoxication (the peritoneal sepsis of Mikulicz), whether operation is done or not. Other cases succumb from the second to the fifth day of the disease with "peritoneal facies," vomiting, paralysis of the bowel, distention, low temperature and thready pulse, a train of symptoms largely due to the suspension of peristalsis and in part remediable by enterostomy.

A certain number of cases survive this stage of the disease only to die of sepsis or exhaustion from the extent of the local suppurative process in the peritoneal cavity, after the diffuse peritonitis has subsided and peristalsis has been again established. Among this number are the cases of subdiaphragmatic and pelvic abscess, which occur after purulent peritonitis.

Finally, cases may die of intercurrent diseases or later complications in convalescence. Pneumonia, uremia, pylephlebitis and thrombosis, liver abscess and the various forms of post-operative intestinal obstruction due to adhesions, each cause a certain number of deaths after diffuse peritonitis.

The tympanites of peritonitis has been attributed to a number of different causes and a brief review of the subject is necessary in the consideration of the value of enterostomy. An increase in the amount of gas in the intestine in peritonitis may be due to increased production, diminished out-flow or diminished absorption. Diminished out-flow is chiefly due to mechanical obstruction of the lumen of the gut, or to diminished or suspended peristalsis.

A sudden and severe irritation or stimulation of the sensory nerves of the abdominal area is capable of causing a reflex inhibition of peristalsis. This occurs in cases of biliary and renal colic (Nothnagel [21]) and is probably the main cause of the suspension of peristalsis which occurs so frequently after laparotomy. This inhibition paralysis is undoubtedly a conserva-

tive effort on the part of Nature. It is certain that active peristalsis greatly favors the rapidity of diffusion of an infecting agent in the peritoneal cavity (Meisel [19]), and absence of peristalsis would tend to limit diffusion and confine the process to a local infection. This theory has its clinical application in the non-operative treatment of appendicitis during the intermediate stages, which has been advocated by Ochsner.

Another form of paralysis of peristalsis has been thought to be due to septic absorption. The toxins of a virulent infection, either within the bowel or in the peritoneal cavity, may act locally upon the nerve endings and muscle fibers of the intestinal wall or through the central nervous system. The tympanites of typhoid fever is advanced by Nothnagel [21] as a type of toxic paralysis of peristalsis.

Paralysis of the muscular action of the intestine has also been attributed to the local effect of infiltration of the intestinal wall by inflammatory products. (Heidenhain, [8] Nothnagel. [21]) Marked examples of this condition are seen occasionally after strangulated hernia and in the intestine forming the wall of an appendix abscess. It has been thought to occur also in diffuse peritonitis, but its importance is probably far greater in inflammatory conditions of a local nature.

Pure mechanical obstruction of the bowel is found to be present in a certain number of cases of diffuse peritonitis. This is especially the case when the peritonitis results from mechanical obstruction or when a local inflammatory process antedates by some time the onset of the diffuse infection. Compression of the bowel by inflammatory exudate may occur as in a pelvic abscess of large extent. Obstruction by bands and adhesions from a previous peritonitis are occasionally reported. The loss of peristalsis by the adhesion of large areas of bowel to the abdominal wound may offer impediment to peristalsis, and twists and kinks of the coil of bowel immediately above the adhesion may close the lumen of the bowel and cause obstruction. Obstruction of the bowel by gauze wicks which have been introduced for drainage is also to be borne in mind as one of the possible causes of mechanical obstruction. The symptoms of intestinal obstruction due to mechanical causes, however, develop as a rule only after the lapse of a period of time sufficient for the formation of firm adhesions. Distention due to obstruction of this nature appears during the convalescence from operation in diffuse peritonitis, or in cases in which a local inflammatory process has existed for some time prior to the appearance of the symptoms of diffuse infection. Much has been written upon the subject of intestinal obstruction of this nature and its relief by operation. An increase of peristaltic activity can often be demonstrated in these cases by visible waves of contraction in the distended bowel, accompanied by colicky pain of an intermittent character. This condition is very different from the absence of peristalsis in the distention of peritonitis. The records of the Massachusetts General Hospital from 1900 to 1904 show 17 cases of acute intestinal obstruction after inflammatory conditions of the peritoneum, which came to operation. Seven cases of more chronic obstruction were also found attributable to this cause. The shortest period of time which elapsed in any case between the first symptoms of peritonitis and the operation for obstruction was six days. This was a case of local appendix abscess of two days' duration which was operated upon by Dr. Codman. Four days later symptoms of mechanical obstruction demanded interference, and a coil of ileum was found twisted upon itself and adherent to the appendix wound. The adhesions were freed, a Mixter tube was tied into the distended coil of ileum and the patient recovered. A secondary operation for closure of the fistula was necessary and the patient is now well. Six cases showed obstruction between seven and fourteen days after the first symptom of peritonitis and 11 cases only after the lapse of a period of time greater than one month. The cause of the mechanical obstruction in these cases was as follows: Volvulus occurred twice, twists and kinks four times and bands and adhesions in 11 cases. In two cases only was the obstruction the result of a diffuse peritonitis, whereas in 16 cases it followed a local inflammatory process in the peritoneal cavity. Of the 24 cases of diffuse peritonitis which are reported in detail at the conclusion of this paper and in which enterostomy was done as a primary operation, distention was present at the time of operation in 16 cases. Of these 16 cases, in 9 adhesions were found in some portion of the peritoneal cavity, in 3 cases the record is not specific on this point and in 6 cases no adhesions whatever were discovered. In only two cases of the entire 24 was actual mechanical obstruction present; this was due in one case to cancer of the colon and in the other to an abscess in the pelvis. The duration of the diffuse peritonitis in these cases averaged 2.4 days from onset to operation. It is apparent, then, that obstruction due to purely mechanical causes occurs chiefly after the lapse of a considerable time from the beginning of the peritonitis and that it is favored more by a local than by a diffuse form of infection. Visible peristalsis and colicky pain are not infrequently observed in the early stages of mechanical obstruction and serve to distinguish from the paralysis of peristalsis which accompanies diffuse peritonitis.

An important cause of paralysis of peristalsis and probably in the later stages of peritonitis and of intestinal obstruction, the most important one, is distention of the bowel by the accumulation of gases within its lumen. The growth of the bacteria which normally inhabit the intestinal canal results in the production of gases of different varieties as by-products in the decomposition of the intestinal contents. (Kukula.[13]) When the out-flow of these gases is prevented, distention of the bowel ensues, the stagnant intestinal contents undergo more rapid decomposition, and

the gases, ptomaines and bacterial toxins which accumulate affect the integrity and function of the bowel wall. Up to a certain point distention of the intestine may occur without permanent effect; beyond this point, however, the thinning of the intestinal wall and interference with its blood supply and nervous mechanism produce a condition of paralysis of the muscular coats of the intestine. Recovery from this condition is of necessity slow and may not occur at all. Examples of paralysis from over-dilatation are familiar in the stretched cervix or sphincter ani or the over-distended bladder. In over-distention of the in estine we thus have the familiar concept on of the vicious circle in another form; more gas, more distention, more paralysis, more decomposition, more gas, etc. It is this aspect of distention against which enterostomy offers most satisfactory relief. Parlaysis of the intestinal muscle, however, is not the only danger of obstruction to the onflow of the intestinal contents. Ptomaines and bacterial toxins are produced in the process of decomposition, and their absorption is followed by grave systemic disturbance. The absorption of these products is probably delayed by the disturbance of circulation in the distended bowel, but that it does occur is proved by the constitutional toxemia of strangulated hernia, and by the experiments upon animals which have been reported. (Kukula,[13] Borscezky.[1]) The thinning of the intestinal wall which results from the accumulation of gases is accompanied by a change in its physical characteristics of such a nature as to allow the ready passage of bacteria from the lumen of the bowel into the blood vessels and even through the wall into the peritoneal cavity. (Borscezky and Generisch.[1]) The significance of this phenomenon in the increase in virulence of a case of peritonitis, and even in the production of a fatal septicemia, is readily appreciated.

Although in theory the different causes of intestinal paralysis and obstruction can be differentiated and discussed, in actual occurrence they merge one into another to such an extent that they can be separated with difficulty or not at all. Schlange[26] distinguishes two main classes of intestinal obstruction, mechanical and "dynamic." Mechanical obstruction is associated especially with local and chronic forms of peritonitis and dynamic or "paralytic ileus" with acute diffuse forms of the disease. However true this distinction may be in the early stages of both conditions, it is a well recognized fact that the distinction fails as the disease progresses to its fatal termination. In pure mechanical obstruction due to a constricting band the over dilatation and toxic paralysis produced by decomposition of the intestinal contents may prevent recovery after removal of the constricting band by operation, or the symptoms of diffuse peritonitis may supervene and mask the original symptoms of intestinal obstruction. In diffuse peritonitis the process may be even more complicated. The inhibition of peristalsis from the irritation of the primary infection merges into the paralysis of toxemia as rapid absorption from the peritoneal cavity takes place. To this is further added the paralysis from over dilatation as gases collect from the fermenting contents of the intestine. The extent to which actual mechanical causes enter into the production of the dynamic obstruction of peritonitis has been much discussed. Körte[12] considers that infiltration of the bowel wall plays an important part in paralytic obstruction, and Kocher[10] believes that slight mechanical causes, such as light adhesions, circulatory changes and the handling of the intestine at operation, are important factors. In all probability many causes enter into the production of the condition, but it must be admitted that to a paretic intestine a mechanical obstacle of almost trivial nature may be insurmountable. The main feature of the distinction, however, hangs upon the presence or absence of peristalsis. When peristalsis is present, as shown by visible contractions and spasmodic pain, mechanical causes are especially to be considered. When pain is continuous and no evidence of peristalsis is to be obtained the graver condition is to be feared and relief must be prompt or not at all.

The more remote effects of accumulation of gas in the intestine are next to be considered. The distended coils of bowel demand more room for their accommodation, which can be obtained only by elevation of the abdominal wall and of the diaphragm. Embarrassment of respiration and even of the action of the heart are not uncommonly observed as a result of this encroachment upon the cavity of the thorax. Another result of paralysis of peristalsis is the increased opportunity for the formation of adhesions between the coils, with the subsequent danger of mechanical obstruction. At the time of operation distended coils may so obstruct the view or the manipulations of the surgeon as to endanger life by prolonging or rendering inadequate the measures for the relief of the disease. Finally, the normal elimination of fecal material and gases by rectum is prevented by suspension of peristalsis, and the normal absorption of fluids and of nourishment by the stomach is interfered with by the vomiting which accompanies obstruction of the intestine.

Against the dangers of suspension of peristalsis in peritonitis there remains to be contrasted only its possible conservative effect in limiting diffusion of the process throughout the general peritoneal cavity. That inhibition of peristalsis is in fact a conservative phenomenon is hardly open to doubt. The occasional success of the opium treatment in cases of diffuse peritonitis before the days of operation attests the correctness of this view, and the Ochsner[22] treatment of appendicitis is based upon this theory. It is not the purpose of this paper to discuss the Ochsner treatment, and it has not been given sufficient trial at the Massachusetts General Hospital to admit of a report upon its value. In fact, so radical a departure from existing tenets of surgical faith requires time for its acceptance. The

dangers of delay in cases which ultimately demand operation and the possibility of error in diagnosis have worked against its general adoption. Cases of peritonitis which are beginning to spread from a local point of origin, such as the appendix, and in which the general cavity presents the condition spoken of above as peritonism rather than peritonitis, can probably be aided toward local limitation by the Ochsner method. Cases, however, in which the greater portion of the peritoneal cavity is already infected, and especially those cases in which a constant source of infection, such as a perforated gastric ulcer or a ruptured appendix abscess, is continually supplying further contaminating material in large amount, the value of the conservative inhibition of peristalsis disappears in the dangers by which it is accompanied,— the dangers of distention, paralysis, toxemia, septicemia and of mechanical hindrance to respiration and circulation.

The advantages of enterostomy in peritonitis are in the main the avoidance of the dangers of distention, by the removal of the decomposing contents of the intestine. The muscular wall of the bowel is enabled to regain its tone and to resume its suspended function. The absorption of ptomaines and bacterial toxins from the intestinal mucosa and their poisonous effects upon the patient are diminished. The escape of bacteria from the intestinal canal into the peritoneal cavity and into the circulation is diminished if not prevented. Pressure upon the diaphragm is relieved and the attendant disturbance to respiration and circulation. In addition to these direct results of enterostomy, however, the surgeon obtains a direct control over the intestine which may be employed to great advantage. Lavage of the bowel through the enterostomy wound promotes the discharge of intestinal contents from far beyond the immediate vicinity of the fistula. A most important aspect of the enterostomy opening is that emphasized by Finney in the statement that it should be regarded "more as a mouth than as an anus." Stimulation, fluids and nourishment may be introduced directly into the portion of the bowel where they are most rapidly absorbed, and where they cannot be immediately rejected by vomiting o by an involuntary dejection. By this means the function of the kidneys may be sustained and the constitutional reaction against the disease supported.

A further advantage of enterostomy which has been noted by many writers is the possibility of the direct introduction of cathartics into the intestine. When a fistula is made, however, lavage of the bowel will be found to supplant the cathartic treatment of peritonitis after operation to a great extent. The reflex inhibition of peristalsis above described and the tendency to paralysis of peristalsis from distention explain the inefficacy of cathartics introduced directly into the bowel at the time of operation in the graver forms of peritoniti. When peristalsis is capable of being excited by magnesium sulphate, its introduction at the time of operation, in the manner advocated by McCosh,[18] produces satisfactory results. When paralysis is present, however, and peristalsis cannot be excited by the irritation of the cathartic, its introduction can have only a toxic effect upon the patient and increase the intestinal irritation and decomposition. During the first twenty-four hours after operation lavage of the bowel is to be preferred. After that time, if spontaneous action does not occur, the use of cathartics introduced through the fistula is generally followed by prompt results.

The disadvantages of an enterostomy are next to be considered and their importance weighed. A fecal fistula is an unnatural condition, extremely revolting to the patient and his attendants and acompanied by dangers of its own. To make a wound in the intestine and insert a Mixter tube prolongs the operation for a few moments, at least, and where every moment under the anesthetic is of importance even this should not be done without its benefit to the patient being well established. After the operation the presence of the enterostomy opening makes the dressings more complicated, and when the fistula is established by the removal of the tube, more frequent and more offensive. The danger of contamination of the peritoneal cavity from the enterostomy wound, before adhesions are established is not to be considered when the Mixter tube is used. After its removal, however, so ling of the wound and continued suppuration must be guarded against by frequent dressings and scrupulous cleanliness. The danger of persistance of the fistula depends largely upon the situation and method of its formation. An opening in the jejunum will rarely close spontaneously on account of the irritating character of the intestinal secretions. Openings in the ileum are less significant in this respect and in the cecum least of all. The nature of the opening in the bowel, whether it is transverse or longitudinal to the long axis, whether it comprises a large or a small portion of the circumference of the intestine, and whether it is above or below the parietal peritoneum, — all are factors which exert an influence upon spontaneous closure. In general it may be said that an opening in the cecum, made by an incision in the long axis of the bowel not more than one-half inch long, and prevented from elevat on above the line of the parietal peritoneum, will almost always close spontaneously. In other cases the persistence of the fistula will demand its closure by operative measures, a serious drawback to the value of enterostomy. Finally, it may be urged that the presence of a fecal fistula increases the adhesions which remain afte the peritonitis and predisposes to hernia and to intestinal obstruction. The dangers and disadvantages of enterostomy are thus of sufficient weight to demand consideration before the operation is adopted. It is obvious also that enterostomy can exert little effect upon certain of the causes of death rom peritonitis. The cases which die in the first twenty-four hours after operation,

whether from the shock of operation or from the septic intoxication of the disease, can be expected to obtain little benefit from enterostomy except that their last hours may be made more comfortable and their distressing vomiting relieved. The cases which survive the operation and recover from the general infection of the peritoneal cavity, only to die of local sepsis and exhaustion or by one of the intercurrent complications, cannot be saved by enterostomy, however much they may have been benefited by the operation in the early stages of their disease. The intermediate cases, however, which ordinarily die from two to five days after operation, with distention, vomiting, low temperature and thready pulse, are the cases which obtain the most marked benefit from enterostomy. In these cases drainage of the bowel reduces the toxemia and relieves the distention, allowing the paralyzed muscles of the intestinal wall to regain their tone and peristalsis to be again established. In such cases the more remote dangers and disadvantages of a fecal fistula are not to be compared with the immediate and positive advantages to be obtained. It is to be regretted that the cases of this nature cannot be selected at the operation, but except within broad limits this does not appear to be possible at the present time. These considerations would appear to justify the performance of enterostomy as a secondary operation. A review of the statistics of secondary operations, however, makes obvious the fact that they have been performed as a rule too late to be of benefit. Diffuse peritonitis is a disease which is measured in hours rather than in days, and delay in waiting for the failure of enemata and cathartics to establish an indication for interference is fatal for the success of the enterostomy when it is performed. Cases of mechanical obstruction due to adhesions which develop in the course of the convalescence from peritonitis demand interference only when the indications are well established, and in these cases, as advised by Lund, a secondary enterostomy is indicated, especially when the cause of the mechanical obstruction cannot be removed by an open operation. The portion of the bowel immediately above the obstruction is the situation to be chosen for opening under these conditions, and secondary closure of the fistula will then be necessary as a rule. In cases of diffuse peritonitis, however, which involve the greater portion of the peritoneal cavity, and especially where paralytic distention is present and no mechanical cause for the obstruction is found, a primary enterostomy is indicated, and for this purpose the cecum is to be preferred. Under these circumstances the mortality of cases of peritonitis treated by enterostomy will still be high, but a certain number of cases will be saved which would otherwise go on to a fatal termination.

The technique of enterostomy is extremely simple The Mixter tube is a bent glass tube of about ½ inch diameter, provided with a flange and collar about ¼ inch apart at the lower end. (Fig. 1.) A purse-string stitch is introduced in the intestine and in its center a linear incision ½ inch in length is made parallel with the long axis

FIG. 1. Mixter tube for enterostomy of cecum. Actual size, about ½ inch in diameter.

of the bowel. In the large intestine the incision should be in the center of one of the longitudinal bands. The flanged end of the tube is inserted into the bowel and the purse-string stitch is tied under the collar, thus preventing leakage and securing the tube from slipping in or out. The end of the purse-string stitch is then carried through the parietal peritoneum just below the margin of the abdominal wound and the opening in the bowel is thus secured below the level of the abdominal wall. (Fig. 2.) The wound is now

FIG. 2. Diagram of Mixter tube in situ, showing purse-string suture and fixation to parietal peritoneum below abdominal wall. Drawings by Miss Florence Byrnes.

dressed in the customary manner and a rubber tube attached to the outer end of the glass tube and conducted through the dressings to a receptacle beside the bed. The chief advantage of the Mixter tube over other methods of enterostomy is the fact that immediate opening of the bowel is obtained without the risk of contamination of the general peritoneal cavity before the necessary time has elapsed for the formation of protective adhesions. The flange and collar also prevent the tube from slipping too far in or too far out of the bowel, an accident which is not infrequent when a rubber tube or catheter is used. Another advantage of hardly less importance is the fact that the fistula remaining

after a Mixter tube enterostomy is below the parietal peritoneum and closes spontaneously in many cases. Tubes of varying weight and size are provided to suit the size of the intestine which is to be opened, and a lighter tube than the one described is advisable for introduction in the small intestine. The purse-string stitch cuts out as a rule from the fourth to the seventh day and the tube comes away. After this has occurred the fistula must be treated by frequent irrigation and its closure promoted by drawing together the edges of the wound. Secondary suture of the fistula in the wound is frequently successful, and if the indications for immediate closure are sufficient, anastomosis or resection may be done. Resection was not necessary in any of the cases here reported. The selection of the cecum rather than the ileum or jejunum for enterostomy has been widely discussed. The jejunum appears to be ill adapted to the purpose for a number of reasons, owing to the facts that the jejunal secretions are extremely irritating to the wound, that the drainage is too high to be effective, that death from inanition threatens unless nutrition is artificially maintained, and that immediate closure of the fistula by operation is attended by a high mo tality. Between the ileum and the cecum no such potent reasons enter into the decision and it is more a matter of the indications of the special case. In cases of diffuse peritonitis, where mechanical causes for obstruction are not found, as a rule the cecum is to be preferred. Paralytic distention affects the large more readily than the small intestine because of its thinner wall. The fistula in the cecum drains the ileum to a certain extent, whereas drainage of the ileum does not affect the cecum. The fistula in the cecum is less irritating, does not affect nutrition and generally closes spontaneously without operative interference. Its lateral situation also makes later mechanical obstruction from adhesions less probable than when the ileum is attached to the abdominal wall.

Forty-one cases of diffuse peritonitis were treated by enterostomy in addition to other operative measures, at the Massachusetts General Hospital between January, 1900, and March, 1904. In 24 cases enterostomy was done at the first operation and of this number 5 cases recovered, 21%. In 17 cases it was done as a secondary operation, generally when the patient was moribund, and only one case recovered. The technique of operation emp'oyed for the diffuse peritonitis is detailed in the abstract of cases, but it may be said that multiple incision, irrigation with salt solution and drainage were employed in the majority of cases. No case that was not actually moribund was refused the possible benefit of operation.

Of the 24 cases of diffuse peritonitis in which primary enterostomy was done, 17 were due to appendicitis and one each to the following causes: cancer of colon with perforation, pancreatitis, perforation of gastric ulcer, stab wound of intestine, cholecystitis, typhoid perforation and post-operative peritonitis. Of the 17 cases of secondary enterostomy 10 were due to appendicitis and one each to the following causes: cancer of colon with perforation, rupture of intestine, pyo-salpinx, perforation of gastric ulcer, perforation of duodenal ulcer, stab wound of intestine and post-operative peritonitis.

Of the 24 cases of primary enterostomy, 19 died. Eleven of this number, 58%, died within twenty-four hours, 2 in the second day, 2 in the third day, and 4 after more than four days had elapsed, on the fifth, sixth, twelfth and thirteenth days. The actual cause of death in the last four cases was determined at autopsy in three instances. One case was due to pancreatitis and diabetes with no further evidence of peritonitis, one to acute fibrinous peritonitis without free pus but with a gangrenous local abscess in the pelvis, and another to a local peritoneal abscess without general infection or distention. In the fourth case no autopsy was obtainable, but death occurred on the thirteenth day after operation and was apparently due to a local abscess in the pelvis. The symptoms of diffuse peritonitis had subsided and peristalsis was well established. In each of these four cases benefit was obtained from the enterostomy, although a fatal result of the disease was not prevented. Of the 19 cases which died 4 only are left as having died on the second, third and fourth day after operation, or 21%. Of the 16 cases of secondary enterostomy which died, one died within twenty-four hours of the first operation, 8 on the second, third and fourth days, 50%, and 7 after the fourth day. In this connection the statistics recently collected by Dr. W. C. Quinby of Boston are of interest. Of 81 cases of undoubted diffuse peritonitis after appendicitis at the Massachusetts General Hospital, 57 cases died, 70%. Of this number, the deaths on the first day after operation were 29%, on the second, third and fourth days after operation, 31%, and after four days, 40%. These figures emphasize two facts in connection with primary enterostomy. The operation has been done only in the graver cases of peritonitis, as shown by the number of cases which died within twenty-four hours, 58% against the 29% of all cases collected by Dr. Quinby. The number of cases dying on the third, second, and fourth days is also reduced by enterostomy from 50 and 31% to 21%. It is to be noted therefore that in spite of the fact that enterostomy has been done as a primary operation only in the graver cases of peritonitis, the mortality of the second, third and fourth days has been notably diminished. Under these circumstances the operation must be accorded a place as a measure of value in cases of grave diffuse peritonitis.

Five cases recovered after primary enterostomy. In four of these cases the peritonitis was due to appendicitis. The process in each case was diffuse throughout the abdominal cavity so far as could be ascertained by multiple incisions, and cultures showed the colon bacillus in three cases and streptococci in the fourth. The fifth case was due to perforation of a gastric ulcer which

had occurred about six and one-half hours previously, and a diffuse peritonitis, with turbid serum and fibrin, was found over all the accessible portions of the abdominal cavity. In this case cultures were negative with regard to the presence of bacteria. No anerobic cultures were made, however, and proof of the presence of bacteria by cover-glass examination of the fluid was not attempted. In all five cases the severity and extent of the infection of the peritoneal cavity were such as to lead the surgeon operating to the belief that the usual operative measures would not be sufficient to ward off a fatal termination. That five such cases recovered would alone appear to justify the operation. In four of these cases the cecum was opened. One closed spontaneously on the eighth day, one on the seventeenth day and one after six weeks. One case was closed by a purse-string suture on the fifth day and never leaked. In the fifth case the ileum was opened and the fistula discharged slightly for ten weeks before closing spontaneously. In the one case of secondary enterostomy which recovered, the fistula was successfully closed on the fourteenth day by a purse-string stitch.

To sum up the points covered in this paper it may be said:

(1) The obstruction of the intestine in diffuse peritonitis is the result of a combination of causes.

(2) The most important cause is suspension or paralysis of peristalsis.

(3) Paralysis of peristalsis is due to inhibition, to toxic paralysis and to the paralysis of distention.

(4) Mechanical causes such as infiltration of the bowel wall and light adhesions in certain cases contribute to this paralysis.

(5) Pure mechanical obstruction due to adhesions is the result of chronic or local peritonitis of at least some days' duration.

(6) Enterostomy is indicated in addition to other operative measures in the graver forms of diffuse peritonitis.

(7) Its greatest advantage is the drainage of the gases and decomposing contents of the bowel and the relief of paralysis of peristalsis.

(8) By enterostomy the surgeon obtains direct control over the intestine for lavage and for the introduction of stimulants, nourishment, fluids and cathartics.

(9) For the relief of paralysis of peristalsis primary enterostomy is to be preferred to the secondary operation.

(10) Enterostomy is best performed by the use of the Mixter tube.

(11) The cecum is the most satisfactory part of the bowel for a primary enterostomy, and the jejunum is to be avoided.

(12) Spontaneous closure of the fistula may be expected when the cecum is opened, if the opening is kept below the level of the parietal peritoneum.

(13) By the systematic use of enterostomy in the graver forms of diffuse peritonitis the number of patients dying on the second, third and fourth days after operation is reduced.

(14) The symptoms of visible peristalsis and spasmodic pain in intestinal obstruction indicate a mechanical cause for the obstruction.

(15) The persistence of these symptoms, unrelieved by enemata and cathartics, is an indication for operation.

(16) Under these circumstances the cause of the obstruction should be removed if possible by operation.

(17) In advanced cases of obstruction of this form enterostomy of the coil of intestine nearest above the obstruction should be done.

ABSTRACT OF CASES.

PRIMARY ENTEROSTOMY.

1. Dr. C. A. Porter, 1902; age forty-five, pancreatitis, diabetes, peritonitis, seven days' duration, pulse 110, respiration 30, temperature 100.6, whites 34,000, tympanites; 2 incisions, irrigation, Mixter tube in descending colon, drainage, purulent bloody exudate in pelvis and between coils; culture streptococcus and bacillus mucos. caps. Died in five days. Autopsy, no general peritonitis, adhesions, abscess in pelvis, pneumonia, chronic pancreatitis.

2. Dr. C. A. Porter, 1901; age twenty-three, appendicitis, peritonitis, four days' duration (?), pulse 100, respiration 34, temperature 100.4, whites 16,000, tympanites; 2 incisions, irrigation, Mixter tube in cecum, appendectomy, drainage, sero-pus in right and left flanks and pelvis and between coils; streptococci. Recovery; no fecal discharge after tube removed on eighth day.

3. Dr. C. A. Porter, 1901, age twenty-six, appendicitis, peritonitis, four days' duration, pulse 150, respiration 30, temperature 104, no tympanites; 2 incisions, irrigation, appendectomy, Mixter tube in cecum, drainage, thick pus in flanks and pelvis and between coils; colon bacillus; magnesium sulphate given through fistula. Died twelve hours. No autopsy.

4. Dr. E. A. Codman, 1902; age ten, appendicitis peritonitis, two days' duration, pulse 140, respiration 24, temperature 101.6, whites 19,000, tympanites; 2 incisions, irrigation, appendectomy, catheter tied in cecum, drainage; foul pus right flank, purulent fluid left side, pelvis and between coils. Lavage and catharsis by fistula. Died in ten hours. No autopsy. The catheter was introduced in the cecum in this case by Kaders method for gastrostomy.

5. Dr. C. A. Porter, 1902; age twenty-two, stab wound of colon, five days' duration, pulse 100, respiration 25, temperature 101, whites 15,000, tympanites; one incision, irrigation, Mixter tube in descending colon, drainage; turbid fluid in left flank and pelvis, no culture. Lavage and nourishment by fistula. Died six days later. Autopsy, fibrinous peritonitis, no free pus, abscess in pelvis.

6. Dr. E. A. Codman; 1901, age five, appendicitis, peritonitis, four days' duration, pulse 180, respiration (?), temperature 107, tympanites; one incision, irrigation, two Mixter tubes in ileum at and above ileocecal valve, drainage; pus throughout, no culture. Died in two hours. No autopsy.

7. Dr. E. A. Codman, 1901; age fifty-three, cholecystitis; peritonitis, two days' duration, pulse 138, respiration 26, temperature 104, whites 21,000, tympanites; one incision, irrigation, Mixter tube in cecum, drainage, pus throughout; colon bacillus; lavage of bowel and cathartics introduced by fistula. Died in twelve hours. No autopsy.

8. Dr. E. A. Codman, 1901; age thirty-seven, appendicitis peritonitis, four days' duration, pulse 104,

respiration 30, temperature 103, whites 4,800, tympanites; 2 incisions, irrigation, 2 Mixter tubes, in ileum and in cecum, drainage; pus throughout; colon bacillus; salt solution and cathartics by fistula. Died in forty-eight hours. No autopsy.

9. Dr. S. J. Mixter; 1902, age nineteen, appendicitis, peritonitis, duration (?), pulse 100, respiration 20, temperature 98.6, whites 15,000, no tympanites; one incision, irrigation, appendectomy, tube in cecum, drainage; pus in right and left flank, pelvis and between coils; colon bacillus; salt solution and cathartics by fistula. Recovery; fistula closed on fifth day by purse-string, no leakage.

10. Dr. R. B. Greenough, 1902; age twenty-three, appendicitis, peritonitis, one day's duration, pulse 100, respiration 35, temperature 103, whites 11,000, tympanites; 2 incisions, irrigation, Mixter tube in cecum, drainage; cloudy serum throughout; colon bacillus; lavage, and catharsis by fistula. Recovery; attacks of hypogastric distention in convalescence relieved by lavage of colon by fistula, fistula closed spontaneously in six weeks.

11. Dr. R. B. Greenough, 1902; age six, appendicitis, peritonitis, two days' duration, pulse 150, respiration 50, temperature 103.8, whites 10,600, tympanites; 2 incisions, irrigation, appendectomy, Mixter tube in cecum, drainage; pus throughout; colon bacilli. Died in twelve hours. No autopsy.

12. Dr. R. B. Greenough, 1902; age twenty-one, perforation of gastric ulcer, peritonitis, six and a half hours' duration, pulse 100, respiration 30, temperature 101, whites 21,000, tympanites; 3 incisions, ulcer closed by suture, posterior gastro-enterostomy by McGraw ligature, irrigation, Mixter tube in cecum, drainage; turbid serum throughout; culture negative; fistula used for drainage and catharsis, no distention after lavage on second day, fistula closed spontaneously on seventeenth day. Recovery.

13. Dr. G. W. W. Brewster, 1900; age forty-seven, appendicitis, peritonitis, four days' duration, pulse 140, temperature 101, no white count, tympanites; one incision, no irrigation, Mixter tube in ileum, drainage; pus throughout; culture mixed growth, cocci and bacilli. Died in three hours. No autopsy.

14. Dr. Farrar Cobb, 1902; age sixty-three, perforation above cancer of colon, peritonitis, three hours' duration, pulse 110, respiration 32, temperature 100, whites 9,000, tympanites; one incision, irrigation, Mixter tube in perforation of colon, drainage, fluid feces throughout peritoneal cavity. Died in ten hours. Autopsy, general fibrino-purulent peritonitis and cancer.

15. Dr. J. C. Warren, 1903; age forty-two, appendicitis, peritonitis, two days' duration, pulse 120, respiration 30, temperature 102, whites 25,000, tympanites; one incision, irrigation, Mixter tube in cecum, appendectomy, drainage; pus throughout; no cultures; fistula used for drainage, lavage and catharsis, no further distention. Died in twelve days. Autopsy, large local abscess in central portion of peritoneal cavity.

16. Dr. R. B. Greenough, 1903; age twenty-seven, appendicitis, peritonitis, six and a half hours' duration, pulse 95, respiration 20, temperature 99.3, no white count, no tympanites; 2 incisions, irrigation, appendectomy, drainage, Mixter tube in ileum, turbid serum in right and left flank, pelvis and between coils; culture colon bacillus. Recovery. Much discharge from fistula, lavage of bowel, no distention, fistula closed spontaneously in ten weeks.

17. Dr. J. G. Mumford, 1903; age fifty-nine, appendicitis, peritonitis, thirty-six hours' duration, pulse 136, respiration 45, temperature 103, whites 21,000, tympanites; one incision, irrigation, Mixter tube in cecum, drainage; pus throughout; colon bacillus. Died in eight hours. No autopsy.

18. Dr. G. W. W. Brewster, 1903; age sixty-four, diffuse peritonitis after operation for resection of colon for cancer with lateral McGraw anastomosis, duration forty-eight hours, pulse 120, respiration 24, temperature 101, no white count, tympanites; operation for peritonitis by 2 incisions, irrigation, 2 Mixter tubes in ileum and in cecum, drainage; pus throughout; no cultures. Died in ten hours. Autopsy showed diffuse purulent peritonitis due to leakage from end of bowel closed by purse-string.

19. Dr. F. B. Harrington, 1903; age forty-three, appendicitis, peritonitis, four days duration, pulse 120, respiration 34, temperature 100, whites 10,000, tympanites; 2 incisions, irrigation, appendectomy, Mixter tube in cecum, drainage; pus throughout; no culture; fistula used for lavage, drainage and stimulation by hot salt solution every two hours; no vomiting, delirium and sepsis. Died two and one-half days. No autopsy.

20. Dr. J. G. Mumford, 1904; age thirty-three, typhoid fever perforation and peritonitis, twenty-four hours' duration, pulse 120, respiration 28, temperature 105, white count 4,300, tympanites (?); one incision; treated dry, Mixter tube in perforation in jejunum, drainage, cloudy fluid with flakes of fibrin throughout; no culture. Died in six hours. No autopsy.

21. Dr. J. G. Mumford, 1904; age fifty-five, appendicitis, peritonitis, four days' duration, pulse 120, respiration 28, temperature 104.4, whites 11,000, tympanites; median incision, treated dry, Mixter tube in cecum, appendectomy, drainage, pus throughout; no culture. Died in ten hours. No autopsy.

22. Dr. F. G. Balch, 1904; age sixty-seven, appendicitis, peritonitis, five days' duration, pulse 120, respiration 30, temperature 101.8, whites 19,000, tympanites; one incision, irrigation, Mixter tube in ileum, appendectomy, drainage, foul pus throughout; no culture; fistula used for drainage, lavage, stimulation and catharsis. Died in thirty-six hours. No autopsy.

23. Dr. R. B. Greenough, 1904; age twenty-one, appendicitis, peritonitis, seven hours' duration (appendicitis, five days' duration), pulse 140, respiration 24, temperature 101, whites 9,000, no tympanites; 5 incisions, irrigation, appendectomy, Mixter tube in cecum, drainage, thin pus throughout; colon bacillus and bacillus mucosus capsulatus. Patient survived the symptoms of diffuse peritonitis but died on thirteenth day from pelvic abscess. No autopsy.

24. Dr. D. F. Jones, 1904; age thirty-four, appendicitis, peritonitis; operation for local abscess four days after first symptoms, five days later diffuse peritonitis and second operation, pulse 124, respiration 30, temperature 99.8, whites 62,000, tympanites; one incision, irrigation, Mixter tube in ileum, drainage, pus throughout, no culture, fistula used for drainage, and for introduction of nourishment and cathartics. Died in forty-eight hours. No autopsy.

SECONDARY ENTEROSTOMY.

25. Dr. C. L. Scudder, 1901; age forty, pyo-salpingitis, diffuse peritonitis, two days' duration, pulse 120, respiration 32, temperature 100.8, whites 26,000, tympanites; one incision, irrigation, salpingectomy, drainage, pus throughout; no growth on culture, bacteria by cover glass; twenty-four hours later Mixter tube in ileum for distention, cathartics introduced by fistula, drainage. Died in thirty hours. No autopsy.

26. Dr. C. A. Porter, 1901; age fourteen, appendicitis, peritonitis, twenty-four hours' duration, pulse 124, respiration 36, temperature 100.8, whites 17,000, tympanites (?); 3 incisions, irrigation, drainage; pus

throughout; forty-eight hours later Mixter tube in colon, drainage. Died in twelve hours. Autopsy, acute general fibrino-purulent peritonitis.

27. Dr. F. G. Balch, 1901; age twenty-one, perforated duodenal ulcer, twenty-four hours' duration, pulse 120, respiration 30, temperature 102.4, whites 24,000, no tympanites; 2 incisions, irrigation, drainage, appendix removed, thin pus throughout; culture showed diplococci, varied bacteria by cover-glass; twenty hours later Mixter tube in ileum on right for distention, used for stimulation and drainage. Died in twelve hours. Autopsy, general purulent peritonitis, from perforated duodenal ulcer.

28. Dr. F. G. Balch, 1901; age twenty-four, appendicitis, peritonitis, two days' duration, pulse 112, respiration 21, temperature 103, whites 15,000, tympanites (?); one incision, dry sponging, drained, pus in right flank, turbid serum in left flank, pelvis and between coils; culture of serum, colon bacillus; forty-eight hours later Mixter tube in ileum on right for distention and vomiting. Died in six hours. No autopsy.

29. Dr. C. A. Porter, 1902; age forty-four, appendicitis, peritonitis, two and a half days' duration, pulse 120, respiration 30, temperature 102, whites 23,000, no tympanites; 2 incisions, irrigation, appendectomy, drainage; pus throughout; culture colon bacillus; forty-eight hours later Mixter tube in cecum. Died in ten hours. No autopsy.

30. Drs. F. Cobb and C. A. Porter, 1902; age fifty-two, peritonitis after ileo-colostomy, three days' duration, pulse 130, respiration 30, temperature 101.6, whites 14,200, tympanites; one incision, drainage; no irrigation, pus in right flank and between coils; no culture; seventy-two hours later Mixter tube in ileum, drainage. Died in twenty hours. Autopsy, general purulent peritonitis.

31. Dr. S. J. Mixter, 1901; age 17, appendicitis, peritonitis, duration four days, pulse 90, respiration 24, temperature 102.6, whites 24,600, slight tympanites; one incision, irrigation, drainage; pus throughout; colon bacillus and streptococcus; four days later Mixter tube in cecum for distention, used for drainage and catharsis. Died twelve hours later. No autopsy.

32. Dr. W. A. Brooks, Jr., 1901; age nineteen, appendicitis, peritonitis, three days' duration, pulse 112, respiration 34, temperature 101.4, whites 14,800, slight tympanites; 2 incisions, irrigation and drainage, pus throughout; no culture; twelve hours later Mixter tube in "bowel," drainage and catharsis. Died in ten hours. No autopsy.

33. Dr. E. A. Codman, 1901; age nineteen, appendicitis, peritonitis, two days' duration, pulse 120, respiration 20, temperature 100.2, whites 13,400, no tympanites; one incision, dry sponging, no irrigation, drainage; turbid serum throughout; colon bacilli; five days later Mixter tube in presenting coil. Died in four hours. No autopsy.

34. Dr. E. A. Codman, 1901; age thirty, appendicitis, peritonitis, two days' duration, pulse 88, respiration 24, temperature 99, whites 28,700, slight tympanites, one incision, appendectomy, irrigation, drainage, fluid throughout; no growth of bacteria by culture, no cover glass examination; four days later Mixter tube in presenting coil of bowel for distention, with relief, opening closed on fourteenth day by purse-string without leakage. Recovery. Ten months later intestinal obstruction by adhesions, operation and recovery.

35. Dr. R. B. Greenough, 1901; age forty-eight, perforation gastric ulcer, peritonitis, twelve hours' duration, pulse 96, respiration 28, temperature 97, whites 12,000, slight tympanites; one incision, perforation closed, irrigation, drainage, milky contents of stomach throughout; no culture; forty-eight hours later Mixter tube in cecum for distention. Died in three hours. No autopsy.

36. Drs. M. H. Richardson and J. G. Mumford, 1900; age twenty-three, traumatic rupture of liver and intestine, two days' duration, pulse 104, respiration 24, temperature 100, no blood count, slight tympanites; one incision, resection of part of liver, suture of intestine, irrigation, puncture of bowel and injection of magnesium sulphate, drainage, blood throughout peritoneal cavity; no cultures; forty-eight hours later Mixter tube in ileum for distention, fistula used for drainage and cathartics. Died in forty-eight hours more. No autopsy.

37. Dr. Farrar Cobb, 1900; age twenty-eight, stab wound of intestine and peritonitis, twenty-four hours' duration, pulse 140, respiration 31, temperature 104, no white count; one incision, closure of intestinal wound, irrigation, drainage, pus and feces throughout cavity; five days later Mixter tube in presenting coil for distention. Died in twenty-four hours. No autopsy.

38. Dr. Farrar Cobb, 1901; age eight, appendicitis, peritonitis, two days' duration, pulse 145, respiration 50, temperature 103, whites 32,000, no tympanites; one incision, appendectomy, irrigation, drainage; pus throughout; no growth on culture; twenty-four hours later Mixter tube in sigmoid for distention, fistula used for drainage, lavage and for introduction of nourishment and cathartics, distention relieved. Died six days later with flat abdomen, pelvic abscess and opening in bladder. No autopsy.

39. Dr. Farrar Cobb, 1902; age twenty-four, appendicitis, peritonitis, two days' duration, pulse 104, respiration 34, temperature 103.4, no white count, tympanites; 2 incisions, appendectomy, irrigation, drainage; cloudy fluid containing colon bacilli by cover glass and culture throughout cavity; forty-eight hours later Mixter tube in presenting coil for distention. Died in two hours. No autopsy.

40. Dr. C. L. Scudder, 1901; age fifty-six, peritonitis from perforation above cancer of colon, six days' duration, pulse 128, respiration 28, temperature 100.8, tympanites, no blood count; 2 incisions, irrigation, suture of colon for later enterostomy, drainage; pus throughout; colon bacillus; colon opened by incision on third day, no improvement. Died two days later. Autopsy, general fibrino-purulent peritonitis.

41. Dr. M. H. Richardson, 1904; age six, appendicitis, peritonitis, three days' duration, pulse 150, respiration 60, temperature 102, whites 40,000, no tympanites; one incision, irrigation, drainage; pus throughout; no cultures; three days later, ileum opened in wound for distention with immediate relief. Fistula used for drainage, but nourishment introduced was not retained; another fistula high in jejunum developed spontaneously on fifth day (?), digestion of wound occurred and patient died on ninth day of starvation and sepsis. Distention recurred just before death. No autopsy.

A COMPARATIVE STUDY OF THE DEATH RATES FOR THE STATE OF MASSACHUSETTS FOR THE YEARS 1850, 1875 AND 1900.

BY WILLIAM F. WHITNEY, M.D., BOSTON.

As is well known, the annual death rate is calculated from two factors, the number of persons alive at the middle of the year and the total deaths occurring during the entire year, and is expressed in terms of so many of the latter to one thousand of the former. The population is only obtainable when a census is taken, which, for Massachusetts, is once in five years. On the other hand, the deaths can be had each year from the Registration Report of Vital Statistics of the State; but from the variation due to epidemics or other causes, the results based on the returns of a single year may be misleading. This can be obviated by taking the average for five years, and the rates which are given below have been figured on that basis, with the census year as the central point of a quinquennial group.

The recently published report for 1902 enables the estimate to be made for 1900 for comparison with the preceding decennia, which are available already.

First of all let us consider the general death rate for each of the ten years from 1850 to 1900, which for one thousand persons living at all ages is as follows:[1]

Year.	Rate.	Year.	Rate.	Year.	Rate.
1850	16.69			1880	19.27
1860	18.73	1875	20.01	1890	19.77
1870	19.45			1900	17.20

In looking at these it is evident that the highest lies midway, while the extremes differ but little from each other. These three are the ones then that should be carefully studied; but their single figure, while it is suggestive, does not tell the whole story by any means, and it will be only after an analysis of their component parts that we can hope to learn it.

To begin with, the rates for the sexes should be found separately, and they are as follows:

MALES (All Ages).

Year.	Rate.	Year.	Rate.	Year.	Rate.
1850	18.60	1875	20.61	1900	18.06

FEMALES (All Ages).

1850 — 16.50	1875 — 19.30	1900 — 16.42

[1] In order that the reader may have a general idea of the size and increase of the population in this community, it may be briefly stated that in 1850 the population was 994,514, and the deaths 16,606, while in 1900 it was 2,805,346 and 48,278, respectively.

If the sexes alone are compared, it will be seen that the rate for females is always lower than that for the males; but in 1875 they were the nearest together. If now each sex is looked at for the fifty years, both will be found to have a lower rate at the end of the century than in 1850, although when the aggregate was taken, as is seen above, the reverse appeared to be true. The explanation is that the proportion of women was greater then than now, and their lower rate made itself felt.

The next step should be to take into account age as well as sex, and for preliminary consideration life may be divided into two periods. The one comprising all ages up to thirty, the other, all over it. These are the figures:

MALES.

	Year.	Rate.	Year.	Rate.	Year.	Rate.
Under 30,	1850 —	15.85	1875 —	20.19	1900 —	14.86
Over 30,	1850 —	17.90	1875 —	21.57	1900 —	22.15

FEMALES.

	Year.	Rate.	Year.	Rate.	Year.	Rate.
Under 30,	1850 —	15.67	1875 —	18.08	1900 —	12.45
Over 30,	1850 —	17.99	1875 —	21.07	1900 —	21.47

Looking at the first half of life, there is a marked rise from 1850 to 1875, with a greater drop in 1900, and a resulting increased difference between the males and females, in favor of the latter.

Turning now to the period over thirty, the picture is not so pleasant to contemplate, for it shows a steady rise for both sexes from the beginning to the present time, with a little more increase for the females than the males. The only encouraging fact is that during the last twenty-five years it has been *apparently* less than before.

But still further subdivision is necessary, and each of the milestones must be examined to arrive at a true conclusion as to exactly where the gain or loss lies. These are given in the following tables:

MALES.

Age.	1850.	1875.	1900.
0 – 1	138.53	172.24	159.55
1 – 5	38.10	35.65	19.78
5 – 10	8.65	9.24	4.48
10 – 15	3.90	4.12	2.77
15 – 20	5.70	6.52	4.63
20 – 30	8.68	9.91	7.22
30 – 40	10.09	10.43	8.92
40 – 50	12.74	12.74	12.48
50 – 60	19.00	18.87	21.71
60 – 70	32.36	35.91	43.19
70 – 80	68.86	77.06	89.02
80 – 100	171.82	180.08	196.24

FEMALES.

Age.	1850.	1875.	1900.
0 – 1	133.91	165.19	146.84
1 – 5	35.20	32.82	18.31
5 – 10	7.97	9.64	4.29
10 – 15	4.52	4.95	2.77
15 – 20	8.00	7.87	4.37
20 – 30	11.53	10.55	6.39
30 – 40	12.50	10.96	8.12
40 – 50	11.97	11.50	10.94
50 – 60	16.06	18.03	19.00
60 – 70	28.54	31.99	36.33
70 – 80	61.94	65.84	78.82
80 – 100	159.40	165.29	180.54

In these, also, 1900 shows a marked decrease, for every period from one year to fifty for both sexes; but from that time till the end of life there is a distinct increase.

If 1850 and 1875 are taken alone into account, there is an increase at every period except from one to five years for both sexes, and from twenty to fifty for females. He would have been a wise man, however, who could have foretold at that time what that little rift in the cloud meant, and with the marked rise everywhere else, the outlook for the future must have seemed very gloomy.

But in spite of the splendid gain that has been made in 1900, there remains much to be done, and the very first line in each of the above tables arrests the attention at once. And the question immediately suggests itself, Why is it that with all the progress that has been made in the other periods of childhood and early life, the death rate for infants under a year is still greater than in 1850? Possibly it may be answered that, although the modification of milk has modified the terrible rate of 1875, it has not been able to equal wholly the maternal combination, which very likely was poured out more freely in 1850 than now, and this, with better air from less crowding, kept down the death rate. But that may not be all, and it is probable that other points of attack might be found if the story of the first year could be written for each month in the Registration Report, especially if it was still further combined with that for the seasons of the year. When it is recalled that the deaths under one year are about ten thousand annually, more than a fifth of the total of all ages, too much attention cannot be given to this period, for it is here, let us hope, that race preservation may neutralize the effects of "race suicide."[2]

But it is not from statistics alone that it can be accomplished; they may be able to show the point at which the greatest care should be exercised, but it depends upon the practitioner to develop and carry this out. If in some way this necessity can only be brought home to him, it must surely lead to redoubled exertions on his part, both for more careful diagnosis and treatment.

And all the more so when he appreciates that it is only in early life that we are encouraged to look for any substantial gain. For after fifty we find there has been a steady increase in the death rate for each decade of life since 1850, and it has been a little greater during the last twenty-five than the first. This again reverses the figures obtained when only the aggregate of all under and over thirty were taken. As to the two sexes, the actual amount is about the same, but as the females started lower, the proportion is a little greater for them.

In conclusion, what does a comprehensive view of the picture show of the expectancy of life then and now? The children that were born in 1850 stood a better chance of reaching the end of their first year, while from that time on the infectious diseases claimed many victims; but those who reached fifty could look forward more confidently to an old age.

In 1875 the new era of medicine had only just begun, and with the passing away of the quieter and simpler modes of living, with the crowding out of fresh air and sunshine, the natural checks upon infection were broken down, and the result was what would be expected. But, fortunately, to-day preventive medicine and hygiene have been able to minimize infection, and thus to more than offset the evil effects of our concentrated, high-pressure civilization up to fifty; after that period, however, modern science appears to be powerless against the diseases of old age, to which the survivors of this strenuous existence seem more readily to succumb.

[2] The following figures show the decrease in the birth-rate for 1,000 females between the ages of 15 and 50: 1850, 97.6; 1875, 91.5; 1900, 88.8.

Clinical Department.

BOSTON CITY HOSPITAL CLINICAL CLUB.

MARCH MEETING.

DR. G. G. SEARS in the chair. DR. L. R. G. CRANDON, secretary.

There were sixty-five members present, and cases and reports were presented as follows:

SEPTICEMIA FROM THE BACILLUS MUCOSUS CAPSULATUS.

BY ABNER POST, M.D., BOSTON.

THE patient, Charles Pothoff, a native of Holland, thirty-seven years old, and married, entered the hospital with a condition which it was supposed might be due an embolus of the femoral artery of the right thigh. For two weeks he had had pain all over his body, especially in the larger joints. Twenty-four hours before entrance, the pain seemed to localize about the right knee, but the patient's account of his symptoms was not very definite.

On entrance, the right leg was greatly swollen from Poupart's ligament to the toes. It was mottled with purpuric spots and the thigh measured five inches more in circumference than the left. Pulsation of the arteries of leg and thigh could not be made out.

Examination showed that there was little change in surface temperature. The foot was not cold, nor was there any interference with the circulation, as the color returned immediately when pressure was made on the nails. The inability to feel the pulsation was due to the great swelling.

It was not an ordinary cellulitis, though it might easily have been mistaken for one. There was no wound to serve as a point of infection. There was no fluctuation, nor especial tenderness. There was no distention that called for an incision. The blood count showed 24,500 whites. One thought of an infection of the gas-producing bacillus, but there was no subcutaneous crackling, and the general condition was entirely different. There was no restlessness nor delirium. The swelling decreased in a few days, and on February 6 it was noted that the right leg was much less swollen, but redness, with a well-defined border like that of erysipelas, extended for a few inches above Poupart's ligament. This subsided in a day or two.

On Feb. 7 there was pain and swelling in left leg, but to a much less degree than the previous swelling

in the right leg, and it subsided more rapidly. The white count on Feb. 13 was 12,000. Meanwhile, Feb. 17, a small incision was made in the right leg and a specimen taken, which showed the presence of the *Bacillus capsulatus mucosus*. The little cut healed by first intention. The patient was never very sick. He lost weight and strength, but not to a marked degree. Up to the time the patient left the hospital various areas continued to be swollen. These areas were fairly well defined. They appeared and disappeared irregularly; at one time there was a well-marked but not very acute lymphangitis of the right leg.

March 6, there was considerable swelling and tenderness of the dorsum of the left foot. A specimen of urine taken by catheter on March 17 showed absolutely nothing.

On the evening of entrance this man's temperature was 101, and pulse 110. Temperature reached 102 Feb. 8 and 9, and became normal on Feb. 25. His pulse was about 90 most of his stay, but fell to about 70 the day before his discharge.

This case in appearance and course was peculiar, and the bacteriological examination alone could solve the mystery. The recurrent swellings, evidently due to some constitutional condition, did not conform to any recognized form of disease. The case seems worthy of note, as it shows a condition hitherto undescribed — at least no case of general septicemia with such recurrent swelling due to the *Bacillus capsulatus mucosus* in the general circulation has found its way into medical literature.

The patient was discharged with normal pulse and temperature, but pale and weak, and with some swelling of the left foot. He promised to return if there were further symptoms. The bacteriological investigations were made by Dr. C. W. Duval, who submits the following bacteriological analysis:

BACTERIOLOGICAL ANALYSIS.

Technique: Blood specimen aseptically obtained from subcutaneous tissue over tibia of involved leg. Incision made penetrating vascular layer of dermis, and approximately 3 cm. of blood and serum removed by sterile pipette and placed in bacillon suspension. From this suspension a series of six agar-gelatin plates were inoculated, and incubated at 37° C. for twenty-four hours. All plates showed numerous semi-transparent, soft, glistening, mucoid colonies, ranging from 1 to 2 mm. in size.

Some days later a second specimen was obtained from the involved limb, about the middle of the thigh. Whole anterior surface cleaned as for a surgical operation. The skin was scarified with a sharp sterile knife until bloody serum exuded. Ten to fifteen loops of this bloody serum was collected in sterile bacillon, and from the suspension agar-gelatin culture plates were seeded as before. After twenty-four hours in the incubator at 37° C., colonies identical in every way with those on the first series of plates appeared. No plate contained less than a dozen colonies. Both the first and second series of plates gave a pure culture.

Third specimen of blood obtained two weeks later. The median basilic vein of left arm was entered with a large hyperdermic syringe and 15 cm. of blood withdrawn. A series of 8 plates inoculated, using 1 to 2 cm. of the blood per plate. The plating was done immediately after blood was drawn from vein. Agar-gelatin tubes had been liquified and cooled to temperature of 41° C. Into each tube of the melted medium a given quantity of blood was introduced before the blood coagulated. The tubes were well shaken to equally distribute the injected blood, and poured into plates, using every precaution against contamination, both in the technique of drawing off the blood and in plating. The plates, after twenty-four hours in incubator, showed the same mucoid colony growth as described in the case of first and second plate specimens. Two plates of the series contained 50 to 100 superficial colonies. Colonies were sub-cultured from the plates of all three series, and the morphology and cultural characteristics observed to be that of *B. Mucosus capsulatus*.

Morphology. — Non-motile, short rods with rounded ends, many almost coccal in shape, varying from 1 to 2 microns in length, and from 0.5 to 1.0 microns in width, occur singly and in pairs. Do not take the Gram's stain. Mucilaginous capsules easily demonstrated by either the Welch or Hiss method, regardless of medium on which bacillus was grown.

Cultural features.—The bacillus grows readily on all the ordinary culture media, and always mucoid or sticky in character when on solid medium. On litmus milk, fermentation with acid production occurs, but never coagulation. Semi-solid medium (containing 1% dextrose) shows slight gas production in twenty-four hours. Mannite serum water shows acid production by pink change in medium, no coagulation. Dextrin serum water shows no change. Dextrose serum water gives acid production and coagulation of medium after forty-eight hours.

In stab cultures there is some tendency to nail-head appearing at exit of needle. This is not true in stab inoculation of a more soft medium, as, for example, semi-solid medium of Hiss.

Conclusion. — In all three platings of blood specimens from the case, a pure growth of a bacillus was obtained, corresponding in morphology and cultural features to that of *B. mucosus capsulatus*.

Bacteriological analysis of the urine gave negative results.

AMPUTATION AT HIP JOINT.

BY W. P. BOLLES, M.D., BOSTON.

THE patient is a girl eighteen or nineteen years old, who has had a tuberculous hip for eleven years. During the first two years she had a number of operations at the Children's Hospital, one of which was probably an excision. She has had numerous discharging sinuses ever since, seven in all. Several are open at the present time. She is small, immature looking, and has the ways and development of a child of twelve or thirteen years only. The heart, lungs and abdominal organs appear to be normal, but she is debilitated by the pain and suppuration from the right thigh.

The leg is four and a half inches shorter than its fellow, the foot markedly everted, the pelvis tilted. The thigh is striped with scars and sinuses, swollen, red, tender. It is useless for standing and walking, and amputation, which was advised several years ago, was at last accepted.

On Feb. 1 she was etherized and the limb removed at the hip by Dr. Bolles, Dr. Kelly assisting. Under ether. First, a femoral gland was removed and the femoral artery and vein tied, then an oblique incision was made, starting at the trochanter and running downward, forward, around the thigh, and up and forward to the starting point. The bone was then dissected out, from above downwards, and the soft tissues cut across. There was no head, but the end of the bone lay near the pelvis and was held to it by ligamentous tissues. Several extensive sinuses were cut out of the stump, leaving it quite irregular. Edges were then brought together and stitched, with two gauze drains.

She showed considerable shock after the operation, and received a "shock enema" besides intracellular salt solution of one and a half quarts. Recovered from shock and ether well by next day, but vomited for several days, and was fed by rectum. Recovery was uneventful. After this she was up in less than three weeks, and discharged in about four or five weeks on crutches, with the sinuses, where the gauze was, not quite healed. She had gained remarkably in physique and strength.

GASTRIC ULCER.

BY E. M. BUCKINGHAM, M.D., BOSTON.

THIS case of gastric ulcer is shown because of the length of time that it has been possible to continue rectal feeding without injury. There can be no question as to diagnosis. The young woman was admitted to a Swedish hospital four years ago for gastric ulcer, accompanied by the vomiting of blood. Since discharge she has been well until recently, except for some headache, which, of course, may have been digestive. About a month before admission she began having pain, occurring after meals, beginning in the epigastrium and extending into the back. At the same time a cupful of blood was vomited, and smaller quantities have been vomited two or three times since. On admission there was rigidity on pressure over the epigastrium, together with tenderness.

Treatment has consisted in absolute rest in bed and feeding by rectal enemata. These consisted of one egg, eight ounces of peptonized milk and ten minims deodorized tincture of opium. They were repeated every six hours and there was one cleansing enema daily. After a few days the peptonized milk in each enema was reduced to six ounces because of intolerance. There has been no pain from the first, while rigidity and tenderness both disappeared after some fourteen days. Nothing has entered the patient's mouth for three weeks except small pieces of ice, and I want to call attention to her very good condition. There seems no reason why this treatment should not be continued a little longer if desirable.

ANEURISM OF THE AORTIC ARCH.

BY CHARLES F. WITHINGTON, M.D., BOSTON.

THE patient is a man of sixty-five years, whose arteries are older than the rest of his body. The right radial, for example, shows evidence of marked atheromatous change. As he is thin, the right brachial can be distinctly seen throughout a large part of its course; it is tortuous and rigid. The left radial pulse on the other hand is difficult to feel; further investigation fails to detect an ulnar pulse on this side, and the brachial can neither be seen nor felt.

An examination as to the cause of this obliteration of the circulation in the left arm is, so far as physical signs are concerned, unsatisfactory. The heart is slightly enlarged, both to right and left, and there is a systolic apical murmur. Percussion shows a slight increase of dulness upward and to the left, the center of this dull area being about the junction of the second left rib with the sternum. This suggests, of course, either a tumor of the mediastinum or an aneurism of the arch. There is, however, no murmur nor pulsation to be detected over it. Neither is there tracheal tug, paralysis of vocal cord, or inequality of pupils. The diagnosis of aneurism would, therefore, remain inconclusive but for the radiograph, which I now pass about, and which shows a circular shadow about one and one-half inches in diameter protruding to the left of the dark area, corresponding to the aorta, and corresponding to the dull percussion area. This makes it evident that the patient has a small circular aneurism near the junction of the transverse and descending portions of the aortic arch, which, doubtless, obstructs to some extent the origin of the left subclavian artery.

The patient has a greatly enlarged prostate, and passes no urine except by catheter. The question of how far a patient with aneurism may safely be subjected to surgical operation is answered in this case by one of my surgical colleagues whom I have consulted, and who thinks the obstruction can be remedied to a considerable extent, and safely, by operation with the electric knife.

BULLET WOUNDS OF THE HEAD, CHEST AND ABDOMEN.

BY H. W. CUSHING, M.D., BOSTON.

ON Jan. 30, 1904, a man aged fifty-three, the victim of these injuries, was shot with a "32" caliber revolver. He was taken to the Boston City Hospital Relief Station. Examination showed two circular wounds in the right parietal region, about one inch apart. The hair was singed about the lower one, marking it as the wound of entrance. The track of the ball was upward and backward. The skull was apparently uninjured.

There was also a circular wound in the front of the chest, three inches to right of the median line at level of the fourth rib, and a similar wound over the left costal arch one and one-half inches from the xyphoid cartilage.

The patient showed considerable shock. Pulse 110, fair quality. There was little external hemorrhage. The abdomen was not distended, but was generally tympanitic, the hepatic dulness being absent. The tympanitic resonance extended into the flanks. There was marked spasm of the abdominal muscles. No cough, hemoptysis, or hamatemesis was observed.

The patient was seen by Dr. F. S. Watson, who advised immediate operation. Under ether the abdomen was opened by a median incision extending from the ensiform cartilage downward about six inches. There was no noticeable escape of gas. Little blood and no evidence of extravasation of gastric or intestinal contents was seen. A small circular wound was found in the anterior wall of the stomach, from which a small amount of gastric contents escaped as the stomach was raised into the abdominal wound. The stomach was not collapsed. This wound was closed by two "purse-string" sutures. No other wound of the stomach was found, and examination of the transverse colon and small intestine was also negative.

No perforation of the posterior wall of the stomach was found. On the under surface of the liver, two inches from its anterior border, just to the right of the median line, a rent one inch long was found, from which there had been considerable hemorrhage. This was one-half inch deep. It was closed by a single silk suture which controlled the bleeding. The abdomen was washed out with sterile salt solution, and drained in either flank and through the median incision. Salt solution by intravenous infusion was also used early in the operation.

The wound in the chest was not found to penetrate the thorax, and healed without incident. The subsequent history of the case has been uneventful. Rectal feeding was used for the first day after operation, after which nutrition by oval feeding was gradually resumed. The drainage from the median wound was removed on the second day; that in the flanks, on the sixth after the operation.

(Transferred from Relief Station to main hospital, service of Dr. H. W. Cushing, on Feb. 18, 1904.)

On March 1 a bullet, located by radiograph and by manipulation, was removed from the left back. It was situated just under the superficial fascia over the tenth intercostal space and three inches to the left of the median line. It was well encapsulated. This bullet probably passed through the stomach to the point where it was found. No other bullet has been found by careful x-ray examination, and it is difficult to understand how the one which caused the thoracic wound could have reached the point where this one was found without more evidence of its course.

The patient has fully recovered from his injuries as far as is now known.

NEPHROCAPSULECTOMY.

BY J. B. BLAKE, M.D., BOSTON.

J. D., thirty-three years old, teamster, was operated upon Sept. 15, 1902, for chronic nephritis, on the first surgical service, Boston City Hospital. He had previously been treated by Dr. Henry Jackson on the medical side of the hospital for two months; he improved for a while and then began to get worse; the prognosis seemed unfavorable. He came to the surgical side and was admitted early in September, 1902, and operated on by Drs. Munro and Blake. His condition at that time was as follows: Color, pale; thin; moderate edema of extremities; heart and lungs negative; urine, pale, 1013, acid, albumen ¼%; no bile or sugar.

Sediment: Numerous hyaline and fine granular casts, of small diameter, and with renal cells adherent. Considerable blood, free and on casts; a little fat on casts; numerous renal cells, with an occasional fatty cell.

He reported once or twice since the operation. He has felt well and done hard work since leaving the hospital, except for occasional vacations, which are sometimes simply alcoholic sprees. On one of these he noticed that his urine was becoming brownish and his feet were beginning to swell. He then stopped drinking, and these symptoms disappeared.

He has worked out of doors in the Adirondacks this winter. He is still drinking steadily, though not to great excess. He looks and feels well. His urine is pale, 1,012, acid, ¼% albumen. Sediment contains a few hyaline and fine granular casts; a few large, round cells, an occasional epithelial cell.

The scars of the operation show as faint white lines. There is no tendency to hernia, no tenderness and no loss of sensation, motion, or strength in or about them.

The operation was a simultaneous double decapsulation, an operator and his assistant standing together on either side. Two layers of capsule were demonstrated, and both removed down to the pelvis of each kidney. The wounds were closed without drainage. A small bit was taken from each kidney for pathological examination. The report was "chronic glomerulo-nephritis, so-called parenchymatous" (Mallory).

The case may be regarded as greatly improved, though not cured.

TREMOR OF RIGHT ARM. LOSS OF MUSCULAR SENSE AND ATAXIA.

BY P. C. KNAPP, M.D., BOSTON.

Case I. This child, eleven months old, was perfectly well until six weeks ago, when he had a moderately severe attack of measles, from which he recovered two weeks ago. Day before yesterday he woke with this tremor of the right arm, — a clonic, jerky tremor, affecting the flexors of the forearm, the hand and the fingers. The tremor persists during sleep. The arm is a little warmer than the other, and manipulation is apparently disagreeable, for he cries a little if it is handled much. He can move the arm fairly well, but he is more disposed to use the left hand to grasp objects, and an attempt to use the right arm exaggerates the tremor. Except for this tremor he appears perfectly well, and examination has shown no other abnormality. The tremor has diminished in the last twenty-four hours under salicylate of sodium. It does not seem probable that a post-infectious encephalitis could occur in so young a child without more serious cerebral and general symptoms. The local heat and tenderness suggest a local disturbance, but such a tremor from any local inflammation is certainly remarkable.

Case II. This patient is a widow, sixty-eight years of age, who was apparently well until about two weeks ago. Examination, however, shows an enlarged heart, albumen and casts in the urine and evident arteriosclerosis. Two weeks ago she had an attack in which she lost control of her limbs, and was unable to walk. This attack was attended with slight vertigo and paresthesia, but no loss of consciousness. After about an hour she gained control of her limbs. Since then she has had other attacks, and there has been a greater or less persistence of the symptoms between the attacks. The striking symptom at present is a very ataxic gait, and great uncertainty of station. She does not stagger like a drunken person or come down on her heels like a tabid person. In addition, there was yesterday great ataxia of the hands, which to-day is much better. Examination shows no involvement of the cranial nerves, no disturbances of tactile, painful, or thermic sensibility, or of the bony sensibility, a tolerably good sense of movement, but a very profound loss of the sense of position of the limbs. There is no paresis anywhere. The tendon reflexes are exaggerated, but not to an extreme degree, and the plantar reflexes are normal. Her condition varies from day to day, and to-night she shows much less ataxia of the arms and a better sense of the position of her limbs than she did yesterday. There has been, in all probability, some vascular disturbance, either thrombosis or hemorrhage, involving the tracts for the muscular sense, which Starr believes to lie in the lemniscus.

CHOLECYSTECTOMY.

BY F. B. LUND, M.D., BOSTON.

A gall bladder was shown, recently removed at an operation, illustrating a type of cases in which cholecystectomy should be performed. The gall bladder contained a single large stone impacted in the beginning of the cystic duct. The walls of the gall bladder were much thickened, averaging nearly one fourth of an inch thick. The cavity of the gall bladder, when opened, had contained a small amount of pus and no bile. The pressure of the stone in the neck of the gall bladder had caused it to nearly ulcerate through. In case operation had been delayed, the stone would, in all probability have ulcerated into the peritoneal cavity within a short time. In case the gall bladder had not been removed, and the operator had contented himself with removing the stone, a sinus would have persisted for a very long period, and the chronically inflamed organ would probably have contracted adhesions which would have caused pain and would have necessitated a subsequent cholecystectomy. It is in this class of cases and in the gangrenous gall bladders that cholecystectomy is indi-

cated. Such a gall bladder as this, if left behind, can never resume its functions, owing to the great fibrous thickening of its walls, which prevents either expansion or contraction, so that the organ remains as a useless and even harmful appendage.

In this case, owing to the fact that the woman had had a febrile temperature for some time, and the liver was greatly enlarged, it was thought wiser to drain the ducts, so after an excision of the gall bladder, a tube was tied in the stump of the cystic duct. During the operation no bile flowed from the duct, owing to the fact that a long incision had been made and the liver had been drawn vertically upward with such force as to kink the ducts, so that no bile could come through.

After the patient was put to bed, there was a copious discharge of bile from the ducts. This bile contained a considerable amount of mucus, and had a more or less irritating effect on the abdominal wall. The amount and character of the discharge, it was thought, justified the procedure of draining the ducts in this case, rather than ligaturing the cystic duct after removal of the gall bladder.

The patient was a woman of fifty-three years of age, who had had her first attack of pain in the region of the gall bladder two weeks before the operation, and during these two weeks had suffered from continuous fever. For the year preceding this attack she had felt weak and ill. She had not been able to do any work. She had had no attacks of pain in the region of the gall bladder at any time until the attack in which I saw her.

The case is instructive, showing that disease of the gall bladder may exist for a very long time without signalizing itself by local pain, which pain may be, and apparently was in this case, a symptom of threatened perforation. These thickened gall bladders, with stones impacted in the cystic duct, are the very cases which not infrequently result in gangrene of the gall bladder, signalized by a sudden severe attack of pain and fever, with marked constitutional symptoms requiring immediate operation. In this case it is evident that perforation, due to local gangrene rather than to general gangrene of the entire gall bladder, would have resulted.

LAMINECTOMY FOR FRACTURED SPINE.

BY F. B. LUND, M.D., BOSTON.

THIS case was shown by DR. F. J. COTTON: The patient fell from a height Jan. 9, 1904, striking his back or seat, just how is not known. When he was brought to the hospital there was obvious injury of the dorso-lumbar region — a distinct knuckle with ecchymosis. There was complete paralysis of the quadriceps, tibialis anticus and extensors of the foot. The thigh flexors and calf muscles were also paralyzed, in part at least. There was no disturbance of the sphincters and no sensory disturbance. The knuckle was in the upper lumbar region.

Jan. 14, 1904, laminectomy was performed under ether by Dr. Lund. The usual incision showed a projection of loose arch and spinous process which proved to be the second lumbar. This was cut away with the Munro forceps, as was also the arch of the third. It was then evident that the cord had been pressed back, apparently by a crushing back of an intervertebral disc into the canal. The dura was opened; no damage to the cord found; the wound drained and closed.

There was no immediate improvement. The wound closed finally in one month, and about this time power began to return to the thigh flexors, calf muscles, and shortly to the anterior tibial. At the time the patient was shown there was action of practically all the muscles, still weak, with reflexes present and sensation unimpaired. The wound was solid. The patient is now walking and apparently entirely cured.

ARREST OF DEVELOPMENT, PROBABLY RESULTING FROM CONGENITAL SYPHILIS.

BY R. C. LARRABEE, M.D., BOSTON.

A GIRL of twenty-one had been under observation in the out-patient department for eighteen months. The family history gave no evidence of syphilis. The patient is stated to have had measles when five years of age, and following this she had much trouble with the eyes until a year or so ago when she was treated by Dr. Bossidy for ulcers of the cornea. There has been obstruction of the left side of the nose for four years, with much discharge. There have recently been several severe nose bleeds from the same side. Further than this there have been no symptoms other than failure of development. She graduated from the grammer school at the age of sixteen and stood high in her class. She has always been able and bright mentally, and a favorite with her friends.

She looks about ten or twelve years old, is fifty-three inches high and weighs seventy-six pounds. The breasts have only within the past few months begun to develop and there is no axillary or pubic hair or other evidence of sexual development. There are several depressed scars on the forehead involving the bone, said to have resulted from wounds. The bridge of the nose is slightly depressed. There is a prominent scar on the soft palate. There are opacities of both corneæ. In the nose there is an ulcer of the septum and a dry catarrh. The radiograph shows that the epiphyses at the wrists are not yet united to the shafts of the radius and ulnar.

MYXEDEMA.

BY R. C. LARRABEE, M.D., BOSTON.

A WOMAN of thirty from the out-patient department, for seven years had had marked gastric symptoms — erudations of gas, heart-burn and distress after eating. Five years ago she had "nervous prostration," for which the ovaries were removed with the resulting cessation of the catemenia. For a year marked changes have been taking place in her appearance, so that her friends sometimes fail to recognize her. She has gained over thirty pounds and her complexion has become dark and yellowish. She is unusually susceptible to cold. There is some dyspnea on exertion. There has been marked mental depression and she has had slight hallucinations of hearing, especially at night, with sensations as if floating on the water or of suddenly becoming large.

She is a large woman with coarse features, the appearance strongly suggesting myxedema. There were at first marked reddened areas over the malars. The hair and skin were dry. She spoke slowly and without expression. The eyelids were thick and the conjunctivæ were slightly reddened. The lips and tongue were not involved. The supra-clavicular fossæ were full. The urine was negative. The temperature was normal.

Sixteen days ago she was ordered thyroid extract and a mixture containing bismuth, magnesia and soda. Since then there has been a noticeable change in the face. The red areas over the malars have disappeared. She speaks much more naturally. The gastric symptoms have wholly disappeared, as have also the nervous and mental manifestations and the susceptibility to cold. She has lost six and one-half pounds in a week. She says that she feels much better in every way.

Medical Progress.

THE PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., AND HAYWARD W. CUSHING, M.D.

(Continued from No. 19, p. 513.)

THE TREATMENT OF GANGRENOUS HERNIÆ BY ENTERECTOMY.

Mr. A. E. Barker has discussed the treatment of this serious lesion in a somewhat extensive article [10] in which the following points are of interest. He states that the question of what to do in a case of gangrenous hernia is one the seriousness of which is well known to all surgeons of experience, and the factors which make such a case grave are also now fairly well recognized. They have been worked out by the anatomist, the bacteriologist and the pathological chemist. A given case of gangrenous femoral hernia presents the following elements of danger: (1) The gut is destroyed by necrosis over a greater or less surface and therefore it cannot be returned into the abdomen; (2) the dead portion is septic in the highest degree; (3) the fluid of the sac, if there be any, is highly septic and may run back into the abdomen and infect it if the constriction has been divided before the sac has been well cleansed; and (4) the condition of things within the abdomen is also fraught with risk. Here the gut above the constriction is loaded with retained fecal matter, which is virulent in proportion to the time it has been pent up in a stagnant condition. The bowel is distended by this fluid, often to an enormous extent and it is paralyzed owing to causes unnecessary to trace for the present. But not only is it distended and paralyzed, but its structure is in many cases much altered. Its mucous membrane is inflamed, or even ulcerated from the point obstructed upwards, often for some feet. The submucosa and muscular coat are edematous and the serous covering is sodden and discolored from extravasation of blood; it may also be flecked with patches of lymph either on its free surface or in its subserous layers. In this condition it is now well known that the bowel, although its continuity is unbroken, can no longer offer much resistance to the passage through its walls of septic organisms, and sooner or later these transude and set up a septic peritonitis. This has been long known of the bowel caught in the sac. But it is now clear that the same infection will take place sooner or later within the abdomen from the unbroken bowel above the constriction if the evacuation of the retained fermenting feces be not provided for. Probably a certain amount of toxic exudation from the obstructed bowel is tolerated by the peritoneum as long as it is sound and is removed by its lymphatics, but the time comes when it is not removed and peritonitis is set up. But beside these dangers the patient has probably been exhausted by vomiting and inadequate feeding for days. The vomited matter has been foul and in many cases it has been inhaled in fluid or vapor form into the lungs with more or less damage to them. Moreover, the patient has been confined to the recumbent position and the bases of the lungs may have been imperfectly expanded, owing to the position and the painful condition in the abdomen and so have become edematous, rendering them particularly vulnerable to infection. Again, the toxins stored up in the bowel above the constriction are absorbed and exert a depressing effect upon the whole economy.

Now it is in these retained contents of the bowel above the constriction and in their local and general toxic effects that the main danger of strangulation with or without mortification lies. Their irritating properties have been known ever since the artificial anus has been made for their evacuation in gangrenous hernia. The rapid production of excoriation or even ulceration of the skin around such an opening bears witness to their acrid nature. Again, the facts so often noted in former times when herniæ were more frequently reduced by taxis alone than now point in the same direction. We have all seen many such cases attacked after reduction by severe diarrhea, with blood-stained stools and other evidence of acute enteritis, often terminating in death. The cause here has been explained to be the rapid rush of the pent-up toxic fluid into the empty and starved intestine below the constriction, setting up there an acute inflammation continuous with the inflamed and sodden tract above. Again, how often have we seen in the days of frequent taxis a patient die from peritonitis starting from the sodden but still unperforated loop returned into the abdomen, or from pneumonia combined with moderate enteritis or peritonitis. Now, if the gut is not viable, experience has shown that the immediate establishment of an intestinal fistula is much the safest procedure, as this permits the immediate escape of the retained toxic products from the proximal bowel. Occasions doubtless arise when an immediate anastomosis can be made, but under ordinary circumstances it is preferable to establish an artificial anus and allow all the contents of the bowel to be rapidly evacuated. Mr. Barker's experience in a fairly large number of cases has led him to the following conclusions: (1) The most imminent danger to the patient with a greatly damaged or actually gangrenous loop of intestine lies in the condition of the bowel for the three or four feet above the constriction. (2) In a case where the patient is in a reasonably good condition, the excision of the dangerous portion of paralyzed and sodden or ulcerated gut *en bloc*, together with all its virulent contents, is relatively the safest course. At one sweep the three or four feet of gut, with pints of toxic material, can be cleanly removed. The great point is to remove at once the contents as well as the diseased bowel and to make our suture junction in relatively sound and clean gut. The procedure Mr. Barker recommends to accomplish this is as follows: When the gangrenous or extensively damaged loop has been drawn well

[10] Lancet, June 6, 1903, p. 1576.

out of the abdominal cavity, as far as the points to be divided, the wound is packed with one end of a long roll of sterilized gauze, none of which can thereby be lost in the abdomen. The first point is to select the spot at which the distal and proximal ends of the damaged loop are to be divided, the first some two or three inches below the constriction and the other at any distance above it, up to six or seven feet, which may be considered to have reached sound bowel. Here the two portions are placed accurately side by side in their long axes and are clamped together firmly with one (first) pair of Doyen's forceps. Next the damaged loop is stretched to its full length, so that each half of the mesentery is evenly applied to the other half. The two halves of this structure are then firmly clamped together with a second Doyen's forceps, placed parallel to and about one inch from the bowel. Another Doyen's forceps is now made to close on the rest of the two leaves of the mesentery if it is too long to be included in one pair. The forceps can start from the point of the second pair, one blade being pushed through the two folds of the mesentery, and should close the latter up to the point at which the two limbs are held together in the first pair used to keep the two limbs of the gut together. This latter pair is now removed and is placed only on the distal portion at the same spot. Another is placed about half an inch more distally, and between the two, the gut, previously packed around with gauze, is divided. The whole of the bowel, still closed by forceps, is now cut away from the mesentery round to the point opposite the forceps on the distal limb. The piece of bowel thus freed at one end and in its whole length is left hanging out of the abdomen, over the edge of the table into a basin and then the forceps closing its end is removed, allowing the contents to escape into the basin and draining the bowel both outside and inside the abdomen. While the latter process is going on, the two halves of the mesentery are stitched together laterally by strong threads passed through them from side to side between the clamps and the cut edges, all being tied on one side and including about two thirds of an inch of mesentery in each ligature. This closes the hole in the mesentery and at the same time the vessels going to the edges cut away from the bowel. All this time the contents of the bowel are running off into the basin on the floor. The anastomosis now remains to be made. But before the junction is begun, the distended gut within the abdomen can be further unloaded by pressure on the abdominal walls and by drawing the coils, if necessary, through the fingers with a kind of "milking" action, until their contents flow off into the basin below.

The junction of the two ends is made as follows: The clamped distal portion and the unclamped proximal, now empty and more or less reduced in size, are laid side by side in such a position that while their attached mesenteric margins correspond at one point, the axes of the two portions cross one another obliquely. When now both are included in one pair of Doyen's forceps at the point at which their mesenteric borders cross, their free margins also correspond by the greater obliquity of the smaller bowel. In other words, when they come to be cut off flush with this forceps, more is cut away from the free margin of the smaller bowel than from the proximal tube which is divided a little obliquely. The two tubes thus held together side by side in one forceps are again clamped nearer the abdomen by another pair as close as possible to the first and then being carefully packed around with sterile gauze are cut with a knife or scissors flush with the distal edge of the first pair of forceps. The freed long coil of intestine and the stump of the distal end held in the forceps applied earlier in the operation now drop off and the gauze packing is changed. Then the forceps at the edges of the approximated tubes is removed, the second pair being left on with the cut edges previously clamped in the first, projecting about a third of an inch beyond it.

Now commencing at the mesenteric border, the adjacent edges of the two tubes are stitched together with a continuous suture, taking up all their coats until the free margins are reached. Here the corner is turned and the opposite edges are similarly stitched until the suture reaches the mesenteric margins again and can be tied with the tail thread at the starting point. Another forceps is then made to clamp both tubes three or four inches nearer the abdomen and the forceps holding them together for the first row of suturing is taken off. This enables the operator to place another line of continuous suture over the first and folding it in. This second row should, of course, take up only the serous, muscular and fascial layer under the latter, avoiding the mucosa. When this has been carried quite round the bowel and has been tied to the tail thread at the starting point on the mesentery, the anastomosis is complete and the forceps higher up is removed. The whole area of operation is now washed with sterile saline solution, especially the anastomosed portion of the gut. The latter is then replaced in good position in the abdomen and this is closed with sutures. Mr. Barker's record, since he began to employ this method of procedure in 1899, is seven enterectomies for gangrenous herniæ, of which five have recovered. The technique of the operation in the original is fully illustrated. This makes the description much more intelligible to the reader.

RESECTION OF THE STOMACH.

J. Boeckel [11] in an article on the partial and complete removal of the stomach reports several interesting statistics regarding gasterectomy. He has compiled 46 cases, which show 28 recoveries and 18 deaths, a mortality of 39%. Nine died from collapse, 7 from peritonitis, 2 from a giving way of the points of suture.

In 21 cases of the recoveries the end result was known. Of these, 11 died from recurrence of the disease after periods varying from five months

[11] De l'ablation de l'estomac, Paris, G. Bailliere et Cie., 1903, p. 192.

to five years. Of the surviving patients, as the case of Weiss, two and one-half years and no carcinoma; Ricard, nearly three years; Rivera, 1 patient, four years; 1 patient almost four years, but with cancer; Brooks-Brigham, five years, now seventy-one years old; and Maydl, eleven years. Of 28 patients on whom the operation was performed, only 4 have lived longer than the fourth year afterwards.

S. P. Federow [12] explains the fact that the esophagus can be united to the duodenum after gastric ablation in the living subject when it cannot be done in the cadaver by supposing that the long-continued weight of the gastric tumor increases the mobility of both the above mentioned points, so that they can be approximated. He reports a case in which the section removed 1½ cm. of the esophagus and the pylorus, yet he was able to make the union by a double suture row. The patient died on the fifth day from gangrene, due to injuries to the blood supply of the esophagus.

A SIMPLE METHOD OF PERFORMING INTESTINAL UNION.

Mr. Alexander MacLennan [13] presents a method of intestinal union by means of bone bobbin. For exact details of this method, the reader is referred to the author's original article. The union is accomplished by means of bone bobbins, the external surfaces of which are grooved, to permit the sinking in of a constricting ligature. The bobbin is inserted into the proximal end of the divided gut and is held in place by a ligature tied around outside and superimposed to the groove; over this ligature is placed a rubber ring. The proximal end of the intestine, so armed, is then inserted into the distal end so far that the distal portion covers the groove. It is then ligated into this groove over the proximal end in a manner similar to that in which the proximal end is fixed to the bobbin. This ligature must be tight. Union is completed by stitching the cut borders of the mesentery. Finally, all distal to the rubber ring comes away. It is claimed that the operation is an exceptionally easy one to perform and takes much less time to carry out than to describe. The bobbins are made of decalcified bone in a series of four sizes and are slightly conical. The length of each is slightly more than its diameter.

INTESTINAL LOCALIZATION.

Dr. G. H. Monks [14] has studied on the cadaver the characteristics of the intestine at various distances from the duodenum and gives his results. He utilized for differentiation the root of the mesentery, which springs from the posterior wall of the abdomen along a straight line six inches in length, starting above on the left side of the spinal column where the duodenum ends and about on a level with the body of the second lumbar vertebra, continued obliquely downward and to the right, to end in a somewhat indefinite way at a point opposite the sacro-iliac synchondrosis. The circulation in this mesentery is one of the valuable points in the localization of the intestine. The arrangement of the main branches of the superior mesenteric artery is in primary and secondary loops; the former predominating and being more marked in the upper end and the circulation becoming more complicated as we descend. There seems to be no fixed rule as to the length of the intestine. Age and sex have little to do with it. Where the intestine is very long, he has sometimes found the mesentery of unusual length and the little straight vessels running from the mesenteric loops to the intestines much longer than the average. Where it is short he has also observed in a few cases that the mesentery and vasa recta were also short. The diameter of the gut is the greatest above and gradually diminishes in size as we go down the tube. In the lower third or so the size remains the same throughout. The thickness is greatest in the upper part on account of the large and numerous valvulæ conniventes and the greater development of the muscle layers. It gradually gets thinner until within two or three feet of the cecum, where it thickens again. This thickening is presumably due to an increase in the muscular elements. The upper part is normally bright pink or red, showing numerous vessels. As we go down the tube the color changes to a gray or pinkish or yellowish gray and the vascularity is less marked. The valvulæ conniventes diminish in number as we go down and about fourteen or fifteen feet from the end of the duodenum they seem to disappear and below this can seldom be seen or felt. The various parts of the intestine show foods in various stages of intestinal digestion. The consistency increases somewhat towards the lower end. It is hardly necessary to suggest that when one end of the loop, which is high up in the bowels, is gently pulled on and meets with resistance, the loop is probably close to the duodenum, and likewise when one low down in the bowel meets with resistance, the loop is probably a short distance from the ileocecal valve. The mesentery varies in thickness in the different parts. The thinnest part of the mesentery is that portion which is adjacent to the upper part of the intestine and it becomes thicker as we go down the tube, largely owing to the deposition of fat. Its translucency varies immensely. Tabs of fat near the mesenteric border of the intestine are another guide, increasing toward the lower region. The direction of the stretched mesentery may also be a guide. Knowing the direction of the line of resistance, we get an approximate idea as to the part of the mesenteric root which resists; we can generally tell whether it is to the left or right. The more it inclines to the left from below upward, the nearer is the loop to the duodenum and vice versa. These conclusions which he reaches are only approximate ones. He gives a fair average, showing that he was within three feet of the true localization in about 75% of his estimations and that the average was not out more than two feet.

(To be continued.)

Recent Literature.

A Laboratory Guide in Urinalysis and Toxicology. By R. A. WITTHAUS, A.M., M.D., of Cornell University. Fifth edition. New York: William Wood & Co. 1903.

A fifth edition of Dr. Witthaus' Laboratory Guide in Urinalysis and Toxicology has been published. It is arranged primarily for the use of students, and contains a large number of tests for the determination of the presence of abnormal constituents and the methods of estimating the presence of poisons and the reactions of the various metals. Blank pages are left throughout the book for annotations, and a brief discussion of chemical terms and methods is introduced for the benefit of the elementary student. The book is made of such a shape and size that it will easily fit into a pocket.

The Medical Epitome Series. Physics and Organic Chemistry. A Manual for Students and Practitioners. Organic and Physiologic Chemistry. A Manual for Students and Practitioners. By ALEXIUS MCGLANNAN, M.D., of Baltimore, Md. Series edited by V. C. PEDERSEN, A.M., M.D., of New York. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

These two small books are of the type with which we have long been familiar. An attempt has been made to reduce to the very smallest possible space the science in the one case of physics and inorganic chemistry, and in the other of organic and physiologic chemistry. Facts are stated without wide discussion, and the volumes are intended particularly for the use of students. To this end questions are appended at the end of the various chapters which are designed to cover the preceding text. As brief books of reference such epitomes have value.

Laboratory Manual of Physiological and Pathological Chemistry. For Students in Medicine. By DR. F. SALKOWSKI, Professor in the University and Director of the Chemical Laboratory of the Pathological Institute, Berlin. Authorized translation from the second revised and enlarged German edition by W. R. ORNDORFF, A.B., Ph.D., of Cornell University. Illustrated. New York: John Wiley & Sons. London: Chapman & Hall. Limited. 1904.

This volume of 263 pages aims to place before the student a practical knowledge of physiological and pathological chemistry, being a translation into English from the second revised German edition. The text concerns itself with a succinct discussion of methods of examination of the various organs and secretions of the body, and should certainly serve its purpose of interesting a greater number in the increasingly important topics of which it treats. Dr. Salkowski's name and position insures the value of the text, and the translation has been well and carefully done by W. R. Orndorff, Ph.D., of Cornell.

The Medical Epitome Series. Microscopy and Bacteriology. By P. E. ARCHINARD, A.M., M.D., Demonstrator of Microscopy and Bacteriology, Tulane University of Louisiana, Medical Department. Series edited by V. C. PEDERSEN, A.M., M.D. Philadelphia and New York: Lea Brothers & Co. 1903.

The author states in his preface that this book is an epitome of matter contained in standard textbooks, and that not only the student but the practitioner may also use such a volume to post himself on the main facts of bacteriology and microscopy. The title is rather misleading as the entire volume except a short chapter on the malarial parasite and ameba coli is devoted to bacteriology.

The microscope and its use are illustrated and described briefly, too briefly perhaps to be clear to medical students untrained in physics. The fundamental principles of bacteriology are discussed in fourteen pages which contain no reference to the recent work of Chester, Hill and others on the morphology of various bacteria. Methods for the preparation of culture media are given. The common methods of staining are well described and the illustrations give one a good idea of the apparatus used. Illustrated chapters on technique are followed by descriptions of pathogenic bacteria.

Brief methods for the examination of water, air and soil as practiced in Europe are given. The better methods devised and used by American bacteriologists are not given.

To each chapter is appended a list of questions which serve to emphasize the salient points of the subjects treated.

Nervous and Mental Diseases. By ARCHIBALD CHURCH, M.D., and FREDERICK PETERSON, M.D. 8vo. pp. 922. With 338 illustrations. Fourth Edition, thoroughly revised. Philadelphia: W. B. Saunders & Co. 1903.

The portion of this work devoted to nervous diseases has been revised and various additions have been made, without materially changing the character of the work. The chief feature of this new edition is the addition to the section on nervous diseases of an elaborate article by Dr. Adolf Meyer, a review of recent problems of psychiatry. This is an excellent critical digest, nearly forty pages in length, of the recent teachings of Kraepelin, Wernicke and Ziehen. Excellent as this digest is it is decidedly out of place in the present work, intercolated as it is between the very commonplace and decidedly antiquated chapters of the section on mental diseases, which ignore every feature of the modern doctrines contained in the digest. It is certainly a question whether this elaborate discussion of these modern doctrines, which are still awaiting acceptance, is not too abstruse for the average student or practitioner for whom this work is intended, but, setting this question aside, Dr. Meyer's chapter in its present surroundings is one of the most striking examples of putting new cloth into an old garment that we have met in a long time.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 19, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE ABSENCE OF EOSINOPHILE CELLS IN PUS.

IN a very interesting thesis published at Geneva in 1902, entitled, 'Du Cytodiagnostic des Pus Chirurgicaux," Tissot reports the results of the cytologic examination of 42 cases of septic suppuration and 37 instances of tuberculous suppuration. It will at once be remarked in reading these experiments that eosinophile cells were absent in every case with one exception, that of a suppurating periostitis, and even here their proportion was very small, being only 0.3%. Tissot is, consequently, in opposition to Williams,[1] who was able to find eosinophile cells in every sample of pus examined by him, but this is explained from the fact that he used pus from acne pustules.

It is quite true that besides the pus of gonorrhea, eosinophiles have been found in the sputum in nearly all vesicular or pustular cutaneous affections, particularly in Deering's disease and blisters. The vesicular and pustular cutaneous diseases may in themselves form the object of a very extensive special cytologic study, but up to date little has been done. But if one studies cases of suppuration in which eosinophiles are present, it will be remarked that the lesion is seated on surfaces covered by epithelium, such as the integuments, the urethral mucosa, or that of the bronchial tubes.

According to Ehrlich and Einhorn, eosinophiles are formed in the bone marrow, but this opinion has been contested by Muller, who points out that these cells are, both by their vital conditions and morphology, different from bone marrow cells. For Vogel the spleen is another organ for the formation of eosinophiles, but this theory has been contested by Deny. Stutz tried to demonstrate that their origin is the same as other white cells of the blood, and that they originated in the intestinal mucosa. Schulze believes that they form in the blood, but the fact that there exist local eosinophilias without any eosinophilia of the blood is not quite in accord with this theory.

Comparative studies, especially by Fink, Schmidt and Leyden, have demonstrated that no relationship exists between the quantity of eosinophiles in the blood and those in the sputum, for example. Mandybur even thought that these cells formed in the respiratory apparatus, perhaps on account of special changes arising in the red blood cells, while Hagar and Klein explain the presence of eosinophiles in pleural exudates by resorption of hemorrhagic exudates, and he also noted a concomitant eosinophilia of the blood.

Fuchs endeavored to show that the eosinophiles were derived from altered red blood cells, while for Marchalkoff they are the result of a metaphasia of non-granular lymphocytes. Biondi, Heidenheim, Bergonzini and Rosin have demonstrated that eosinophiles are present in microscopic sections of tissues in the stage of inflammation just preceding suppuration. Pappenheim thought that their origin might simply be from the connective tissue, and that a local eosinophilia is primary and not secondary to that of the blood, as is upheld by Ehrlich.

Tissot believes that the explanation of the complete absence of eosinophiles in the pus cases that he studied may be found in the theory emitted by Ehrlich, that the bacterial toxins act by positive chemotaxis on the neutrophile polynuclears, and on the contrary, by negative chemotaxis on the eosinophiles, since both are endowed with the property of diapedesis. Pappenheim believes he has found a proof in favor of this theory from the fact that eosinophiles are found in the liquid of blisters as long as the serum remains clear, but as soon as it becomes purulent and contains many neutrophile polynuclears, the eosinophiles disappear. This is quite contrary to the theory of Posner and Lewin who, like Muller, believe that eosinophiles are derived from neutrophile polynuclears.

As may be seen, the question of eosinophilia is far from being elucidated, both as to the origin and mode of formation of these cells, as well as their significance. We would simply point out

[1] Boston Medical and Surgical Journal, Sept. 19, 1901.

that in no instance were they found when the pus was derived from deep structures, and that their presence in products of suppuration coming from cutaneous or mucous surfaces would lead one to believe that they are derived, if not from the epithelial cells themselves, at least from the connective tissue cells directly underneath the epithelium.

It is also not impossible that eosinophiles may be present during the early stages of suppuration, but the frailness of these elements is such that they are the first to undergo a degenerative process leading to liquefaction of the eosinophile granulations and to the destruction of the cell body, after destruction of the nuclear chromatin has occurred.

REPORT OF A CANCER RESEARCH FUND.

We are in receipt of the first number of the scientific report on the investigations of the cancer research fund under the direction of the Royal College of Physicians of London and the Royal College of Surgeons of England. The pamphlet concerns itself with the zoölogical distribution, the limitations in the transmissibility, and the comparative histological and cytological characters of malignant new growths.

In approaching the subject from this standpoint the attempt has been made to investigate cancer in accordance with the extent to which it pervades the animal kingdom, and the opinion is expressed that a solution of the problem in man, far from being the rational starting point, is really the logical destination toward which all research must converge. In following out this object the report offers an interesting discussion of the distribution of cancer among the various lower animals. As a part result of this necessarily somewhat imperfect series of observations it is concluded that clearly the conditions of human life have not called cancer into being, and the suspicion is even suggested that these conditions have not led to a greater incidence of the disease. It is maintained that the essential factors in the causation of the disease must be sought in the possibilities residing in the cells themselves rather than in the conditions of life under which malignant new growths are found. Such external agencies must at least be relegated to a secondary place in determining the existence of the disease. A review of the various facts, up to this time demonstrated regarding the transmission of cancer through transplantation, points to similar conclusions, again carrying us away from the various external agencies which have at times been supposed to be productive of the affection. Finally a section, amply illustrated, follows on the comparative study of the cells of malignant new growths. This matter, however, demands further observation in other tumors than those studied before a definite generalization may be made.

It is noticeable, in looking over this first product of the researches of this committee, that no attention is paid to the parasitic origin of the disease. We suspect that this is but a forerunner of the attitude toward the problem which we may look for in the immediate future. With all the painstaking research which has within the last few years been expended upon the supposed parasite of cancer, it is safe to venture a probable prediction that, attractive as that theory seemed to be, it will not serve to explain the existence of the disease. The account before us reverts to a position which has been rather lost sight of in the eagerness to discover a specific cause.

AMERICAN SOCIAL SCIENCE ASSOCIATION.

The tendency toward narrowness and overmuch specialization is met in a measure by such societies as the American Social Science Association which held its general meeting in Boston last week. The object of this association is to discuss matters of public concern in the field of social economy, finance, education, jurisprudence and medicine. The broad scope of its work evidently entitles the association to a prominent place, and the character of the papers read at this last meeting justifies its wide recognition as a channel of information from experts in various lines to the public at large. It is of particular interest to the medical profession from the fact that through its agency matters of conspicuous concern to the laity find expression. At this meeting, for example, an excellent presentation of the arguments in favor of animal experimentation was given by Dr. H. C. Ernst. It is evidently desirable that this subject should be discussed elsewhere than before legislative committees, and that those interested in the progress of science in its broadest aspects should have an opportunity of hearing a plain statement of the case from one authorized to speak upon it. Dr. W. T. Porter also read a paper on the "Use of Physical Measurements of Public School Children," a matter with which his name has long been identified, and which is of wide pedagogical as well as medical interest. The matter of tuberculosis was taken up by Dr. E.

O. Otis, president of the Boston Society for the Relief and Control of Tuberculosis. We have frequently commented on the fact that the hope of extermination of this disease lies in the far-reaching education of the public regarding its dangers and its methods of propagation. The campaign is already well started, but the matter can hardly be too widely advertised if interest in the extermination of the disease is to be maintanied. Water supplies a'so received their share of attention. In calling a tention to this meeting it is our purpose merely to lay stress upon the fact that, particularly in this day of extreme specialization, it is desirable that certain associations of men interested in widely diversified branches of human activity should hold meetings for the purpose of bringing out the interrelationships of their work. This end the American Social Science Association appears to accomplish.

MEETING OF THE AMERICAN GYNECOLOGICAL SOCIETY.

The twenty-ninth annual meeting of the American Gynecological Society will be held in Boston Tuesday, Wednesday and Thursday of next week. The medical public at large is cordially invited to these meetings, an invitation which will no doubt be accepted by many whose interests lie outside of the general topics under discussion. There are few special fields in medicine which have so wide and practical a bearing upon the work of the more general practitioner, and the opportunity offered is an unusual one for men engaged in various departments of medicine in this vicinity to learn what has been accomplished by specialists during the last year. We have before commented on the increasing desirability of Boston as a place of meeting for national societies, particularly at this season of the year when it offers those out-door attractions to visitors which are rightly coming to be an essential part of these yearly gatherings. The meetings of the society, under the presidency of Dr. Edward Reynolds, will be held at the Medical Library.

MEDICAL NOTES.

Death of Prof. E. J. Marey. — News has just been received by cable that Prof. E. J. Marey died on May 16. Physiology has thus lost one of its ablest exponents and a leader in the application of methods of physical research to the study of biological phenomena.

Mr Rockefeller's Gift to the Johns Hopkins Hospital. — In the final presentation of his gift of $500,000 to the Johns Hopkins Hospital Mr. Rockefeller added $1,600 which represented the interest on the gift from April 4, the day on which it had been announced, to the time of its final presentation.

Bequest for the Study of the History of Medicine. — It is announced that Herr Puschmann has bequeathed in his will 500,000 marks to the University of Leipzig for the purpose of furthering the study of the history of medicine. Herr Puschmann was formerly connected with the University as a teacher of this general subject.

Samuel Smiles, M.D. — Dr. Samuel Smiles died recently in his ninety-second year. He retired from the practice of medicine in 1837, and became the editor of a Leeds newspaper. He was the author of a life of George Stephenson and other biographies and books. His name, however, is associated with "Self Help" and the "Self Help" Series. "Self Help" was published in 1859.

Retirement of Dr. William T. Bull. — Dr. William T. Bull recently delivered his last lecture in the medical department of Columbia University as professor of surgery. At the conclusion of his lecture he made certain appropriate remarks, commenting on the excellence of medical students as a class and expressing his gratification that his successor was a graduate of the same school of medicine. When he had finished his remarks he was presented with a silver loving cup by the third and fourth year classes.

Smallpox in Chicago. — According to the *Bulletin* of the Chicago Health Department four cases of smallpox were sent to the isolation hospital during the week ending May 7. None of these had ever been vaccinated. Two were colored persons, one of whom came from Memphis, Tenn., a few days ago, and the other from Omaha, Neb., while in the eruptive stage of the disease. The other two contracted the disease from persons who in turn had contracted it from Ohnett, the "Dowieite," making twelve cases of smallpox known to have been caused by this anti-vaccinationist.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, May 18, 1904, there were reported to the Board of Health of Boston

the following cases of acute infectious diseases: Diphtheria 48, scarlatina 11, typhoid fever 11, measles 172, smallpox 0.

Appointment of Dr. Myles Standish. — Dr. Myles Standish has been appointed assistant professor of ophthalmology in Harvard University.

A Centenarian. — Mrs. Delight B. Upson has recently died in Burlington, Conn., at the reputed age of nearly one hundred and three years. She is said never to have called on the services of a physician until after her hundredth year, and so secluded was her manner of life that she saw a train of cars for the first time six years ago.

Tuberculosis Before the Monday Evening Club. — James Alexander Miller, M.D., who has charge of the Tuberculosis Clinic of Bellevue Hospital, New York City, spoke of the dispensary management of cases of tuberculosis, and Miss Lilian Brandt, statistician of the New York Committee on the Prevention of Tuberculosis, spoke of the social aspects of tuberculosis, before the Boston Monday Evening Club, May 16.

NEW YORK.

The Sanity of an Eddyite. — A woman Eddyite was recently taken to the psychopathic ward of Bellevue Hospital to be examined as to her sanity because, in carrying out her beliefs to the logical conclusions which other Christian Scientists balk at except in the single matter of disease, she refused to take food any longer. She is certainly to be admired for her consistency in this respect.

Change in Existing Labor Laws. — The Governor has signed an act passed by the legislature effecting an important amendment of the existing labor laws. It transfers from the factory Commissioner to the Commissioner of Labor jurisdiction over tenement-house factories. It provides that no license for such factories shall be issued while there exists in the tenement concerned any communicable disease or any violation of the local ordinances in regard to sanitary conditions. The commissioner may require the abatement of any nuisance, and if any filthy or unsanitary condition is habitually maintained, he is authorized to "cause to be affixed to the entrance door of such apartment a placard calling attention to such facts, and prohibiting the manufacture, alteration, repair, or finishing of said articles therein." The commissioner must inspect tenement-house factories at least twice a year, and local health authorities are required to co-operate with him.

Legal Value of a Boy and a Girl. — In New Jersey the legal value of a boy and a girl has been fixed at $6,000 and $3,000 respectively. On May 13, in the Circuit Court sitting at Newark, Judge Adams refused to alter a verdict for $6,000 returned by a jury in favor of Evan N. Eastwood, whose son lost his life in a railroad grade crossing accident at Clifton Avenue, Newark, Feb. 19, 1903, when a number of children on their way to school in a trolley car were killed. Judge Adams also reduced to $3,000 the verdict of $5,000 which had been awarded Henry Werpapp, whose daughter was killed in the same accident, basing his decision upon the hypothesis that the value of a girl's life from a wage-earning standpoint is about half that of a boy's.

Charitable Bequests. — By the will of the late Solomon Loeb, of the banking firm of Kuhn, Loeb & Company, more than $100,000 is left in charitable bequests. Among the institutions favored are the following: Mount Sinai Hospital, $10,000; Montefiore Home and Hospital for Chronic Invalids, $10,000; New York Sanitarium for Hebrew Children, $5,000; General Memorial Hospital, New York, $2,500; Jewish Hospital at Cincinnati, Ohio, $5,000; Jewish Hospital at Worms, Grand Duchy of Hesse, $5,000, to be known as the Leopold and Rosina Convalescent Fund; University of New York, $10,000 for the support of a chemical library, provided his son, Prof. Morris Loeb, shall be a professor of the university at the time of the death of the testator.

Dr. W. P. Spratling, Superintendent of Bellevue Hospital. — At a meeting of the board of trustees of Bellevue and Allied Hospitals held May 13, Dr. William P. Spratling was appointed Superintendent of Bellevue Hospital, in the place of Dr. William Mabon, who has resigned. For the past nine years Dr. Spratling has been superintendent of the Craig Colony for Epileptics, at Sonyea, N. Y., and it was his admirable work in the organization and administration of that institution which led to his selection on the part of Dr. Brannan, president of the Bellevue board. He is a native of Alabama and was graduated from the College of Physicians and Surgeons, Baltimore, in 1886. From 1891 to 1895 he practiced in New York City, and in the latter year took the civil service competitive examination for the superintendency of the Craig Colony, his name standing at the head of the list.

Improved Accommodations for House Officers at Bellevue. — It has been announced that in order to increase and improve the accommodations for the house staff of Bellevue Hospital, the top floor of the building in the hospital grounds, which was formerly occupied by the Bellevue Hospital Medical College, is being renovated and partitioned off into dormitories for the internes.

A Case of Smallpox. — Just as he was about to be transferred on April 25, from Bellevue Hospital to the Metropolitan Hospital on Blackwell's Island, it was discovered that a negro patient, twenty years old, was suffering from smallpox. The case had developed rapidly while he was in Bellevue, and the ward in which he had been treated was at once quarantined. The negro was admitted on April 22, and at that time smallpox was not suspected.

Carpentier Professorship of Pediatrics. — At a meeting of the board of trustees of Columbia University held May 2 it was announced that a gift of $60,000 had been received from Horace W. Carpentier, a graduate of the Academic Department in the year 1848, for the support of a chair in the Medical School, in memory of his brother, the late Dr. Reuben S. Carpentier. The trustees voted to apply the income of this fund to the chair of diseases of children, and in recognition of the gift they named the chair, which is now occupied by Dr. L. Emmett Holt, the Carpentier Professorship of Pediatrics.

"Crowner's Quest." — The antiquated "crowner's quest," it seems, is not yet to be banished from New York. The bill passed by the legislature abolishing the coroners is one of those in which, as involving the interests of the city, the mayor has the right to veto, and Mayor McClellan has seen fit to return the bill to Albany with his disapproval. Before doing so he gave a public hearing on the matter, and for more than four hours listened to arguments for and against the measure. Dr. H. R. Purdy, who has been one of the most active workers in behalf of the proposed change, has made the following comment on the present situation: "The friends of reform are not discouraged, for the mayor's veto means only temporary delay — not final defeat. The habitual inertia of our people — if the mayor properly represents them — toward the acceptance of new and improved methods has apparently not yet been overcome, but they will in time be made to see that the coroner system is not only useless, but is a malignant growth in the body politic, and that the only cure is in a radical operation."

Obituaries.

ROBERTS BARTHOLOW, M.D.

Roberts Bartholow, M.D., of Philadelphia died in that city May 10, at the age of seventy-three. He was graduated from the University of Maryland in its medical department in 1852, and later received the degree of LL.D. from St. Mary's College of the same state. After serving for eight years in the medical staff of the army he resigned in 1864, and accepted a professorship in the Medical College of Ohio, giving instruction in the theory and practice of medicine and becoming dean of the faculty. In 1879 he allied himself with the Jefferson Medical College of Philadelphia, and the remainder of his life was passed in that city. At the time of his death he was emeritus professor of materia medica, general therapeutics and hygiene at this institution.

His literary work was concerned largely with treatises on materia medica and therapeutics, and it was in this general branch of medicine that he attained his greatest reputation. He was a member of many learned societies, and although he no longer actively taught, he was at the time of his death engaged in professional work. In 1880 he delivered the Cartwright Lectures in New York on the subject of "Antagonism between Medicines and between Remedies and Diseases."

SIR HENRY THOMPSON.

Sir Henry Thompson died in London, April 18, in his eighty-fourth year. His origin was somewhat obscure. He studied medicine in London and graduated from University College at the mature age of thirty-two years. He was early interested in genito-urinary diseases and especially in lithotrity, and studied under Civiale in Paris. In this department of surgery he was for many years in the front rank of his profession, and enjoyed a large income. He was always a bold operator, and his boldness was sometimes carried to undesirable extremes. As a general surgeon he was not highly regarded. He had a strong but not a generous nature. This was evidenced in his reception of Dr. Bigelow's operation of litholapaxy when presented by Bigelow at the International Medical Congress in London.

Sir Henry interested himself in a variety of subjects not germane to surgery, — in painting, in pictures and china, in gastronomy, in cremation, in praying for the sick, in astronomy. He wrote several books, one on ood and some novels.

Miscellany.

UNDESIRABLE MARRIAGES.

IN connection with the subject of undesirable marriages and how they may be prevented, the *Lancet* in a recent issue discusses the difficulty of passing a law which will control the marriage of imbeciles, habitual criminals and persons unfit to propagate their kind in general. The following suggestions are made, which seem to be both ingenious and practical:

We have somewhere seen the excellent suggestion that every girl, through her parents or natural guardians, should insist upon the acceptance of her intended husband by a responsible insurance company before consenting to marry him; and this is a requirement in support of which public opinion might without any great difficulty be enlisted. The benefits of insurance are now rendered available for persons and classes of very moderate means; and we doubt whether the attraction between the sexes, or rather between particular individuals, is in any large number of cases sufficiently overmastering to cause the complete neglect of prudential considerations if these were but rendered prominent as matters of education, and strengthened by the common consent and practice of those to whom they would chiefly apply. Medical practitioners might do much to promote a proper estimation of the facts among their patients. They would seldom be justified in interfering with unasked advice as to any particular alliance, but they should earn the gratitude of the public by keeping the facts of physiology and pathology in relation to marriage under the notice of the numerous parents who might be prevented by such knowledge from consigning their children to lives of misery.

AUTOMOBILES AND MEDICINE.

THE use and abuse of the bicycle from a hygienic point of view came in for much discussion at one time, and the turn of the automobile seems to have arrived. Its therapeutic and pathogenic powers were the subject of a thesis recently presented by Dr. Blanchet to the University of Lyons. The thesis was founded partly on personal experiences and partly on the opinions collected from a number of medical men whose patients included numerous automobilists. The author considers the matter chiefly from the point of view of the treatment of phthisis. He himself had influenza in April, 1898. Previously he had had good health, but the attack was followed by pleurisy with effusion. The latter disappeared with some rapidity, but a dry pleurisy continued for a long time. Eighteen months later he had symptoms of slight bronchitis, and tubercle bacilli were found in the sputa. He then began to lose flesh and appetite, and had slight fever; fifteen months later he had to give up work. Some six or seven months of rest and open air treatment restored his health sufficiently for him to recommence work, but he was still below his usual weight, and had little appetite. Upon resuming work he bought an open automobile, and went out twice a day, covering on each occasion 60 or 70 km. After a year of this experiment he recorded the results, which were that he had entirely got rid of his cough, entirely regained his appetite, and had increased 6 kilos in weight, in spite of being actively engaged in professional work all the time. His chest capacity had also increased between 500 and 900 ccm. Summing up his own experiences and those cited from a number of medical friends, the author concludes that automobile exercise will gradually abolish or greatly diminish the cough of tuberculous patients and of those suffering from chronic bronchitis, and at the same time produce healthy sleep and appetite. On the other hand, the exercise will increase pyrexia if the latter already exists, and may cause it in those who are excitable. In view of the long stay in the open air which automobile exercise implies and the increased atmospheric pressure entailed by the rapid motion, it is quite natural that benefit should be experienced in cases of early pulmonary tuberculosis. It is essential, however, that the body should be duly protected from cold. It is also most important to avoid dust, and for this reason unfrequented roads should be selected. There is still more reason to believe that the exercise will prove of value in all conditions which are accompanied or brought about by ineffective or slow tissue metabolism. Examples of distinct benefit in neurasthenia have come under our own notice and, on the other hand, we have had reason to conclude that a catarrhal condition of the upper air passages may be kept up indefinitely by motoring under ordinary conditions and on frequented roads. — *British Medical Journal.*

Correspondence.

LEPROSY IN MASSACHUSETTS.

BOSTON, May 13, 1904.

MR. EDITOR: May I be permitted to offer some comments upon your interesting editorial on this subject in the JOURNAL of May 12?

Leprosy is a contagious disease, as tuberculosis and syphilis are contagious. It is preeminently a bacillus disease, for this organism is found in nearly all the tissues and fluids of lepers far more universally and abundantly than are the bacilli in those of a tuberculous patient. The bacillus of syphilis has not yet been seen, as we do not yet know the proper reagents to make it visible. Not long ago the same was true of tuberculosis and leprosy. Undoubtedly the human tissues are less favorable to the fruitful reception of the infective germs of leprosy than they are to those of these other two affections, and no other animal receives them at all; but then we must not minimize the danger which does exist. Lack of knowledge of it has led to dire results, both in past centuries and recent years. The mistaken conclusions of Boeck and Danielsen and of the Virchow and English commissions had, without doubt, much to do with the revival of the disease in modern times.

It is often maintained that leprosy is not contagious, because one has known of a few cases in a community which have not given rise to other cases, so far as is known. Can we not say the same of innumerable cases of tuberculosis and syphilis we have known? It is the

positive not the negative evidence to which we must give heed, nor should we forget that the period of incubation of leprosy is uncertain and very prolonged, so that it is not easy to determine the possible results of the occurrence of any case of the disease in a community. Certain so-called sporadic cases of natives of the United States who have never been out of the country can only be explained by chance and unrecognized association with resident lepers. I have known several lepers to have remained long unsuspected in this vicinity, who may have communicated the disease in instances as yet undeveloped or undiscovered. But of well-known individual cases of contagion, there are examples more than enough: Father Damien, other clergymen, nuns, physicians, nurses and ward tenders connected with lazarettos. But the recent spread of the disease in countries previously unaffected bears wholesale evidence of its contagious character, as in British Guiana, Trinidad, New South Wales, certain Spanish and Russian maritime provinces, etc. The rapid increase of the disease in some of these instances, as earlier in Hawaii, shows that it must spread by infection from person to person. The results of isolation in its control is another illustration of its infective character. In 1870 the number of lepers in Norway was 2,607. In 1885 government passed restrictive laws and established lazarettos. In 1893 the number had been reduced to 800.

Differences in the customs of living account, no doubt, for the greater prevalence and more rapid spread of the disease in some countries; such change in habits may explain the dying-out of the disease among the Norwegian immigrants here in New Scandinavia. They no longer sleep in the same bed with lepers or wear the clothes of the deceased, as formerly at home.

We have believed until lately that cases of ulcerating tubercular leprosy were alone dangerous, and that infection took place by surface contact with such lesions. Now we know that the nasal secretions of *all* lepers, and from the earliest stages, contain the bacilli, to be disseminated by exhaling and sneezing. This is probably the most common channel of inception of the disease.

May I add that within my knowledge there have been several instances of the disease in Massachusetts among native Americans, that there have been more than "half a dozen" lepers in this state in the past twenty years, that there are at least two here at present, and that Dr. Smith, superintendent of the lazaretto at Tracadie, reported in 1894 that "he found leprosy cropping out in unexpected places, and that he fears for years to come that new cases will be met with, and that by only permanent detention and isolation can it be kept checked or stamped out."

The fear of leprosy, although unreasonable in degree with us at the present time, may be regarded as a holy horror, and it were better for mankind were it divided up and bestowed in impartial measure upon tuberculosis and syphilis as well.

I am still of the opinion, Mr. Editor, presented to the Congress of Physicians and Surgeons in 1894: "That graded hospitals should be established by the national government in insular localities, where possible, within which both suspected and confirmed cases should be isolated, and to which all access should be prevented excepting under proper restrictions."

Very truly yours,

James C. White, M.D.

ANNUAL MEETINGS OF MASSACHUSETTS MEDICAL SOCIETY AND AMERICAN MEDICAL ASSOCIATION IN CONFLICT.

Fall River, Mass., May 12, 1904.

Mr. Editor: At a meeting of the Bristol South District Medical Society held this day it was unanimously voted: "That the councillors of the Bristol South District Medical Society be directed to endeavor urgently to secure a change in the time of meeting of the Massachusetts Medical Society so that it will not conflict with that of the American Medical Association."

Very truly yours,

A. J. Abbe, M.D.
Secretary.

RECORD OF MORTALITY
FOR THE WEEK ENDING SATURDAY, MAY 7, 1904.

Cities.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 3,957; under five years of age, 1,004; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 968; acute lung diseases 795, consumption 491, scarlet fever 46, whooping cough 13, cerebrospinal meningitis 81, smallpox 5, erysipelas 13, puerperal fever 16, measles 53, typhoid fever 62, diarrheal diseases 110, diphtheria and croup 69, influenza 9.

From whooping-cough, New York 8, Philadelphia 1, Baltimore 1, Pittsburg, 2, Worcester 1. From smallpox, Philadelphia 5. From cerebrospinal meningitis, New York 77, Boston, Brockton, Adams and Gardner, 1 each. From erysipelas, New York 5, Philadelphia 2, Cambridge 2, and Boston, Worcester, New Bedford and Taunton 1 each. From typhoid fever, New York 8, Chicago 6, Philadelphia 38, Baltimore 1, Pittsburg 6, Boston 1, Lynn 2.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending September 23, the death-rate was 16.0. Deaths reported 4,697; acute diseases of the respiratory organs (London) 127, whooping cough 215, diphtheria 42, measles 199, smallpox 6, scarlet fever 34.

The death-rate ranged from 5.1 in Willasden to 25.6 in Warrington, London 16.0, West Ham 13.9, Brighton 16.5, Southampton 13.9, Plymouth 16.5, Bristol 15.2, Birmingham 22.4, Leicester 12.6, Nottingham 13.0, Liverpool 19.8, Bolton 13.1, Manchester 22.0, Salford 19.4, Bradford 16.3, Leeds 16.2, Hull 17.3, Cardiff 13.9, Rhondda 17.5, Wigan 17.4, Marthyr Tydfil 17.9, Reading 11.6, Halifax 15.5.

METEOROLOGICAL RECORD.

For the week ending May 7, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

SOCIETY NOTICES.

THE AMERICAN CONFEDERATION OF RECIPROCATING EXAMINING AND LICENSING MEDICAL BOARDS. — The third annual meeting of the American Confederation of Reciprocating Examining and Licensing Medical Boards will be held in the Great Northern Hotel, Chicago, Tuesday, May 24, 1904.

B. D. HARRISON, M.D., Secretary.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY. — The tenth annual meeting of the American Laryngological, Rhinological and Otological Society will be held at Chicago, Ill., May 30, 31, June 1, 1904, in the Auditorium Hotel. The profession is cordially invited to attend.

WENDELL C. PHILLIPS, M.D., Secretary.

SUFFOLK DISTRICT MEDICAL SOCIETY. — There will be a meeting of the Section for Obstetrics and Diseases of Women in Sprague Hall, Boston Medical Library Building, 8, The Fenway, Wednesday, May 25, at 8 P.M. Papers: Dr. Charles H. Harwood. "Some Injuries of Parturition, Their Cause and Treatment;" Dr. A. Palmer Dudley, "Dudley's Operation for Restoration of the Perineum."

W. H. GRANT, M.D., Secretary.
DANIEL H. CRAIG, M.D., Chairman.

RECENT DEATHS.

BENJAMIN FRANCIS MOULTON, M.D., M.M.S.S., of Lawrence, died May 3, 1904, aged fifty-eight years.

BERNARD MACKAY, M.D., a wealthy retired New York physician, was run over and killed by a fire engine, near Madison Square, on May 12, the accident being due to Dr. Mackay's deafness, from which he had suffered for many years. He was seventy years of age and a son of Col. William Mackay of the British army. He was born and received his medical degree in England, and although he had been in the United States for over forty years, he always remained a British subject.

WILLIAM WATERWORTH, M.D., of Brooklyn, N. Y., died on May 11. He was born in Salem, Ohio, in 1851, and was graduated from Adelbert College and in 1878 from Bellevue Hospital Medical College, New York. He had practiced in Brooklyn for twenty-two years, and at the time of his death was attending surgeon to the Brooklyn Eye and Ear Hospital.

WILLIAM H. MCGEE, M.D., a prominent physician of Warren County, died at his home in Belvidere, N. J., on May 11, at the age of fifty-six years.

Clinical Lecture.

DR. WATSON AND MR. HOLMES; OR THE WORM THAT TURNED.

BY J. W. COURTNEY, M.D., BOSTON.

"Ah, good morning, Holmes," said Dr. Watson, without even raising his eyes from the paper which lay before him on the table, at his clinic for diseases of the nervous system. "Somewhat surprised, I see, that I should know who it was," he continued, as he went on reading. "It's very simple, as you are wont to say." He pushed back his chair, looked up and extended his hand. " In the first place, I had just looked at my watch and seen that it was a quarter after eleven. Now under no circumstances is a patient admitted after eleven; and when I looked over the assembly on the benches some ten minutes ago, there wasn't a soul there that didn't have some defect in his gait. My assistants and the hospital attendants are trained not to enter without knocking. What's more, there came to my nostrils, above the stuffy odor of the clinic, the smell of that awful Red Herring brand of cigarettes, which you alone of all my extensive acquaintance are able to smoke. Now, my dear fellow, as to your being surprised. You can't deny that since your awful experience with our late friend, Moriarty, your nerves have got the faintest bit on edge. As I read, your legs from the knees up fell just in range of vision from the tail of my eye, and I was able to see that my salutation produced the faintest upward twitch of your trousers through an involuntary contraction of the thigh muscles. 'Pon my word, though, you are the most unsatisfactory fellow! I've been begging you to come here for years to see the only really interesting phase of human morbidity, and you have persistently denied yourself this intellectual treat. And now you drop in upon me from the clouds, when I haven't a bally thing on hand that's worth while."

During this outburst, so astonishingly long-winded for the erstwhile shrinking and self-effacing Watson, Sherlock the magnificent stood gazing at him with the well-known look of amused superiority which he invariably kept on tap for his mix-ups with the upstart Lestrade. Not a muscle of his long, keen face relaxed, but his pallor deepened, until Watson, who watched him narrowly, wondered if he really did have pernicious anemia, or if his lemon-yellow complexion were merely the result of the excessive use of breakfast food subcu, coupled with the inhalation of the fumes of Red Herring cigarettes. He knew that his quondam mentor was decentering the tigroid bodies of his higher cortical cells in the act of thinking, but just what was at the bottom of these obvious mental gymnastics eluded his penetration.

For the benefit of our readers, we will explain. Holmes was miffed, for it was now disagreeably obvious to this twentieth century prodigy that during his long demise his microcephalic ex-serf, the doctor, either by the excessive use of that minute portion of his anatomy which lay under his thatch, or by the vicarious function of some other organ, had developed his rudimentary faculty of thought. It was also annoyingly evident to him that the pathways between the place — wherever it might be — that Watson used in thinking, and the organs whereby he externalized thought, had been thoroughly cleared of all the tangle and pseudo-intellectual underbrush which formerly so effectually impeded them. In his wildest flights of cocainized fancy no such thing as a rival had ever taken shape. And now suddenly to bump into the possibility, so to speak, in tangible form, and that, too, in the form of this low-grade idiot of a Watson, made him feel like a four-ply Rip Van Winkle.

During this prolonged fit of abstraction Holmes had made up his mind on at least one point: Watson must be squelched, once and for all.

"You're right, my dear Watson," he said finally, with assumed cordiality. "I ought to have come round before, but you know how many really important things I have to disentangle, and how little time I have to waste on the obvious, but I've made up my mind to devote a morning to you, and if you'll name a day I'll be here."

" Any day will suit me," said Watson, politely refusing a proffered Red Herring cigarette. "I'll go along with you now and we'll decide as we walk."

Watson rang the bell for an assistant, left the remaining patients in his charge, and started from the hospital with Holmes, arm in arm.

It was Monday and the throng about the doors was of the usual large proportions after the Sunday inactivity of the out-patient departments. At the exit from the lodge the way was temporarily blocked to Holmes and his *fidus Achates* by a burly fellow on crutches, who seemed to handle the one under his right arm with peculiar difficulty for a man of his powerful build. As they went along Holmes turned to Watson and said with a tinge of malice, "Why can't the duffers of surgeons give these poor devils proper crutches? It's bad enough to think of that chap's family being without his support for a long time on account of his foot, but an extra two months' loaf with a crutch-maimed arm is an outrage. There are an awful lot of incompetents in your profession, Watson."

Watson stopped and eyed the man with the crutches keenly, his face flushed with indignation at Holmes' sneer at the profession.

"I think you're entirely wrong in your conclusions, my friend," was his only reply. Then as the object of their remarks came along, he stopped him and said, "You'd have been better off without the liquor, wouldn't you, my good man?" Watson's question was accompanied by a significant glance in the direction of the big fellow's right hand.

The lout, with the instinct of his class, at once recognized the professional calling of his questioner, hung his head sheepishly and replied, "I guess it was the booze that did me up all

right, for I was doing fine with the foot till I got out with a crowd of my friends Saturday night. Nothing would do them but they must stand treat to celebrate the getting better with the foot. I was loaded when I got home, but the hand seemed all right then. Yesterday morning, though, when I woke up, it was all numb and deadlike, and it ain't been no use to me since."

During this reply Holmes appeared restless and uneasy, and at its conclusion he took Watson by the arm and said, "I'm in quite a hurry, old man, and if you're coming along with me, you'll have to come at once."

Watson hastily directed the man to come to his clinic the next day and started along with Holmes.

Holmes was consumed with inward rage; he knew that Watson would rough him at the earliest opportunity, and decided to give him no opening. He immediately started in and talked a blue streak on the probable cost of the midnight oil consumed by Homer while writing the "Iliad." He figured it out by a secret process of calculation, which he knew would excite Watson's envy, and this in itself brought a certain amount of balm to his wounded feelings.

Watson let him rattle on until they were near Holmes' lodgings, and then butted in with "I say, old chap, do you still hold the views on surgical incompetency that you expressed a while ago, and do you still feel that you should not waste your time on the obvious?"

Holmes grunted and quickened his pace.

"Because if you do," went on the imperturbable doctor, "I think a morning at my clinic will prove a strong mental corrective. By the way, I must make a note to send you a reprint of my lecture on the fallaciousness of the apparently obvious in clinical diagnosis. This case we just saw exemplifies my teachings beautifully, and you must confess, my dear Sherlock, that you did not give due consideration to all the factors entering into it. Had you noticed the soiled condition of the padding on the tops of the crutches, it would have been obvious to you that the padding had been put there at the time the crutches were given. This fact in itself demonstrates that the surgeon was cautious, and precludes to a large extent the possibility of crutch paralysis; now this is Monday, and the day on which we usually get a crop of Saturday-night paralysis, that is to say, paralysis of the radial nerve caused by a drunk's sleeping on his arm; but enough of this. You come round on Friday and I'll try to show you something interesting."

On Friday morning Watson left the place that most people call home, but which with him was merely a place to stay when he wasn't needed by Holmes. He proceeded to the latter's lodgings in Baker Street, and the two went on together to the hospital. Arrived there, Watson cast a searching glance over the benches and ushered Holmes into the consulting room. Then he rang the bell and ordered the externe to show in first the musician on the front seat.

"I'm sorry, sir," said the externe, "but I haven't had time to take any histories, and I don't know who you mean."

Watson walked to the door, threw it open, and beckoned to a man sitting on the front seat. The patient entered and sat before Watson's table.

"Musician, did you say?" asked Holmes apathetically.

"Yes, musician, and I should add, a player on a wind instrument."

Holmes examined the man's buccinators in their normal condition, and then got him to puff out his cheeks. He appeared satisfied with his examination, and when Watson asked him if he had made up his mind as to how he, Watson, had arrived at his conclusion as to the man's occupation, he answered in a tired way, "Why, certainly, you have only to look at the muscles of his lips and cheeks; they tell the story."

"Wrong," said Watson; "it's much simpler than that. Just observe the little goatee he wears. I venture to say he believes the loss of that would prevent his playing for a week. Am I right?" he asked, turning to the man.

"Oh, yes, sir. I wouldn't cut that off for the world; it's strengthening to the lip, and I shouldn't be able to play till it grew again."

Watson soon got at the facts of the case, examined and disposed of it.

During this time Holmes looked absently out of the window.

The next patient was ushered in, and without speaking, presented a note to Watson. The latter, without looking at the note, exclaimed, "Ah, a teamster, I see."

"That observation was superfluous," broke in Holmes superciliously. "I knew he was a teamster the moment I saw him. He has the complexion of a man much exposed to the weather and wears the sort of clothes common to people of that class."

"That may all be true, but it would apply equally well to a cabman; and it is dangerous to draw conclusions on such general grounds. Perhaps you did not notice that this man took the note he brought me out of his hat — a typical teamster trick."

Holmes made no reply, but bit his lips furiously while Watson read the note. Watson turned the case over to his assistant and called for the next patient. It proved to be a man with a marked tremor of the right hand. Without a word, Watson took hold of the trembling hand and observed it closely for a few moments. Then he said quietly, "Here, my dear Holmes, is an interesting tremor in a left-handed plasterer, who has done no work for some time. Am I right, my man?"

"Quite right, sir," was the answer. "I'm left-handed and I'm a plasterer by trade, but this cursed shaking has laid me up for nearly six months now." At this point Holmes was about to say something, but hesitated and looked the man over carefully in silence. Watson sat quietly back in his chair and observed his friend's

scrutiny of the patient with an amused twinkle in his eye.

Holmes' face was a study. It had grown several shades yellower than usual, and again made Watson think of pernicious anemia. The powerful magnifying lens was now brought into play and the man's nails, ears and eyebrows thoroughly examined by its aid. Obviously Holmes was stumped. By this time he was breathing hard and mopping his brow.

After a time Watson broke in with: "Well, my dear Holmes, what do you say?"

"Nothing, except that it's beastly stuffy in this room," growled Sherlock, the peerless.

"Well, let's have a window open, and then, perhaps, I can show you a thing or two of interest about this man that you may have overlooked with your glass. You will first observe that the tremor involves the right hand. On looking at this hand closely, you will see a half-softened callus over each joint of the thumb, and similar ones over the root joint and the one next to it of the forefinger. You see none over any other joints. This shows that these particular joints mentioned must habitually come in contact with some hard surface. Now, from my study of artisans' hands, I know that this condition is peculiar to the plasterer, and that it is brought about by the contact of the mortar board. In this case it is the right hand that shows the condition, so the man must do the actual plastering with the left. I hardly need mention that the somewhat softened condition of the calluses indicates this man's abstinence from work for some time."

While Watson was engaged in demonstrating the reasons for his conclusions, Holmes paced rapidly up and down the room, apparently paying not the slightest attention. Finally he whipped out his watch, looked at it, and said, "By Jove, Watson, I must go. I've got an important engagement that I had almost forgotten."

"Oh, don't be in such an infernal rush," replied the doctor. "I've got to get away early myself. I'll tell you what I'll do. I'll just turn this man over to my assistant, see the next case or two hurriedly, and then go along with you."

At Watson's order the next case was led in. "This man," said the externe, "is a rubber-cutter, and his complaint is of headache and dizziness."

"Now, Holmes," said the doctor, "won't you just look at this fellow's gums with your glass and see if you don't see a dark line at the junction of the gums and teeth. You do — thank you. It's a clear case of lead poisoning, just as I thought. Now, my man, let me look at your tongue."

A sudden exclamation from Holmes caused Watson to look at him. As he did so he noticed that his friend's face had suddenly taken on an expression very like what one might expect to see in a mummy that had been spoiled in the making. "Did you speak?" he asked, somewhat maliciously.

"No," growled Holmes between his clenched teeth, "but the diagnosis in this case is too absurdly clear. This man has either been doing some painting at home, or else he uses a hair wash containing lead. Isn't that so, my good fellow?" asked Sherlock, addressing the patient.

"Aw, I never washes me hair," was the reply; "and I have enough to do in the shop without bothering with no painting at home. It ain't in my line."

Holmes collapsed in his chair.

"Perhaps if he will tell us just what his functions as a rubber-cutter are, it will help you to arrive at a correct solution of the problem," put in the doctor, dryly. "Exactly what is your work, my man?"

"I just puts the patterns down on the sheet rubber and cuts around them with a knife," was the answer.

"Does that help you, Holmes?" asked Watson.

The great detective sat dejectedly and made no reply.

"Well, we won't waste any more time on it," rattled on Watson, "but the situation is just this. From your extensive reading and observations, you must know that in the preparation of rubber there is used a considerable amount of litharge, or the red oxide of lead. Now you don't have to examine this fellow's hands very closely to conclude that soap is not a large factor in his items of expenditure. My glance at his tongue showed me that he is an habitual tobacco chewer. On the basis of these two observations, I concluded that the transference of really considerable amounts of the lead from fingers to mouth was a daily occurrence. And now I'm about ready to toddle along with you. From certain sounds I have heard in the last few minutes, I think there's a deaf man with general paralysis in the further room. I'll just run in and look at him, and then I'm at your service." Watson rose from his chair and went toward the door. As he was about to turn the knob, he heard a low moan followed by a thud, and looking round, he saw that Holmes had fallen apparently lifeless on the floor.

SULPHUROUS ACID AND ITS SALTS AS FOOD PRESERVATIVES, AS AIDS TO FRAUD, AND AS POSSIBLE CAUSES OF LESIONS OF THE KIDNEYS.

BY CHARLES HARRINGTON, M.D., BOSTON,
Assistant Professor of Hygiene, Harvard Medical School.

SULPHUROUS acid and its sodium and calcium salts have long been used as preservatives of various articles of food and drink, as fish, meats, sausages, fruits, jams, dried vegetables, cider and wines; and, more especially, for their action in producing an improvement in appearance suggestive of superior quality. Thus, canned corn

and canned asparagus are bleached to a uniform white, and meats are made to acquire the redness of arterial blood. The salts are used both in powdered form and in solution, and sometimes in conjunction with borax and boric acid.

In the treatment of meat, the sodium salt ($Na_2 SO_3 . 7H_2O$) is the compound most commonly employed. While this is used to some extent in and on meats as commonly bought and sold, its chief field of usefulness is in the preparation of minced or ground meat, which is sold to an enormous extent on the Continent under the name "Hackfleisch" and in this country as "Hamburg steak." This is made in great part from trimmings and various inferior parts not otherwise salable, which accumulate in the receptacles for waste in meat stalls and naturally acquire an extensive bacterial flora. Without the addition of a chemical preservative, the commercial life of the finished product would necessarily be very short. But this is not the sole, nor the main, reason for the employment of this particular agent, than which several more efficient preservatives are known. The chief incentive to its use is the fact that it exerts a preservative influence on the hemoglobin and favors the formation of the markedly redder oxyhemoglobin, and thus causes the meat to look invitingly fresh, even though the original material was stale, of bad appearance, and swarming with bacteria. Moreover, it acts as a deodorant. Not only does it cause the characteristic, faint and not unpleasant odor of fresh meat to disappear very quickly, but it masks the foul odors of decomposition. Thus, although apparently fresh to the eye and nose, the prepared mass may be well advanced in decay and teeming with bacteria. Altschuler [1] found that untreated meat yielded 1,829,100,000 bacteria per gram at the stinking stage, while another portion which had been treated with 1% of the salt did not stink until its bacterial content was 4,757,000,000 per gram. Long before this stage is reached, however, a physical change occurs, which reveals itself to the touch. Fairly fresh Hamburg steak feels but faintly moist; it can be handled without adhering to the fingers. Very stale specimens, on the other hand, feel slimy, and particles thereof adhere to the fingers with such tenacity that scraping is necessary for their removal.

The red color which is produced is most intense on the exterior of the mass; indeed, the interior may be quite dark in color; but exposure of the inner portions to the air brings about a rapid change to bright red. The persistence of the redness is dependent largely upon the amount of the salt used.

As a preservative, sodium sulphite is not powerful. Various observers, including Landolt and Rubner, Kisskalt, Gartner and Kionka, say that it can confer redness without exerting much action as a preservative. Altschuler finds that it has an appreciable influence due to its power to inhibit bacterial multiplication; that when present even to so slight an extent as 0.05% it is more or less active; that its maximum influence is exerted when it is present to the extent of 0.5%; and that more than 0.5% confers no additional power. He saw untreated meat grow in bacterial content from 1,200,000 per gram on the first day to 1,829,100,000 on the fourth, while that to which 0.5% of the salt had been added yielded but 2,500,000 on the fourth and 300,500,000 on the ninth. In my own laboratory, a piece of solid meat (round of beef) was hashed and then divided into two equal portions, one of which was treated with 0.2% of the sulphite and the other left as it was. The two portions were kept in a refrigerator under precisely similar conditions, and the number of bacteria per gram was determined from day to day, as follows:

	Plain Meat.	Treated Meat.
After 1 day	610,000	1,760,000
" 2 days	1,045,000	1,600,000
" 3 "	2,709,000	2,709,000
" 4 "	6,579,000	3,999,000
" 5 "	10,346,000	2,322,000
" 6 "	26,313,000	3,483,000
" 7 "	Very foul odor	Faint mouldy odor

It must be remarked, however, that the influence of the salt is seen to best advantage when the meat is kept at a low temperature, for at ordinary room temperature it appears to lose its power very markedly. Indeed, by itself at room temperature, it appears to have less preservative influence than the low temperature of a refrigerator, as was shown by Gartner,[2] who found that untreated meat kept at 39° F. in a refrigerator yielded 320,000 bacteria per gram after twenty-four hours and 575,000 after forty-eight hours, while meat not so stored, but containing 0.09% of the sulphite, yielded 448,750 and 5,385,000, and containing 0.36% yielded 448,750 and 678,000. Janke,[3] too, experimenting with meat containing 0.2, 0.4, and 0.6%, found its preservative effect to be slight, but agreed that the salt can cause decomposing meat to have a normal appearance. Lange [4] found that in the decomposition of treated and untreated meat there was but a slight difference in time when 0.5 and 1.0% of the sulphite was employed, but that when as much as 2.0 to 4.0% was added the meat kept well for a time and then broke down suddenly. Stroscher [5] found that treated meat decomposed about as quickly as that to which nothing was added. Mayer [6] found that 10 samples containing from 0.304 to 0.573% of sulphite yielded from 1,695,000 to 471,511,000 bacteria per gram, whereas home-made specimens yielded from 4,560 to 890,154. The latter retained the natural red color for a time and then changed to the brownish tint that untreated meat acquires on standing, but the admixture of 0.5% of the sulphite after twenty-four hours produced the abnormal redness described. Portions kept forty-eight hours and then treated did not change their color.

[6] Hygienische Rundschau, September 15, 1901, p. 877.

Contrary to what one would naturally suppose, the bacterial content of a specimen bears no relation to the amount of added preservative, as has been shown by Stroscher and others. Thus, Stroscher determined the number of bacteria per gram in 16 samples which contained from 0.029 to 0.520% of sodium sulphite. The two highest counts, 62,096,000 and 54,056,000, were yielded, it is true, by samples containing but 0.065 and 0.075% of the salt, but the next highest, 50,917,000, was yielded by one that contained the largest addition (0.52%). That which contained 0.43% yielded but 147,000, while that with 0.47% gave 14,138,000, or about 600,000 more than one that contained but about a sixth as much (0.08%).

The reason why no such relationship exists is, however, very clear, for, as has been said, much of the material used in manufacture may be swarming with a rich bacterial flora before it is introduced into the hashing machine.

For the production of the desired effects, the presence of at least 0.1% of the salt is necessary, but the addition of 0.2% is generally recommended. It would appear, however, that the manufacturers adhere pretty strictly to the rule of thumb, for the amounts used are very widely variable; and although less than 0.1% is often found, it is more commonly the case that far more than the recommended 0.2% is employed, and even as much as 4.0% has been found. Quantitative determinations in the foreign food laboratories show how generously the salt is administered. Thus, reports from Dresden show that of 54 samples, 38 contained less than 0.4%, 11 contained between 0.4 and 0.6, 1 contained between 0.6 and 0.8, and 4 contained between 0.8 and 1.0%. From Breslau come reports of 0.4 to 0.8% in 7 samples, and of 0.856, 1.708 and 2.80% in others; from Weimar, 0.612, 1.024, and 1.50; from Essen, 0.52 and 0.6; from Aachen, 0.44 and 0.64; from Dusseldorf, 0.156 to 0.960; from Crefeld, 0.28, 0.44, 0.48, 0.56, 0.64 and 0.68; from Cologne, 2.24; from Hamburg, 5 samples with less than 0.4, and 11 with from 0.4 to 1.02; from Altenburg, 1.756. In a number of places in Germany it has been proved that the great majority of meat dealers use it, and in Dantzig no fewer than 112 of the 121 butchers were haled to court therefor a year after its use was forbidden by the German government. So far as I am aware, the subject has received but slight attention in the United States and no statistics are to be had; but in Boston as will be seen — and the conditions here will doubtless be found to be the same elsewhere — its use is the rule, 50 samples examined by me showing its presence in amounts ranging from 0.061 to 1.225%, with not a single one free from it. They were collected in different parts of the city from dealers supplying all classes of customers — from stores and market-stalls patronized by the rich and well-to-do, and from small shops in the poorer quarters. The prices paid ranged from 7 to 15 cents per pound, but 10 cents was the rule. In the following table, the samples are placed in the order of their content of sodium sulphite, from the lowest to the highest.

Sample Number.	Percent Sodium Sulphite.	Sample Number.	Per cent Sodium Sulphite.
22	0.061	1	0.300
16	0.078	40	0.301
32	0.081	8	0.304
45	0.099	50	0.322
14	0.172	11	0.338
18	0.179	12	0.355
19	0.196	33	0.360
17	0.199	2	0.372
35	0.208	20	0.388
9	0.210	37	0.390
38	0.241	31	0.392

44	0.246	34	0.405
43	0.251	26	0.415
46	0.251	27	0.436
23	0.255	30	0.436
10	0.257	15	0.442
41	0.261	49	0.446
47	0.266	5	0.463
29	0.267	6	0.466
24	0.274	28	0.527
7	0.277	4	0.581
13	0.287	21	0.628
25	0.290	3	0.648
39	0.297	42	1.225

Average — 0.335.

The most brilliantly red specimen, Number 16, contained but 0.078%, and owed its intense color, which was uniform throughout the mass, chiefly to the presence of an anilin dye. Many of the specimens were sticky and slimy and gave off peculiar, disagreeable odors. Several gave off the characteristic odors of putrefaction. Number 42, which was richest of all in sulphite, was exceedingly sticky and slimy, and had a very peculiar odor, but was of pleasing appearance.

In the stomach, sulphites are attacked by the gastric juice, with liberation of sulphur dioxide. The energy with which the gastric juice acts is dependent upon its content of hydrochloric acid, which averages about 0.2%. In conditions of hyperacidity, therefore, such as are common to a number of pathological conditions, the decomposition of the salt occurs at the maximum rate. Stroscher asserts that the presence of even 1% of acetic acid is sufficient to bring about the change; and hence when sulphited meat is prepared as beefsteak à la Tartare the opportunity for the disengagement of sulphur dioxide is thereby increased. It would appear from various writings on the subject of sulphited meat that the influence of sulphur dioxide on the system was shown first in 1869 by Bernatzik and Braun,[7] who administered 80 mgm. of free sulphurous acid in 360 cm. of sugar-water in divided doses extending over twenty-four hours to each of 14 women with various disorders of pregnancy. Only two could bear the dose at all well; the others bore it very badly and suffered from eructations of sulphur dioxide, unpleasant taste, violent diarrhea, vomiting, and general discomfort lasting a whole day. Doses of 1 gm. of magnesium sulphite also were badly borne, the chief manifestation of ill effects being vomiting and diarrhea. Doses of 3.75 gm. of sodium

[7] Wiener medicinische Wochenschrift, xix, 1869.

bisulphite were given to 12 women, but only 4 showed no ill effects; several were purged soon after the first dose. In 1884, Ogata [8] showed that sulphur dioxide is an active poison to animals when inhaled, the lesions appearing in the lungs. Pfeiffer,[9] experimenting with aqueous solutions of sulphur dioxide applied to the gastric mucous membrane, observed remarkably intense action, even with very dilute solution of the gas. Intense gastritis was produced by 0.5 to 1.0% solutions, and death was caused in a very short time by a 5% solution, with marked corrosion not only of the several layers of the stomach wall but even of the surface of neighboring organs.

Borntrager [10] states that he cannot eat certain sausages nor drink certain Rhine and Moselle wines without suffering from eructations of sulphur dioxide and hydrogen sulphide, and from weight in the stomach, discomfort and headache lasting for some hours. Pfeiffer asserts that he and others suffered from oppression and discomfort after a half gram of sulphite in very dilute solution, and Leuch,[11] that wines containing free sulphur dioxide cause discomfort much more readily than those that contain it in combination, 45 mgm. of the former being equal in power to 250 of the latter. These amounts, taken in about a third of a quart of wine, caused irritation of the throat and headache; and 55 and 350 mgm., respectively, caused more severe headache with diarrhea. He observes that individuals vary widely in susceptibility.

The fact that many persons show distinct evidence of disturbance from as little as 0.01% of the anhydride or 0.04 of the salt, leads Borntrager to the conclusion that the continued ingestion of small amounts of sulphites causes serious injury to the organs without the manifestation of any outward sign of sickness.

It is true that after the addition of sodium sulphite to meat it becomes slowly oxidized to sulphate and then loses its toxic properties, since in that form it cannot be split up by the gastric juice. Gartner states that he has recovered from 56.8 to 87.3% of the original amount as sulphite, twenty-four hours after the admixture to meat, but Polenske [12] recovered no less than 81% from a sausage after three months, and from 72 to 77% after six months. Borntrager states that about a third of the amount present is lost during cooking.

The first to show definitely what harm may result to the system from the continued ingestion of sulphited meat was Kionka,[13] who, in 1896, reported that repeated small doses administered to dogs produced serious lesions in various parts of the system. In 1898, the use of sulphites in foods was forbidden by the German Imperial Board of Health, which body, in answer to the assertion of the butchers that the addition of a sulphite to minced meat is necessary, replied that it is possible to prepare minced meat from freshly slaughtered meat without the use of chemical preservatives, but with the observance of strict cleanliness, and that on storage at low temperatures its natural red color can be retained longer than twelve hours; that the addition of sulphites and of preservative preparations containing them tends to improve the color but not the meat itself, and to give the meat an appearance of superior quality; and that the constant use of minced meat containing sulphites can injure the system, especially in the case of the weak and sick.

The findings of Kionka and the Imperial Board of Health have been attacked by Liebreich and others as unwarranted. Kionka's experiments were repeated by Lebbin and Kallmann,[14] one of whom is a chemist and the other a veterinarian, but neither of them a pathologist, who reported an entire absence of lesions on autopsy. A new series of experiments on a more extensive scale gave Kionka and Ebstein [15] results identical with those obtained before, which were confirmed also by Schultz.[16] In both of Kionka's series of experiments and in those of his opponents as well, the dogs employed showed at no time any outward appearance of injury, but on the contrary, in one series, gained in weight up to the ninth week, when they were killed. Two of Schultz's dogs soon showed evidence of illness; they were purged and were reluctant to eat, but all showed a gain in weight at the end. In all of Kionka's and Schultz's dogs, nephritis was a constant result. In my own experiments, which were begun before I knew of Schultz's paper and of Kionka's second series, I employed cats, which have the advantage over dogs in experimental feeding that they are not subject to idiopathic nephritis, which occurs in about 25% of dogs kept under observation in cages. Six cats were fed for twenty weeks, five receiving six feedings weekly of meat containing 0.2% of sodium sulphite, and the sixth receiving the same meat with no addition. The latter showed a constant gain in weight to the end; the others gained until about the ninth week and then began to lose ground, frequently refusing food or leaving it largely uneaten, but otherwise they showed no evidence of injury. At the end of twenty weeks they were killed with chloroform and examined by Dr. E. E. Tyzzer of the Department of Pathology of the Harvard Medical School. There was no macroscopic evidence that the chemical had produced any changes in the organs, but thin slices were cut from each of the organs of each cat, fixed in Zenker's fluid, and then imbedded in paraffin and cut. Eosin and methylene blue were used for general staining, and Mallory's stain was employed, also. The microscopical findings were by no means so extensive as those yielded by Kionka's dogs. Indeed, apart from some slight inconstant variations in the spleens, all of the organs of each animal were

FIG. 6.

perfectly normal, with the exception of the kidneys, which in all but the control cat, showed marked changes. Following are the findings as to this organ:

Cat No. 1. (*Control.*) Kidney. The epithelium of the convoluted tubules contains fat, but in small amounts as compared with the other five, and there are no accompanying degenerative changes.

Cat No. 2. Kidney hyperemic, especially in intermediary zone. Vessels of glomeruli dilated. All tubules of labyrinth extremely fatty. Tubules of medullary rays give evidence of marked cloudy swelling. The cells of the collecting tubules are irregular and dissociated and much larger than normal. They stain deeply and the nuclei are shrunken and irregular in places. These tubules contain collections of fibrin in the shape of small needles, which sometimes are collected in the lumen of the tubule, sometimes between and sometimes enmeshing groups of cells.

Cat No. 3. Kidney. Vessels injected. Bowman's capsules are somewhat dilated and contain collections of large fatty epithelial cells, which have been pushed in from the neighboring tubule. These are not attached to the capsule and are dissociated one from another. The epithelium of the convoluted tubules is loaded with fat. In places, this is accompanied by considerable degeneration of the cells. There is marked cloudy swelling of the tubules of the medullary rays, *i. e.*, Henle's loop, and more marked of the collecting tubules. On account of the increased thickness of the epithelium, the tubules are larger, with smaller lumina. The epithelium is tall, columnar, due probably to proliferative changes. The cells stain deeply, are dissociated, and in places are desquamated in masses. Nearly all of these tubules contain masses of fibrin in the lumen or enmeshing cells.

Cat No. 4. Kidney. A few Bowman's capsules contain desquamated epithelium from the adjoining tubule. The convoluted tubules are very fatty and there is marked cloudy swelling of the tubules of the medullary rays, identical with the changes found in the preceding cases. In addition, there is infiltration of areas of interstitial tissue with lymphoid and plasma cells. These foci are elongated and extend parallel to the tubules. The lesions are most numerous near the line of junction of the medulla and cortex, but some are situated wholly in the medulla and others extend into the cortex almost to the capsule in the kidney. These lesions bear no relation to the larger blood vessels and are probably secondary to parenchymatous changes.

Cat No. 5. Kidney. The convoluted tubules are extremely fatty. Tubules of the medullary rays show marked cloudy swelling, as in the other cases. Interstitial tissue is not affected.

Cat No. 6. Kidney. The convoluted tubules are very fatty. Cloudy swelling is marked in the medullary rays, especially in the first portion of the collecting tubules (the so-called intercalated tubules). In these the cells are desquamated, swollen and irregular, and the tubules contain fibrin.

DESCRIPTION OF PLATE.

No. 1. Normal kidney of cat, multiplied 175 diameters. In the normal kidney there is a slight amount of fat in the cells, shown by the vacuolation in the epithelium. (From Cat No. 1. Control.)

No. 2. Kidney of cat with intense fatty infiltration of tubules in the pyramid. Multiplied 175 diameters. (From Cat No. 5.)

No. 3. Kidney of cat. Degeneration of proximal convoluted tubules. In most of the tubules there is an increased amount of fat, shown by the vacuolation, with separation of cells from their attachment. The attached masses of cells press into the capsular space of the glomerulus. Multiplied 175 diameters. (From Cat No. 3.)

No. 4. Kidney of cat. Degeneration and partial desquamation of cells of intercalated tubules, with granular detritus in lumen. Multiplied 250 diameters. (From Cat No. 2.)

No. 5. Kidney of cat. Focus of lymphoid cellular infiltration in pyramid. Multiplied 60 diameters. (From Cat No. 4.)

No. 6. Spleen of cat. Large foci of epithelioid cells and slight necrosis of follicles.

NOTES ON RADIUM.

Production of the Gamma Rays from the Beta Rays of Radium; Use of Radium in Some Diseases of the Eye.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

Physicists now consider that the beta rays from radium correspond to the cathode rays and the gamma to the x-rays. The cathode rays strike the platinum anode of a vacuum tube and x-rays are produced. It seems, therefore, reasonable to suppose that if a plate of heavy metal were put in the path of the beta rays, not only would a part of them be reflected, but a portion also would be converted into gamma rays. In order to test this supposition I made last winter the following experiment:

A mass of lead, L, 6 inches (15 cm.) thick from end to end, was placed on the apparatus as shown in Fig. 1, so that practically no rays from the specimen of 50 mgm. of pure radium bromide, R, could reach the barium platinocyanide screen S.

The radium R, in a metal box with a mica cover, was wrapped in black paper and so placed that the rays emitted issued at right angles to the long axis of the apparatus and toward a lead plate, P, standing at an angle of 45° to the rays. Under these conditions, when the room was dark, the screen of barium platinocyanide S, which was 48 cm. from the middle of the lead plate P and the radium R, was brightly illuminated. Second: If, however, a plate of aluminum, A (see Fig. 2), $\frac{3}{16}$ inch ($\frac{1}{2}$ cm.) thick (this thickness of aluminum absorbs all the beta rays, but the gamma rays pass through), was interposed between the plate P and the fluorescent screen S, most of the light was shut off from the screen S.

Third: With the aluminum plate A still placed as in Fig. 2, the fluorescent screen S was moved toward the plate P until the screen S seemed to be as bright as when the apparatus was arranged as in Fig. 1, that is, when no aluminum plate was interposed between S and P. Under these conditions, the scale on the apparatus showed that screen S was 25 cm. distant from the center of plate P. Fourth: If the plate of aluminum A

was removed from the position shown in Fig. 2, and placed between the radium R and the lead plate P, the fluorescent screen S was not illuminated at all.

The different results observed on the fluorescent screen S, with the different positions of the aluminum plate A or its removal altogether, prove that gamma rays were produced when the beta rays struck the lead plate P. Let us go over the process, step by step. If the aluminum plate A is placed between the radium R and the lead plate P, the fluorescent screen S is dark, because the beta rays are absorbed by this thickness of aluminum before they can reach plate P. That is to say, when the beta rays were prevented from reaching plate P, no gamma rays were produced, and likewise, of course, there were no beta rays at P to be reflected on to screen S. (The alpha rays need not be considered, as they are absorbed by the mica covering the radium.) To make this clear, let us remove the aluminum plate A from its position between R and P and place it, as once before, between S and P. (See Fig. 2.) By thus changing the place of the screen A, we have allowed the beta rays to strike the lead plate P, and as a result the screen S is illuminated, but only faintly so, because though the beta rays have reached the lead plate P, owing to the removal of the plate A from between R and P, they are unable to reach the screen S, because the aluminum plate A has now been placed in their path between S and P. (See Fig. 2.) Therefore, the illumination observed in this case is due to the gamma rays that were produced when the beta rays struck the lead plate P; the remaining beta rays that were reflected as such from plate P being absorbed by the aluminum plate A on their way to screen S. Now let us remove the aluminum plate A altogether. (See Fig. 1.) The screen S, under these circumstances, is brightly illuminated, because the beta rays, no longer being absorbed as in the previous instance, have added their brilliancy to the fainter light from the gamma rays.

The brightness of the fluorescent screen S, when illuminated by the gamma rays alone, seemed in one instance, as we have seen, equal to the amount of brightness observed when screen S was struck by both the beta and the gamma

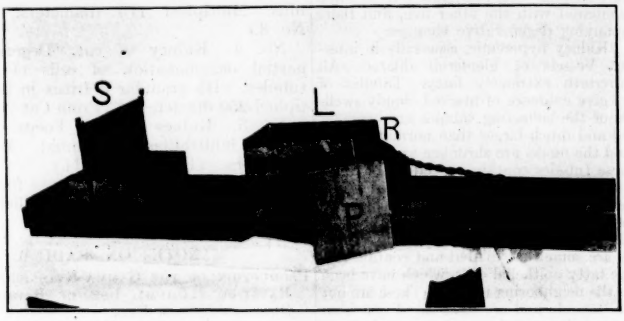

FIG. 1 shows a base of wood with a centimeter scale attached to its side. On its upper surface is a block of wood, which may be slid lengthwise, and which carries a screen of barium platinocyanide, S. Another block supports a mass of lead, L, and 50 mgm. of pure radium bromide, R. Standing at an angle of 45° with the long axis of the apparatus is a lead plate, P.

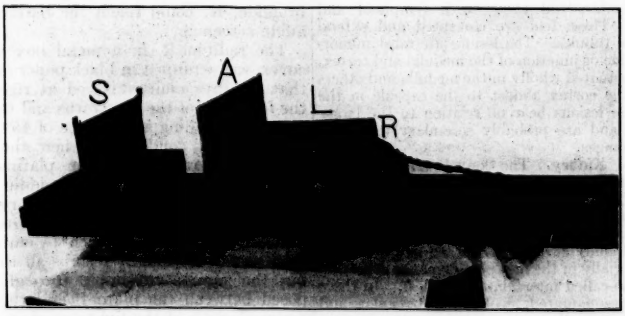

FIG. 2 is the same as FIG. 1, with the addition of the aluminum plate A.

rays. This will be readily understood when we remember that the amount of light diminishes as the square of the distance, and that the brightness resulting from the gamma rays alone, in this case, was due to the fact that the fluorescent screen S was moved from the position which it held, when struck by the beta and gamma rays, of 48 cm. distance from the centre of the lead plate P to within 25 cm. distance from the center of plate P.

The following experiment that I have made with radium will also be of interest, I think: It is well known that when strong radium is held near the closed eyes of an individual who has been for some time in a dark room it causes a well marked sensation of light. I placed a specimen of 50 mgm. of pure radium near one of my eyes, and this sensation of light was produced. I then interposed a plate of aluminum that was thick enough to absorb all the beta rays, but allowed the gamma rays to pass. Under these circumstances the sensation of light produced in my eye was the same as before the interposition of the plate of aluminum. This experiment shows that the sensation of light in the closed eye can be caused by the gamma rays alone.

The beta rays seem likely to prove a convenient and useful remedy in certain diseases of the eye, particularly those which have not yielded to other methods of treatment. Among these I may mention trachoma, a very obstinate and difficult disease to treat, and one that requires many months or even one or two years, — opacity of the cornea, and inflammatory conditions of the neighboring parts. Four or five years ago I used the x-rays in some diseases of the eye with good effect, and recently I have applied the rays from radium.

In trachoma I have found that good results have followed promptly from exposures of two or three minutes to 50 mgm. of pure radium bromide, given at first once a week and later twice a week. The radium was held about ½ cm. from the everted lid, or was placed even nearer to the closed lid opposite the diseased area.

A very good example of the usefulness of the radium rays in opacity of the cornea and inflammation of the neighboring parts is afforded in a case brought to me by my brother, Dr. Charles H. Williams. The patient was a woman of middle age, who was suffering from a rather severe uveitis and an opacity of the cornea, which involved the lower and outer quadrant, and was so great that through portions of it the iris could not be distinguished. This opacity also included to some extent the central portion of the cornea. At this time the vision was less than 0.1. As the patient had only one eye, I felt that I was taking a good deal of responsibility in deciding either to use the radium or to decline to use it, but I determined on the former course, as Dr. Williams told me that everything that had offered hope of relief had been tried without success; therefore the use of radium seemed the only chance of saving the patient from blindness. My experience in employing radium was at this time sufficient to make me confident that I could use it with such ca e as to do no harm.

The exposures were made at intervals of three to seven days, the lids being held apart and the radium placed first about ½ cm. from the cornea, later about 1 cm., and still later 2 to 3 cm. Slight improvement was noticeable within two weeks, and at the end of ten weeks the improvement was marked; the inflammation had decreased throughout, the opacity of the whole cornea had diminished greatly, and the vision was 0.4. The patient at this writing has a vision of more than 0.5, and can read ordinary print. I hope that Dr. Williams will report fully on this case.

It is hardly necessary to mention the great convenience of using radium as compared with the x-rays. The output of the rays from radium is uniform, and the rays may be easily applied. The greatest care should be employed when diseases of the lids or eyes are treated with this powerful agent.

The use of radium in the fluorometer, an instrument for estimating the output of x-rays of a given vacuum tube, I have already described in the third edition of "The Roentgen Rays in Medicine and Surgery," pages 640–642.

Radium is also of use as a test for determining whether or not the eyes of the practitioner are in a suitable condition for making fluoroscopic examinations. This test can be carried out by means of the spinthariscope, which contains a small amount of radium. If the scintillations appear bright to the practitioner, his eyes are ready for use; if dull, he must wait for a while longer in the dark room before attempting to make a fluoroscopic examination.

VAGINAL SECTION IN THE TREATMENT OF EXTRA-UTERINE PREGNANCY.*

BY FRANK A. HIGGINS, M.D., BOSTON.

In reporting these few cases of extra-uterine pregnancy treated by vaginal section, it is not my intention to appear in any way as an advocate of the vaginal operation for this condition. But the experience in these cases has been somewhat unusual, to me at least, has shown certain difficulties and contingencies in the way of treatment which had not been met with before, and also reveals certain errors of diagnosis which are not uncommon, and which serve mainly to emphasize the frequently repeated statement that a correct diagnosis of extra-uterine pregnancy is often impossible. It has been the usual experience, however, that other conditions in the pelvis are more often taken for extra-uterine pregnancy than that extra-uterine pregnancy is overlooked.

There are still a few men who advocate and perform the vaginal operation for nearly every abnormal condition in the pelvis. Yet I believe

* Read at the meeting of the Obstetrical Society of Boston, January 19, 1904.

it is now pretty generally recognized that in the main the advantages of vaginal section are confined to those cases in which there is an acute collection of pus in the pelvis, the removal or drainage of which is necessary, which is of comparatively easy access from below, and where an operation by the abdominal route would result in an incomplete operation with drainage, and also in considerable danger of infection of the general peritoneal cavity. In such cases the collection of pus is usually quickly and readily reached and evacuated by means of a posterior vaginal incision.

By the vaginal operation for pus accumulations, there is only slight hemorrhage and rarely any serious amount of shock. With care there is little danger of infecting the general peritoneal cavity, and the drainage is thorough if the incision is ample. The convalescence also is usually rapid, but of course largely dependent upon the general condition of the patient previous to operation. These are, in brief, the chief conditions which favor the vaginal operation for pus collections in the pelvis, but on the other hand the operation is often an incomplete one and it may be necessary to open the abdomen later for relief of pain or other symptoms.

Vaginal operation or exploration in extra-uterine pregnancy has been advocated chiefly for diagnosis in doubtful cases by means of a small puncture, and also for those cases in which the hemorrhage has not been free or severe and has been confined to the pelvic cavity or other limits. It is to be presumed that few men, if any, would advocate a vaginal operation for a condition involving free hemorrhage into the peritoneal cavity, because of the manifest difficulties in reaching and controlling the source of the hemorrhage, and also because of the practical impossibility of draining into the vagina free blood which has escaped high into the abdomen.

With respect to diagnosis, so much has already been written that there is nothing new of value which can be said at present. Frequently abnormal conditions of the tubes and ovaries cause symptoms strongly pointing to extra-uterine pregnancy before rupture. Conditions in the pelvis giving rise to a mass with an acute pelvic tenderness, and also in many cases showing some evidence of slight, general peritonitis, which are accompanied by irregularities in the menstrual flow, are the ones which are most likely to occasion difficulties in diagnosis in differentiating for extra-uterine pregnancy.

Within the last few months, the writer has had three cases of extra-uterine pregnancy operated upon in the acute stage in the presence of profound shock, but in the absence of the other typical symptoms of ruptured extra-uterine pregnancy.

These cases, briefly reported, are as follows:

The first patient was seen May 14, 1903. A. A., thirty-one years; married seven years; three normal labors; the last menstrual period occurred March 31, about six weeks before. Six days ago she began to flow and continued flowing a little but only when passing water. Two days later began to have pains resembling labor pains, and these have continued ever since intermittently. Four days ago her pain becoming so severe, she sent for a physician who etherized her and took "the child away," that is, I suppose, emptied the uterus probably by curettage. Since then, her abdomen has become distended, she has had several slight chills and has vomited constantly for three days. Bowels have moved once, and then from an enema.

The hospital records say that the patient looks very sick, emaciated and extremely pallid; marked anemia of mucous membranes; eyes normal; tongue dry, white coat; pulse rapid, regular, of poor volume and tension; heart and lungs negative; abdomen markedly distended, tympanitic and moderately tender to pressure over all portions.

The writer saw the patient shortly after her entrance to the hospital. There was no question as to her extreme condition. There was constant and most severe vomiting. Abdominal examination gave no more evidence than is stated above. On vaginal examination, there was general pelvic tenderness with induration and bogginess of the vaginal vault, especially posterior. In view of the history of curettage four days previous, it seemed probable that we had to do with a case of acute pelvic infection with an abscess following the operation, and with some extension into the general peritoneal cavity. A vaginal section with drainage which could be rapidly performed appeared to offer the best hope of relief, but even this was believed to be very slight in the patient's extreme condition.

A transverse incision was made posteriorly close to uterus, opening directly into the peritoneal cavity, and a large amount of dark fluid blood immediately escaped. It was found possible without much difficulty to forcibly retroflex the uterus into the vagina through the incision, and a mass consisting of tube distended with blood clot attached to the ovary was brought into view and shelled out from the right side. The tube and ovary were ligated en masse and removed. The hemorrhage apparently being controlled, the uterus was replaced and the pelvis irrigated and iodoform gauze drainage inserted. The operation was short, being completed in about ten minutes and practically under primary anesthesia. The patient was in a critical state for some time after the operation, but slowly gained in general condition, and the abdominal distention gradually subsided.

The patient improved steadily for about two weeks when suddenly she developed a high temperature with abdominal pain and tenderness, and a mass tender to palpation could be felt about midway in the abdomen between the pubes and the umbilicus. The abdomen was opened at once with a median incision into a cavity containing a considerable amount of old bloody fluid, with clots and foul smelling débris. Connecting with this cavity was a fistulous opening into the small intestine. This cavity was thoroughly sponged and washed out with hot salt solution and drained with iodoform gauze wicks. The patient made a good recovery from this second operation, and was discharged in about two months after her entrance, the fecal fistula eventually healing without operative closure.

Before the vaginal operation, the question of the possibility of extra-uterine pregnancy was considered, but it was given up in view of the history of probable abortion and curettage. It was plain after the operation, however, that the case was undoubtedly a typical one of ruptured

extra-uterine pregnancy, and it was believed that if the patient had been seen at the onset of her symptoms, and a good history could have been obtained, there is little doubt but what we should have performed an abdominal section primarily. But taking into account the fact that the patient had been etherized and curetted for a supposed abortion four days before, it seemed natural to ascribe her symptoms to a pelvic infection originating in the uterus. I was also convinced at the time that she would not be able to withstand an abdominal operation, so extreme was her condition, but in looking back at the case and comparing her condition with other patients operated upon for extra-uterine pregnancy, I am not as strong in my opinion on this point, as I was at that time. Many very desperate cases recover after abdominal section if the hemorrhage is quickly stopped, and the free blood evacuated from the peritoneal cavity.

It was a simple matter in this case to retroflex the uterus into the vagina, to ligate off the bleeding tube and remove it, and then replace the uterus and insert gauze drains around the stump. But the so-called toilet of the peritoneum cannot be effectively accomplished from below, and free blood may remain in the abdominal cavity as a source of trouble later, as occurred in this case. The collection of blood high in the abdominal cavity became infected possibly from the vaginal drainage, or probably from the bowels as they were found to be connected by a fecal fistula which had evidently ulcerated through.

As the patient ultimately recovered, I do not think it can be said that the vaginal operation was in any way detrimental to her, and it may be considered a successful case as she might not have recovered had the abdomen been opened when she was first seen, so critical was her condition.

This was the only case in which I was able to bring the uterus down into the vagina in the operation, in the others it apparently being firmly fixed forward. It is interesting to know, however, that this procedure in no way interfered with the return and maintenance of the uterus in normal position, as on a recent examination of the patient, about eight months after operation, the uterus was found in good position anterior, and the patient well and free from symptoms.

The second case, F. B., entered the hospital Sept. 28, 1903. Twenty-four years; married two years; one induced abortion. Two days before entrance, she was taken suddenly with very severe pains in the lower portion of the abdomen, accompanied by nausea and vomiting. Patient believed she had an accidental miscarriage a few weeks earlier when about six weeks pregnant. There had been constant flowing necessitating two or three napkins a day for about four weeks, or since the time of her supposed miscarriage. Nausea and vomiting for three weeks with more or less fever and chills.

The patient appeared to be very sick, there was intense pallor of face and her features were pinched. The pulse very rapid, irregular and scarcely perceptible at the wrist. Lungs and heart negative. Abdomen not much distended, somewhat rigid and very tender, especially on the right where a mass could be felt above the groin, through the abdominal wall, about the size of a navel orange. A boggy, indurated mass on the right could also be felt on vaginal examination. Leucocytosis 23,600. The probable diagnosis was made of an acute pyosalpinx, and a vaginal operation decided upon.

Under light anesthesia in the Pean position, the uterus was curetted with very little material being obtained. The usual incision was made behind the cervix, enlarged with the scissors, and dissection carried on with fingers. The large mass described above was entered and considerable blood evacuated. The ruptured sack was then clamped at both ends and clamps left in position, as the mass could not be quickly shelled out and there appeared to be some recent hemorrhage. The cavity was left tightly packed with iodoform gauze. Salt solution under breasts was given during the operation, as well as other stimulants, and the patient put to bed immediately and treated for severe shock. The pulse which at the end of the operation was 160, dropped under this treatment to 140 and improved in quality. Patient passed a fairly comfortable night, the pulse coming to 120 finally, and the temperature slightly above normal. Her color was much better early the next day, but towards night, however, the abdomen became distended and she complained of considerable pain and vomiting began, and there was marked palor.

Accordingly as it seemed evident that hemorrhage had begun again, the abdomen was opened by a short median incision, and the peritoneal cavity found filled with blood. There was fresh hemorrhage from the right tube which was tied off and removed. The intestines were found to be somewhat injected with evidence of beginning peritonitis. The abdominal cavity was thoroughly flushed out with hot saline solution, and about 50 cm. of a saturated solution of Epsom salts were injected directly into the intestine. Wick drainage and mass sutures.

Patient made a very good recovery from ether, and for twenty-four hours did well, when she ceased to gain and began to go to pieces and died forty-eight hours after the second operation.

This second case illustrates the impossibility in most cases of controlling hemorrhage from below even when its origin is in the pelvis, as well as the dangers and disadvantages of the vaginal operation. In certain cases it may be possible to accomplish it, but one has no assurance of being able to do so, and the danger of secondary hemorrhage is undoubtedly much greater than when the hemorrhage is controlled from above. It is also evident from this case that even in the presence of a definite mass in one side, we cannot by any means be sure that hemorrhage is not still going on, and that we have a hematoma which is walled off from the general peritoneal cavity. It seems probable now that this patient would have stood a very good chance of recovery had the abdomen been opened at the first operation, and the hemorrhage controlled from above.

Case III. H. V. H., entered hospital Nov. 17, 1903. Thirty-six years; married eighteen years; six pregnancies; last, ten years previous. Nearly constant flowing for one month, accompanied by slight general abdominal pain. Two days ago was taken with very

severe general abdominal pain and patient thinks she fainted. Pain is still very severe and is apparently becoming localized in the left lower quadrant. Considerable vomiting.

Appeared very sick; pulse rapid, regular, of fair volume and tension; dyspnea and pallor; heart and lungs negative. Abdomen not distended but lax, although there was considerable tenderness on pressure over entire surface, but especially over lower portions. In left inguinal region a distinct mass could be outlined, somewhat tender to palpate. She was given salt solution, strychnine, and a shock enema to improve her condition. Leucocytosis 26,200. Vaginal examination showed cervix pushed forward by a large bulging mass behind the uterus extending outward towards the left side. The patient rallied somewhat after a few hours from her profound shock, and vaginal section under light anesthesia was performed. A cavity was opened, walled off from the abdomen, and containing a large amount of old clotted blood. There was no fresh bleeding, the cavity was irrigated with salt solution and left packed with iodoform gauze. The patient rallied quickly and eventually made a good recovery.

This last case illustrates very well, I believe, a type of case in which if we could be absolutely sure of the condition in the pelvis before operation, the vaginal operation would be satisfactory and be safer and simpler than an abdominal operation. That this cannot always be determined beforehand is shown by the second case. The patient was undoubtedly suffering from severe shock as the result of hemorrhage, probably into the broad ligament. Such a cavity after being evacuated of its contents can be packed and the hemorrhage controlled in that way very well from below.

It is rather difficult to see just why there should be so much shock as there was in this case without free hemorrhage into the peritoneal cavity, or without large loss of blood, but we know that we do sometimes get practically the same amount of shock in either condition. I have had several cases of pelvic hematocele, one of which was in rather an acute condition, which have been opened by vaginal section. But as in none of these cases was it possible to determine positively that the condition arose from an ectopic pregnancy, they have not been included in this paper. The experience gained in these three cases is of course not large, but it is quite enough even with two recoveries in three desperate cases, to convince me that the abdominal route is by far the safer and more satisfactory method when once the diagnosis is made, even though it seems scarcely possible for the patient to undergo the shock of a laparotomy. The time required is a little more by the abdomen but the results in the control of hemorrhage are much more certain.

I am not sure, however, that if one, in a mistake of diagnosis, opens by vaginal section into a ruptured extra-uterine pregnancy, he should always immediate y follow it up by an abdominal operation. I should say not if he feels certain that he has been able to control the hemorrhage, or unless the patient is in unusually good condition, or later she shows evidence of continued hemorrhage.

We must, I believe, continually keep in mind the possibility of extra-uterine pregnancy in a woman exposed to pregnancy, and in the presence of severe abdominal pain and tenderness, a rapid pulse, vomiting, or other peritoneal symptoms, a rupture of a pregnant tube can never be absolutely excluded.

Clinical Department.

CLINICAL REPORT FROM THE WARD FOR SKIN DISEASES AT THE MASSACHUSETTS GENERAL HOSPITAL.

A CASE OF CUTANEOUS TUBERCULOSIS OF REMARKABLE EXTENT. DERMATITIS HERPETIFORMIS OF TWO YEARS' DURATION. ULCERATED NEVUS VASCULARIS.

BY JOHN T. BOWEN, M.D., BOSTON.

Physician for Diseases of the Skin, Massachusetts General Hospital; Assistant Professor of Dermatology, Harvard University.

SINCE the opening of the ward for skin diseases, in October, 1903, many interesting cases have been received and treated. The following are among those observed during October, November and December:

A CASE OF CUTANEOUS TUBERCULOSIS OF REMARKABLE EXTENT.

The patient is a man of thirty-two, born in Massachusetts, who has nothing of importance in his family history, with the exception that his mother died with pleurisy. He has one brother and three sisters living and well. When eight years old, he had lung fever, and was ill three months, but recovered perfectly. When ten years old, a small nodule appeared on the nose, on the right side, which steadily spread. This was followed by swelling of the nose, and by similar small nodules on the lower lip. At this time the diagnosis of lupus was made, and he came to the Massachusetts General Hospital, where the lesions on the lower lip were curetted. From this time onward the lesions constantly extended, spreading outward over his face. When fifteen years of age, the middle finger of his right hand swelled, became sore, stiff, and then contracted. The next lesion to appear was on the right buttock, a little later than the finger. Next, the front of the upper arm was attacked, and this was followed by a lesion at the flexure of the elbow, which healed spontaneously.

When admitted to the ward, on Oct. 10, his face from the eyebrows to the middle of the under part of the chin, was a mass of scar tissue of a pale red, clear in the center, but with scattered cutaneous nodules. The lower part of the nose was entirely gone, exposing the nasal septum, and the lips tightly drawn and contracted, with some crusted lesions at the edges. There was marked ectropion, especially of the right eye. There were extensive infiltrations of tuberculous tissue over the sternum, right upper arm, right wrist, left upper arm, and the outer and inner sides of both thighs and buttocks. Intermixed with these more or less active lesions was a large amount of cicatricial tissue. The hands were greatly distorted, anchylosed, and presented a striking resemblance to the main-en-griffe of leprosy.

This man had visited various parts of Europe in search of a cure, and had been an inmate of several of the better known dermatological institutions. His

general health had always been good. During his stay in the hospital an epithelioma has developed upon the right cheek near the angle of the mouth, which thus far has proved rebellious to the x-ray treatment which has been of much value for many of the tuberculous lesions. Different parts of his body have been treated by the Finsen light method and by the high-frequency current.

DERMATITIS HERPETIFORMIS OF TWO YEARS' DURATION.

This patient is a man of thirty, born in England, and first affected in March, 1902. The disease first made its appearance on the scalp in the form of blisters, which rapidly followed one another. In August of that year, the bullæ were present on the arms, ankles and also the toes; and afterwards the eruption spread rapidly to the back. This patient was seen by me in 1902. At that time his body was pretty well covered with a purely bullous eruption, grouped in places, as about the mouth and nose and in the groin. The patient stated that he had been unable to work, and at one time had been hardly able to move on account of the extent of the eruption. Very little multiformity was seen, the lesions being pure bullæ and vesicles. There were large areas of erythema and pigmentation, which represented the areas that had been affected by the disease. At one period, the affection had almost disappeared, and the patient thought that he was surely going to recover, but another attack quickly followed.

When admitted to the ward on Oct. 9, the eruption was situated upon the neck, where confluent clusters of vesicles and bullæ on an erythematous base were seen. Vesicles were also clustered about the mouth; the scalp was crusted, with the appearance of new vesicles; the abdomen was free. There were numerous bullous lesions on the back, more or less grouped. Mingled with crusts and erythema, there were very numerous pigment stains over the entire body. Upon the lower limbs, the affection was grouped about the genitals and the inner surface of the thighs, consisting of large and small closely clustered vesicles and bullæ. In general, the type was that of medium sized bullæ. On the thighs and buttocks the lesions are very numerous, so that sitting down is very painful.

This patient has never suffered in his general health; in fact, he has gained weight since the affection began two years ago. No abnormal signs were found on physical examination. Examination of the blood showed polynuclear leucocytes, 63%; lymphocytes, 19$\frac{5}{10}$%; eosinophiles, 17$\frac{5}{10}$%; white blood corpuscles, 25,500. An examination of the contents of the bullæ gave polynuclear leucocytes, 46; lymphocytes, 4; eosinophiles, 50.

The patient remained in the ward until Jan. 21, 1904, when he was discharged, relieved. During this time, the skin affection went through various phases. At first new lesions were constantly appearing, generally over the parts mentioned above. It was noted that there was a marked tendency to grouping and that the bullæ, especially the larger ones, had an angular outline. He developed, also, a few lesions on the mucous membrane of the mouth. The anterior surface of the trunk remained pretty free from the lesions, while the back was at times almost completely covered. The groins continued to be a very favorite site for the appearance of the lesions.

Various methods of treatment were tried, both internally and externally. The x-ray seemed to have no effect either on the duration of existing lesions or on the appearance of new ones. Burow's solution, a mixture of acetate of lead and alum, was of much value in combating the odor of the macerated epidermis and as a soothing dressing. It was thought at one time that arsenic was exerting a somewhat controlling effect, but the appearance of an active new outbreak dispelled these illusions. Quinine, which has had an effect in certain cases of this character, was tried for a considerable time without result. When discharged, he had only a few scattered lesions over the areas that had been generally affected before. As the eruption became less, the percentage of eosinophiles diminished, so that there was only about 5% when he left.

On the ninth of March he was readmitted with a fresh attack. Up to three days ago the affection had been confined to the chin. Now it has appeared in both groins, extending over the perineum. There are also lesions on the back and on the lower limbs. The patient is still in the hospital, repeating his experience of three months before. There has never been very marked pruritus, although he has complained of some at times.

The affection must be classified with dermatitis herpetiformis on account of its recurrence, its grouping, and the general well-being of the patient. The multiformity was not marked in this case. Apart from some few areas of erythema, the affection has been vesicular and bullous or pustular from the start. It will be noted, also, that the itching is not severe.

ULCERATED NEVUS VASCULARIS.

This occurred in an infant of eleven months, of foreign parentage, with no obtainable history except that she had been born with a birth mark of the left cheek, which had grown rapidly with the growth of the child, and had become ulcerated three months ago. On examination the infant, who was poorly nourished, presented over the left cheek an area of about four by one and one-half inches deeply ulcerated, with a thin secretion. Surrounding this ulcerated area, there was a small area of angiomatous tissue; but most of the tumor had become ulcerated. The case was interesting on account of its unexpectedly favorable termination. The child being poorly nourished and the ulceration extending rapidly when she was admitted, it could hardly be expected that the process would be stopped. Undoubtedly the improved hygienic conditions had much to do with the continuous improvement that took place. It was treated locally with sulphonapthol and myrrh wash and a borated ointment. The patient was admitted on Dec. 7, 1903, and on Jan. 1, 1904, the ulcer had practically healed, leaving a red cicatrix.

THREE CASES OF HEMORRHAGIC DISEASE OF THE NEW-BORN.

BY HENRY B. STEVENS, M.D., WEST ROXBURY, MASS.

THE following brief reports of cases are of some interest:

CASE I. C. B., was born April 8, 1901. First child; normal delivery; O. D. P., male.

On the second day child vomited small amount of bloody matter of a dark color, followed after a while by more of same nature and accompanied by frequent tar-colored stools. Moderate fever. A diagnosis of hemorrhagic disease of the new-born was made. Dr. J. L. Morse was called in consultation. Supporting and stimulating treatment advised, and the child was kept perfectly quiet in its basket, fed with diluted breast milk by dropper and given small doses of

brandy. Continued to vomit bloody matter and tar-colored stools kept up. Marked yellowish pallor developed with extreme prostation. Child gradually failed and died on April 11.

CASE II. A. O., was born Jan. 5, 1902, in immediate neighborhood of Case I, the two houses being within stone's throw. Third child; normal delivery; female.

Case presented almost identical symptoms with Case I, the hemorrhage commencing after about thirty-six hours.

Gelatine, moderately thin solution in water in teaspoonful doses was fed freely to the baby, who took it readily. Dialized iron and Fl. Ex. Ergot in drop doses were given every hour alternately.

After a few doses of gelatine the hemorrhage from the bowel, which had been alarming, began to abate while the vomiting stopped entirely after the first dose. The characteristic pallor became marked, prostration and emaciation were extreme, so that death seemed imminent, but the treatment was kept up faithfully and the child lived.

CASE III. G. B., brother of Case I, was born June 19, 1902, in same house and room. Normal delivery.

A few hours after birth, with the idea of possibly forestalling trouble, gelatine was given in teaspoonful doses about once in three hours. Baby took it well. After about forty-eight hours there was a bloody movement, followed shortly by another. Gelatine was increased. Baby had in all but three movements of blood, did not vomit bloody matter nor show any appreciable effect from the hemorrhage. Gained and developed as a normal baby. Dr. C. W. Townsend saw the case in consultation.

All three children were well developed and nourished when born. Family history was negative. There was no sepsis in any of the cases, no bleeding from cords or evidence of hemorrhage other than as stated.

Three cases are hardly enough to build theories upon; but perhaps the circumstance of three cases of a rather rare disease, occurring in one practice, in one neighborhood, all within fifteen months, may add weight to the theory already advanced that hemorrhagic disease of the newborn is of an acute infectious nature. Gelatine in these cases seemed to act almost as a specific. It was readily taken, well borne and certainly merits a trial.

Medical Progress.

THE PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., AND HAYWARD W. CUSHING, M.D.

(Continued from No. 20, p. 543.)

ON THE OCCURRENCE AND SIGNIFICANCE OF CUTANEOUS HYPERALGESIA IN APPENDICITIS.

VERY little attention seems to have been paid by surgeons to the subject of cutaneous tenderness in appendicitis, and in the more recent textbooks of surgery and monographs on appendicitis no mention is made of it. In order to discover the frequency with which this sign is present in appendicitis and to test the teaching that it disappears on perforation of the appendix, Mr. Sherren [15] undertook this research, hoping to find an additional guide to operation in appendicitis. For this purpose, during the time that he was surgical registrar at the London Hospital, he examined all the cases of appendicitis that were admitted to the hospital, as far as circumstances would permit. He based his observations entirely upon cases in which the notes were taken by himself and in which the diagnosis of appendicitis was confirmed by operation at which he was present. He has also included those cases of appendicitis operated on by himself since that time, as assistant surgeon to the hospital.

Two varieties of tenderness are met with in appendicitis — the superficial, or cutaneous hyperalgesia, and the deep. The laws which govern the appearance and distribution of deep tenderness in connection with affections of the peritoneum have been worked out by Head. Sherren's observations confirm the statements of Head in every particular with regard to the appearance of this form of tenderness as a consequence of diseases of the appendix. He confines his attention to the conditions associated with the appearance of cutaneous hyperalgesia. Cutaneous hyperalgesia is tested by gently pinching or stroking the skin, beginning, if possible, in an area which is not tender and working towards the suspected tender area and so marking out its boundaries. Care is necessary, in order to avoid bringing out any deep tenderness which may be present. The skin only must be stimulated and all pressure on deeper structures avoided. In appendicitis, cutaneous hyperalgesia varies from a complete band extending on the right side from the middle line below the umbilicus in front to the lumbar spines behind, down to a small circular spot a little above the middle point between the umbilicus and the anterior superior spine. This band corresponds to the eleventh dorsal area of Head. Very often the tenderness extends somewhat into the tenth dorsal area also and occasionally, but not often, into the twelfth dorsal area, sending a tongue-shaped process over the gluteal region. The width of the band is in an adult about three inches.

This wide area, however, is not the one that is most often present. The usual area is on the right side of the abdomen and of a triangular shape. So often is this triangular area present that Sherren is in the habit of describing it in his notes as the "appendix triangle" of cutaneous tenderness. This triangle is situated in the right iliac region. Its lower boundary reaches almost to Poupart's ligament, its inner almost to the middle line, and its apex is a little outside the anterior superior spine, sometimes extending to the mid-axillary line.

He fortunately has been able to watch cases in which the hyperalgesia diminished from the complete band to the small circular area and many cases in which the "appendix triangle" gradually disappeared, leaving the small circular spot. He never examined a case of cutaneous hyperalgesia in appendicitis in which the posterior area alone was present. Cutaneous tenderness in appendicitis is occasionally bilateral.

[15] London Lancet, Sept. 19, 1903, p. 816.

Mr. Sherren has had the opportunity of seeing two such cases, in both of which the hyperalgesia was most marked on the right side.

He has never yet seen a case in which the hyperalgesia was present on the left side alone. This hyperalgesia is probably present in the majority of cases of first attacks of appendicitis, but in the gangrenous type of the disease no such tenderness can be discovered when the patient comes under observation, and it is probable that this form of the disease does not lead to the conditions which can produce reflected pain and superficial tenderness. If a patient is progressing favorably the hyperalgesia clears as the other symptoms of the disease improve, rarely persisting in the first attack after the sixth or seventh day. In subsequent attacks, however, where a stricture has been produced as the result of the first attack, it may persist much longer and remain after all the other symptoms of the disease have disappeared.

This hyperalgesia accompanies the reflected pain due to the changes in the appendix in exactly the same way as the reflected pain produced by the diseases of the stomach or other parts of the intestinal tract may be associated with superficial tenderness. It may, however, persist after all pain has ceased, especially where the appendix has been inflamed previously. Like all visceral hyperalgesia it is caused by the close association between the nerves which conduct impulses from the appendix and those which conduct similar impulses from the skin to the same segments of the central nervous system. When the otherwise painless stimuli from the skin reach those segments of the central nervous system which are directly connected with the appendix the skin appears to be tender. If a peripheral nerve be inflamed the skin within its distribution may become tender. But the cutaneous tenderness seen in appendicitis is not due to inflammation of the nerve trunks as is sometimes seen in cases of pleurisy (Head). For it may occupy the territory of the posterior primary division as well as that of the anterior division of the nerve, and it is inconceivable that the former division could ever be directly affected in appendicitis, and it appears early in the disease while the inflammation is still limited to the appendix. The reason for the anterior area remaining longer than the posterior and often being the only one present seems to be anatomical and to depend on the comparatively greater importance of the anterior primary division of the dorsal nerves.

Cutaneous tenderness does not vary with the positon of the appendix and is the same whether the appendix is in its normal position, pointing into the pelvis, on the outer side of the cecum or curled up behind it. Mr. Sherren has seen it typically present in a case of appendicitis where the cecum was undescended. Here, although the cecum was in close relationship to the liver, the superficial tenderness occupied the usual band in the eleventh dorsal area. The stimulus necessary to call forth this reflected pain and cutaneous hyperalgesia seems to be that of tension and not of irritation of the nerve endings in the appendix by the inflammation. Head has already shown this to be true for other hollow viscera, particularly the heart. That the stimulus is one of tension is seen by the fact that with perforation or gangrene of the appendix the superficial tenderness completely disappears, even although the perforation be small and the remainder of the appendix not gangrenous. This could not be explained on the supposition that the stimulus is one of irritation, the result of inflammation.

It is anatomically possible for other portions of the lower intestinal tract to cause cutaneous hyperalgesia in a similar situation to that caused by the appendix and Head has recorded such cases. Sherren has examined all the cases of abdominal disease which have come under his notice in the surgical wards of the London Hospital and has never met with cutaneous hyperalgesia in other diseases of the intestinal tract from the duodenum downwards.

The cutaneous hyperalgesia met with in renal colic might be mistaken for that seen in appendicitis, but as a rule it is higher, is more widespread, and tends to pass down into the first lumbar area, and where an anterior area only is left it is over the margin of the bony thorax about the situation of the tenth and eleventh ribs. The areas met with occasionally in gallstones and gastric ulcer are too high to be mistaken for that of appendicitis, and in gastric ulcer is often present only on the left side. Inflammation of the uterine appendages may give rise to cutaneous hyperalgesia but its occurrence is rare and it is, as a rule, bilateral.

It is well known that pleurisy at the base may cause pain over the abdomen. Head states that "if a pleurisy is acute the intercostal trunks may become implicated in the inflammation and pain appear over their terminal distribution, exactly as pain appears in the little finger when the ulnar nerve is injured. Thus an acute pleurisy may cause pain over the abdomen or even the iliac fossa of the same side. This is not a visceral reflected pain, for it is only present over that portion of the nerve trunk distal to the inflammatory lesion and is not present over the back. It may occasionally be accompanied by superficial tenderness. But unlike the superficial tenderness that is associated with true visceral reflected pain the tenderness that may accompany a pleurisy is only present in front of (on the distal side of) the patch of pleural inflammation." But, in Sherren's experience, the pain of pleurisy referred to the right iliac fossa is rarely associated with superficial tenderness that could be mistaken for that of appendicitis. Barnard has recently drawn attention to the simulation of appendicitis by "pleuro-pneumonic disease."

As an aid in determining operation the disappearance of hyperalgesia is of the utmost importance. If well-marked superficial tenderness disappears without coincident amelioration of the general condition of the patient it is a sign of

perforation or gangrene of the appendix. Unfortunately, a large number of cases of appendicitis which come under the care of the surgeon are not seen when hyperalgesia is present. But the absence of hyperalgesia is as important an indication of operation as its disappearance. In cases such as these coming under observation usually about the third or fourth day, with the signs of appendicitis well marked, Mr. Sherren considers absence of hyperalgesia the determining factor in operation. In over twenty cases of early appendicitis without superficial tenderness on which he has operated, he has found perforation or gangrene in the appendix without exception.

Conclusions. — 1. Cutaneous hyperalgesia is probably present at some time during all first attacks of appendicitis, except perhaps in the fulminating type, and depends upon tension within the appendix. 2. It may be absent in attacks after the first, if the first attack was of sufficient severity to destroy nerve tissue in the wall of the appendix. 3. When present in attacks subsequent to the first it often persists long after all other signs of the disease have gone, owing to the tension within the appendix being kept up by the presence of a stricture. 4. It gradually disappears during convalescence as the other signs of the disease clear up. 5. Disappearance of cutaneous hyperalgesia without improvement in the general condition of the patient is a sign of perforation or gangrene of the appendix and should be a signal for immediate operation. 6. The presence of cutaneous hyperalgesia is no contra-indication to operation. Abscesses may form and general peritonitis may develop while it is present. 7. Its absence, on the other hand, is of great importance. Absence of cutaneous hyperalgesia, the patient coming under observation early in the first attack of appendicitis, is a sign of gangrene of the appendix unless the case is obviously a mild one and the patient is rapidly getting well. 8. Cutaneous hyperalgesia is, as a rule, absent in cases of abscess of the appendix. 9. The age of the appendix and the position of the appendix have no influence upon the cutaneous hyperalgesia. 10. It is occasionally of use as an aid to the diagnosis of appendicitis.

THE BEST METHOD OF DEALING WITH THE STUMP IN APPENDECTOMY.

Dr. Lilienthal[16] in an article on this subject emphasizes the following points: — He speaks in favor of treatment of the stump by ligation and cauterization. He claims from examination of specimens of appendices treated by ligature and from the results of his observations clinically, that the ligature cuts through the mucous membrane and destroys it at the point of constriction. In each case the submucous fibrous coat and the peritoneum were uncut and held firmly. In regard to cauterization, he recommends the application to the mucous lining of the stump of 95% carbolic acid, applied with the tip of a closed artery clamp. According to his observations the stump so ligated was found to be cast off with its ligature and only a smooth cicatrix on the surface of the cecum remained. He also notes that he has never found an adhesion in this location, no matter how numerous they were in other parts of the abdomen. He claims that the stump formed by ligation, as described, is cast off completely in six days and with it any temporary adhesion that may have formed disappears. He recommends this method after a satisfactory test of ten years' use in many hundred cases.

COLOPEXY IN TREATMENT OF RECTAL PROLAPSE.

The resection operation in extreme cases of rectal prolapse is not without danger, is followed at times by stricture formation at the suture line, and does not always produce a permanent cure. Colopexy is regarded as an operation far less dangerous and yielding good results. J. Roller, who has written an interesting article on this subject,[17] mentions the Eiselsberg operation which consists of suturing the sigmoid by its lower end to the parietal peritoneum through an incision in the left hypogastrium. But he has noticed that the adhesions thus formed were not very firm while the scar between the peritoneum and the surface uncovered by it showed unusual firmness. Taking this fact into consideration Roller has operated in two cases where he has sutured intentionally the sigmoid to the abdominal wall which was denuded of peritoneum. For the details of technique of these cases (in one of which an anastomosis between the colon and the pelvic portion of the sigmoid in addition to the parietal fixation was made) the reader is referred to the original article. The results were satisfactory in both cases.

THE TREATMENT OF ACUTE PERFORATION — PERITONITIS.

The treatment of acute peritonitis resulting from perforation due to typhoid ulceration and necrosis by laparotomy and the formation of an artificial anus has been discussed by Escher.[18] He reports three recoveries in four cases. The patients' ages ranged from eight to nineteen years. The operation was done in the end of the third or the beginning of the fourth week. The favorable results are attributed to the omission of the primary suture of the intestine, which shortens the operation, and the formation of a fecal fistula, which overcomes the obstruction to fecal circulation in the intestine. He considers that the suturing at the site of the perforation not only prolongs the operation and thus increases the risk to the patient but also favors the further development of the intestinal pariesis. It is only under special favorable circumstances completed. On the other hand the fixing to the abdominal wall of the diseased intestine by the above recommended operation and the packing off of the peritoneum with gauze tampons is the surest protection against danger from subsequent

[17] Deutsche Med. Wochenschr., 1903, no. 32.
[18] Mittheilungen a. d. Grenzgeb. der Med. und Chir., Bd. xi.

perforations. The healing of the intestinal ulcers is also favored by the temporary removal of the fecal contents of the intestine.

RECOVERY FROM TUBERCULOUS PERITONITIS.

H. W. Freund has described in a recent article [19] different stages in the healing process in cases of tuberculous serous, ulcerative, suppurative and adhesive peritonitis and illustrates each type by quoting cases. All of these three varieties he considers amenable to operative treatment. This relieves the abdomen of the presence of the effusion with or without its pathogenic germs and the intervention is followed by proliferation of connective tissue which destroys or encapsulates the morbid products. Mild cases may be treated conservatively but severe ones require surgical aid. In a series of fifteen cases he tries to emphasize the beneficial results obtained. In some the cure has persisted for years. Concomitant tuberculous lesions in pleura or lungs have healed with the healing peritoneum. Experiences of many surgeons to date show that 65% of these cases have been cured by operative treatment and 25% permanently for years to date.

RECURRENT RETROPERITONEAL LIPOMA.

Heinricius [20] reports two cases of this unusual neoplasm in which the disease recurred. The site of recurrence was at the site of the original tumor. The point of origin of such lipomata is in the depth of the retroperitoneal fat. The portion of the intestine with which they are found in contact is the ascending colon or the sigmoid flexure. In a majority of cases the tumor appears to have developed behind the cecum, or ascending colon, and pushes it forward before it or to the left side. In 1900 Heinricius collected (and described) thirty-five cases of the class of growth.

FIRST SUCCESSFUL LIGATION OF THE HEPATIC ARTERY FOR ANEURISM.

The result indicated by the above title is reported by Kehr.[21] After removing a distended gall bladder the hepatic artery, portal vein and common duct were isolated. Then after ligating the artery in two places and dividing it between the ligatures the sac was opened and emptied. This operation is reported to have been followed by an uneventful recovery. The difference between this satisfactory result and the results obtained by animal experimentation is thought to be due to the fact that in pathological cases the gradual progress of the disease gives an opportunity for the collateral circulation to be sufficiently established to permit the ligation of the main vessel.

THE RESULT OF LIGATION OF THE FEMORAL VEIN BELOW POUPART'S LIGAMENT.

Halberstædter [22] calls attention to the fact that while in some cases of ligation of the femoral vein close below Poupart's ligament this operation is not followed by any especial disturbance in others it causes severe disturbance of circulation, even of gangrene. In 54 cases collected by him of ligation of the vein gangrene occurred twice. When the artery and vein were ligated simultaneously gangrene was observed in 14 out of 24 cases.

Finally while removing a tumor, after being compelled to resect a portion of the femoral vein and seeing septic gangrene of the extremity follow, Halberstædter attempted by experimentation to ascertain the reason why the femoral ligation was followed by so different results in different cases. He found [23] that the restoration of the circulation depended on the amount of blood pressure, the function of the valves, and finally on the extent of previous ligation of veins in separate tracts.

In consequence of such investigation Halberstædter concludes that in cases where the femoral vein is injured the method of controlling the hemorrhage should be selected which preserves the lumen of the vessel, indeed lateral closure, and best by venous suture. When operating for the removal of tumors the femoral vein is enveloped in a neoplasm, Halberstædter advises to save as much as possible of the vein trunk and especially of its lateral branches. The surgeon must under all circumstances make every effort to save the femoral artery. The most careful antisepsis must be observed and all hemorrhage entirely controlled in order to avoid extravasation into the cellular tissue. When the artery is saved and the blood pressure good the limb should be elevated after the operation. Under conditions of lowered pressure or simultaneous ligation of the artery the elevation of the limb is contra-indicated.

LIGATION OF THE FEMORAL VEIN AT POUPART'S LIGAMENT.

Contrary to the purely anatomical investigations of Braune, both the injection experiments of Braun as well as fifty-three actual successful clinical results of the ligation of the vein in man (Dr. Franz's [Berlin] case being included in this list) have demonstrated that the ligation of the femoral vein at Poupart's ligament is possible without danger to the life of the extremity involved.[24]

This knowledge of this freedom from danger after ligation is of especial importance to military surgeons. The work of Halberstædter gives one indeed the impression that one should almost always avoid using a ligature and should substitute the vein suture. This is indeed possible in many cases but not when the vein wall is stiffened or changed by inflammatory processes. The suture holds surely only when the vein wall is elastic and normal. When these conditions do not obtain the surgeon must choose between a lateral clamp or ligation. A lateral ligature is possible only with an elastic vein wall. Now, if in the regulated conditions of a hospital the

lateral compression has the disadvantage that one does not know when to remove the clamp without danger of secondary hemorrhage, how much more difficult would it be for the surgeon in the field where the vessel is clamped to-day and five to seven days later the patient is transferred to another hospital where the surgeon there has not to check hemorrhage temporarily but to treat the case to the end. It is gratifying to learn, says Dr. Frank, that (if experience does not refute the above statement) the femoral vein can be ligated at Poupart's ligament without dangerous conditions resulting from the procedure.

(To be continued.)

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOM STORER, M D., BOSTON, SECRETARY.

MEETING of January 19, 1904, Dr. G. H. Washburn, in the chair.

DR. F. A. HIGGINS reported "Three Cases of Extra-uterine Pregnancy treated by Vaginal Section."[1]

DR. F. H. DAVENPORT: I think the lesson to be learned from these cases is that in the majority of cases the abdominal route is the safer. I have been noticing lately that there is a reaction in France and Germany against the vaginal route. In Boston we have never been especially enthusiastic about that route, and it is pleasant to see that in the countries where it has been most in favor the tide is apparently swinging the other way. In these cases the difficulty of diagnosis between pus and extra-uterine pregnancy is very great, yet it is of the highest importance.

DR. F. S. NEWELL: I have operated upon only one case of extra-uterine pregnancy by the vaginal route and then I thought I was going to find pus. The patient had been in the hospital six months previously with a pus tube. During the operation a severe hemorrhage occurred which it was thought was controlled by packing. The patient was watched for an hour, and as then no improvement was apparent I opened the abdomen to find that the packing only partially controlled the bleeding. The patient made a good recovery but I was impressed with the difficulty of being certain that by packing we are really stopping a hemorrhage.

DR. CHARLES M. GREEN: I should agree that the abdominal route is the safer, and should attack from below only when I thought pus was present. I have only once operated from below and then I thought pus was present. If there is any question as to the nature of the mass, preparations should be made to open the abdomen if necessary. The difficulty in diagnosis between extra-uterine pregnancy and inflammatory masses is all the greater because the two are often associated.

DR. EDWARD REYNOLDS: I too have only once attacked an extra-uterine pregnancy from below and then it was thinking that pus was present. The symptoms were strongly pointing to pus. On turning out an old clot from the broad ligament an alarming hemorrhage began which was finally controlled by packing. This packing was removed twenty-four hours later through a misunderstanding of orders, and another severe hemorrhage began which was very difficult to control.

DR. J. B. SWIFT: I see that Dr. J. R. Goffe in advocating the vaginal route says that it is not necessary to get all the blood clots out of the peritoneal cavity as it can safely take care of a certain amount of blood. I am interested in these cases as I have now under my care a case where an extra-uterine pregnancy was left alone with recovery. The patient first came to the hospital in December with no evidence of trouble but moderate pain in the side. She stayed only a few days. Later in the month she returned with a history of flowing and now a mass was to be felt. This was thought to be a fibroid and the abdomen opened. The pelvic cavity was found to be entirely walled off by adherent intestines and the diagnosis was changed to pelvic abscess. The abdominal wound was closed and the mass attacked from below. A cavity was opened full of blood clot into which a tube was inserted and the patient finally went home recovered. The tube had undoubtedly ruptured into the broad ligament. I feel myself that the abdominal is the safer route.

Recent Literature.

The Practice of Obstetrics. Designed for the Use of Students and Practitioners of Medicine. By J. CLIFTON EDGAR, Professor of Obstetrics and Clinical Midwifery in the Cornell University Medical College; Attending Obstetrician to the New York Maternity Hospital. Octavo, with 1221 illustrations, many being in colors. 1111 pages. Philadelphia: P. Blakiston's Son & Co. 1903.

This book by Dr. Edgar is the most elaborate and comprehensive work on obstetrics from a single author, which has come to us for review. It is so comprehensive in its size, scope and material, as to make it a most valuable volume for extended reading and for a book of reference for the library, but at the same time it is questionable if the work is as well fitted for the average undergraduate medical student as a more concisely written textbook. This criticism, however, in no way detracts from the great merit and value of the book, which has no doubt required years of labor on the part of the author in its preparation.

In place of the usual chapters the volume is divided into ten parts, each of which is suitably subdivided into sections. Each part has its own table of contents, but these would be improved if the page references were given in connection with them. The author has adopted for part headings the names, Physiological Pregnancy, Physiological Labor, and Physiological Puerperium, instead of using the terms Physiology of Pregnancy, Physiology of Labor, etc. This is an improvement, we believe, over the old terms. The arrangement of the subject matter in the book does not at all times tend to increase the ease of reference or the conciseness of the volume, but otherwise than this the general plan of the book is excellent. For example, the usual section on the anatomy of pregnancy is omitted,

but the same material is introduced in appropriate places under the physiology of pregnancy and of labor. An instance where a subject seems to be apparently misplaced is that of the treatment of placenta previa which is taken up in the early part of the book in the chapter on the Anomalies and Diseases of the Placenta, bringing it even before the treatment of normal labor.

The author's asepsis is thoroughly modern, and the details of his practice are carefully explained. He strongly urges the use of rubber gloves as a routine measure. He accepts the belief that the vagina does not contain pyogenic cocci under normal conditions, and that autoinfection is impossible. He asserts that the physician in a majority of cases is the responsible person, but that even with sterile gloves danger of infection still remains. The importance of the shower over the tub bath in preparing the patient for labor is well emphasized from the danger of the soiled and infected water entering the vagina, a point which has recently been brought to the front by foreign writers.

Several pages are devoted to the subject of cephalometry, and although the proceeding has not gained much standing otherwise than in the hands of a few French writers, yet Edgar says the results go to show that the method is of undoubted value in determining the relative size of the fetal head and maternal pelvis and the choice of time for the interruption of pregnancy.

In his treatment the author is thoroughly modern and yet conservative. He takes a broad view of the subject of pregnancy and tuberculosis, and while he says that future generations must decide on the propriety of the interruption of pregnancy in tuberculous subjects as a routine measure, yet the obstetric treatment has now come to be regarded, theoretically at least, as the proper course; it still meets, however, with considerable opposition from conservative sources.

In the discussion on the determination of sex, there is considerable space allotted to the theories of Schenk, more we think than is necessary or warranted by Schenk's methods or results which are now pretty generally discredited.

The author rejects the time honored theory that flexion of the fetal head begins with labor, and says that he believes that flexion is complete or nearly so before the onset of labor, a position which we believe will ultimately be found to be correct.

Another example, showing perhaps the author's over-enthusiasm on the subject, is the devotion of ten complete pages of illustrations to various monstrosities and deformities, many of which have no bearing whatsoever on the subject of obstetrics.

Obstetrics is a subject which well repays good illustrating, and the book is very thoroughly provided for in this respect, and the majority of the illustrations are above criticism. Some might as well be omitted, as Fig. 195 which shows two tin cans of chloride of lime and sodium carbonate, also certain obsolete and discarded forms of instruments and methods. If only the better ones are shown and illustrated in modern books, the older and poorer ones will eventually disappear. This must necessarily of itself tend to improve obstetric practice, and obstetric books as well. This book is, however, a splendid one as it is, and worthy of very high commendation, but in our opinion would be improved by considerable elimination, and by a rearrangement of its matter.

The Treatment of Neurasthenia. By A. Proust and Gilbert Ballet. Translated by Peter Campbell Smith, L.R.C.P., L.R.C.S., Edinburgh. 12mo. pp. xiv, 213. New York: Edward R. Pelton. 1903.

This little volume is really a treatise upon the whole subject of neurasthenia, nearly half of it being devoted to a discussion of the nature, causes and symptoms of the disorder. It is written, of course, from the French point of view, and some of the statements seem strange to the American physician, namely, that neurasthenia is commoner among men and very rare in the laboring class. The book is very suggestive, and the discussion of the various forms of treatment, dietetic, psychical, hydrotherapeutic and the like, is sound and full. The translation is satisfactory, but the proofreading is defective. The intelligent compositor had perhaps a method in his madness when he substituted "painist" for pianist.

Roger on Infectious Diseases. Their Etiology, Diagnosis and Treatment. By G. H. Roger, Professor Extraordinary in the Faculty of Medicine of Paris, etc. Translated by M. S. Gabriel, M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co.

This volume of 874 pages, Dr. Roger's work on Infectious Diseases, is translated into English by Dr. M. S. Gabriel. The book occupies a somewhat unique position among medical publications in that it combines in rather unusual degree the results of laboratory investigation with a wide and well digested clinical experience. This double function, so often missed in the modern textbook, Dr. Roger is peculiarly capable of undertaking, since his work has led him not only into the study of cases at the bedside, but also into the fundamental problems underlying the causation of disease. With this equipment he has produced a book certainly of much value, and one which in reality covers a far wider field than its title would indicate. The practical study of the subject is also given due weight in the final chapters devoted to a consideration of the therapeutics of infectious disease.

The book is excellently printed, liberally supplied with large type as an aid to the reader, rather sparingly illustrated as books now go, and with relatively few references to original sources, although the names of investigators are freely used throughout the text. We cordially recommend the book to those desiring to base their information upon broad and solid foundations.

The Practical Medicine Series of Year Books. Issued monthly under the general editorial charge of GUSTAVUS P. HEAD, M.D. Vol. IX. Physiology, Pathology, Bacteriology, Anatomy. Edited by W. A. EVANS, M.D., ADOLPHUS GEHRMANN, M.D., and WILLIAM HEALY. August, 1903. Chicago: The Year Book Publishers. 1903.

Though this series is intended primarily for the general practitioner, this small volume is of value also to the specialist. The editors have been very successful in offering reviews which are not only readable but far more accurate than the average.

The section devoted to physiology in its seventeen well chosen reviews hardly covers the extensive recent literature on this subject. In the 100 pages on pathology are given the newer methods of technique and laboratory diagnosis, as cyto-diagnosis, cryoscopy, and improvements in blood examination. The questions of paratyphoid fever and certain parasitic diseases are well discussed. The few pages devoted to hygiene and anatomy emphasize the recent advances in these lines. The glossary of newer medical terms is fairly complete and forms a valuable feature. That the volume is well up to date is evident from the fact that there are many reviews of papers published the month in which the book was brought out.

The Elements of Pathological Anatomy and Histology for Students. By WALTER SYDNEY LAZARUS-BARLOW, B.A., B.C., M.D., F.R.C.P. Philadelphia: P. Blakiston's Son & Co. 1903.

This book deals both with general and special pathological anatomy. All physiological considerations have been excluded, and the present treatise forms a complementary volume to the author's well known manual of general pathology. The two books together cover the entire field of pathological anatomy and pathological physiology.

The author believes, and rightly we think, that it is better to present to the elementary student clearly and fully the fundamental pathological alterations than to burden and confuse his mind with the names and definitions of relatively unimportant subvarieties. Special attention is given to those pathological conditions that are of greatest interest and importance to the clinician, and the book may be recommended to the practicing physician and clinical student because the subject is presented from their point rather than that of the laboratory worker.

The subject of retrograde change is first considered. This is followed by excellent chapters on inflammation and its sequels. One of the best sections is that devoted to tumors. The etiology of neoplasms is well discussed. The author regards the parasitic theory of cancer-formation as resting upon a very slender foundation. About two thirds of the volume are devoted to the pathological anatomy of the various organs and tissues. The author evidently has a first hand knowledge of the subject and these pages contain original observations of value, but it is a pity he has not inserted the results of important pathological studies made during recent years by European and American pathologists. For example, in discussing the relation of diabetes to lesions of the pancreas there is no mention of the Islands of Langerhans; and no reference is made to the characteristic proliferation of endothelial cells in the lymphatic apparatus of the intestine in typhoid fever which Mallory has shown to be the essential lesion.

The book is profusely illustrated with admirable drawings, all of which are original. The histological pictures represent faithfully the actual appearance of corresponding sections and will be an aid to all students of pathological histology who select this book as their guide.

Anesthesia in Dental Surgery. By THOMAS D. LUKE, M.B., F.R.C.S.E. New York: Rebman Company, 10 West 23d St. 1903.

The opportunity for witnessing the methods of using the different kinds of anesthetics and of studying their action must necessarily be limited up to the time the recently graduated dentist begins his practice. With the best of facilities and the best of instruction it is not possible to drill the average dental student so that awkwardness and apprehensiveness will not affect his early efforts in administering anesthetics.

This little book furnishes so much accurate information that it will serve in many cases in lieu of experience. The descriptions of the apparatus in use are clear and sufficient. The comparative values of the different agents are well drawn and the dangers are pointed out without prejudice and in such a way as to warn the practitioner without alarming him.

The book is essential to the young dentist, and the older man in the profession will find many suggestions that will enable him to improve his practice. The suggestions as to sterilization of mouthpieces when using nitrous-oxide are most timely.

S. A. H.

Lectures on Diseases of the Lungs and the Heart. By JAMES ALEXANDER LINDSAY, M.D., F.R.C.P., (Lond.) M.A., Professor of Medicine, Queen's College, Belfast, Physician to Royal Victoria Hospital, Belfast, etc. New York: William Wood & Co. 1904.

A pleasant, readable book, covering many points of diagnosis and treatment in an adequate manner. It has the disadvantages but, also, in large measure, the advantages of lectures put into book form; lacks the systematic, comprehensive presentation but carries a certain individual charm which, of course, finds its most ready recognition in the appreciation of those who have been students of the author. It offers no new facts, lays no special claim to originality, leaves out inevitably some points of diagnostic value, and very wisely neglects controversial issues. It is a book for general reading rather than for reference.

LABORATORIES OF PATHOLOGY AND PHARMACOLOGY AT THE UNIVERSITY OF PENNSYLVANIA.

The new laboratories of pathology, physiology and pharmacology at the University of Pennsylvania will be dedicated and opened for inspection on June 10. In connection with the opening of these very extensive and fully equipped laboratories it is of interest to call attention to the increasingly important place which laboratory teaching is taking in the modern medical curriculum. Even within the memory of men who are still young a great part of the teaching was done without the assistance afforded by laboratory methods, and it is sometimes hard to realize that the vast development of this type of instruction has come within the last two decades.

Tracing the methods of teaching in the University of Pennsylvania, which is the oldest medical institution in the country, we find that for upwards of one hundred years, from 1765 to 1868, the methods of instruction were relatively little changed in spite of the great accessions to medical knowledge during that time. Didactic lectures were the essential basis of the medical course, together with clinics at the Pennsylvania and Philadelphia Hospitals, which were at first optional and later obligatory. No systematic teaching was done at the bedside, and practical work in laboratories was unknown. A new method developed in 1868, exactly one hundred years after the graduation of the first class. The change consisted in certain lectures in pathology and in microscopy, together with practical demonstrations. In the years from 1868 to 1873 laboratories of chemistry, physiology, histology, pathological anatomy and pharmacology were established, and succeeding years saw their full equipment. This was a pioneer step on the part of the University of Pennsylvania. A further development of the laboratory method from the years 1877 to 1903 was inaugurated by the completion of the new medical department in West Philadelphia. It was then supposed that the facilities for teaching would be adequate for a period of fifty years. This, however, proved not to be the case, and the necessity for a new and much more extensive laboratory building has become apparent within the last few years, with a result that funds were obtained for the building of the new laboratories which are now completed and about to be put to practical use.

We have before commented on this building, and certain of its architectural features, and therefore we simply call attention to some of its main characteristics. It is two stories in height, and measures 340 feet front by 200 feet depth, the front exposure facing north for the purpose of securing the best light for microscopic work. Physiology and pharmacology occupy the first floor, and the second will be devoted exclusively to pathology and pathological bacteriology, with special provisions for surgical pathology, neuropathology and practical clinical pathology. A museum of pathology is arranged in close connection with the laboratory for purposes of teaching. Abundant private rooms for special research are provided, and in general, although prophecies in such matters have again and again proved fallacious, would seem to be adequate for any expansion which these subjects are likely to undergo in the future.

It is not to be expected that any definite reaction from the stress now laid upon laboratory teaching is likely to take place. At the same time it must be acknowledged that we are now seeing a phenomenal and possibly somewhat disproportionate devotion to what is popularly known as the theoretical side of medicine. There is danger that the sense of proportion may be lost in our enthusiasm for the type of research which such laboratories as this under consideration represent. At any rate, it behooves the great mass of medical men, whose interests may include but still lie beyond the laboratory, to see that facilities for practical instruction do not take a secondary place, and that the proper proportion be established and maintained between the all-important theoretical side of medicine

and its practical application. The simultaneous development of hospitals is an indication that this end is likely to be realized. We congratulate the University of Pennsylvania on this accession to its facilities for teaching, an accession which has a bearing on medicine far wider than the region which will be immediately benefited thereby.

DEVELOPMENT OF FREE PUBLIC BATHS.

AFTER a delay of one year, largely on account of the building trade strikes, the Milbank Memorial Free Public Baths were opened in New York with appropriate ceremonies on May 19. The building, which is on East 38th Street, is the gift of Mrs. Elizabeth Milbank Anderson. It was erected at a cost of $150,000, and will accommodate 4,800 bathers daily. This, together with the Rivington Street public baths and others established by various charitable societies, provides in New York, it is stated, facilities for every person in the city, not otherwise provided, to have a cleansing bath twice each week. The opening ceremony consisted in the formal presentation of the property by Mr. A. G. Milbank to the New York Association for Improving the Condition of the Poor, which has been entrusted with the management of the institution, and Mr. R. Fulton Cutting, as president of the association, accepted the gift. Dr. Darlington, president of the Board of Health, made a short address, and among the physicians present was Dr. Simon Baruch, who was the originator of the free "rain bath" in this country and to whose persistent efforts is due the present free bath system of New York City.

The history of Dr. Baruch's fight for free public rain or shower baths dates back to August, 1889, when through a Philadelphia medical journal he made the first plea of the kind. Shortly afterward he spent a year in Europe studying the systems of the public baths there, and he returned convinced that his original idea of the rain bath for public use was the best. The chief advantages of this form of bath are economy of space, water and care, without the danger of communicating disease through careless attendants. The temperature may be gradually reduced after the cleansing; it is more refreshing than a tub bath, and prevents danger from relaxation. "Tubs," says Dr. Baruch, "are not the proper thing for a free bath for the poor. If you have tubs you must employ a force to fill and empty them, and if they are to be kept in strictly sanitary condition they must be cleansed after each bather. With the rain bath, as fast as one person takes his scrub, another may step up." With several city administrations he labored persistently, but accomplished little. Then the New York Academy of Medicine gave formal approval of his method, while two or three charitable societies took it up and constructed public baths in accordance with his ideas. In 1895 a mandatory public bath bill was passed by the Legislature, but it was not until two years afterward that a committee was named to wait on Mayor Strong to urge the building of a public bath under the provisions of the law. The mayor gave his permission, and the same day steps were taken toward the building of the bath in Rivington Street. Last year 700,000 working people made use of this bath, and in the public schools 30,000 children used the rain baths which have recently been established in the schoolhouses through Dr. Baruch's efforts. On the occasion of the opening of the Milbank bath Dr. Baruch said: "Naturally enough, it is a matter of considerable satisfaction to me to be able to tell you that outside of New York there is no city in the world where anybody may go into a public bath, as he goes into a public park, and enjoy its privileges without cost. I think the realization of that fact alone is ample compensation for all the years of hard work it has cost, to say nothing of what has been achieved in other communities all over the world."

It is worthy of note that on the day following the opening of the Milbank bath, May 20, the Board of Estimate and Apportionment appropriated more than $1,000,000 for the construction of new public baths. Of this sum, $633,000 is for four baths in the Borough of Manhattan, $345,000 for three in Brooklyn, and a large sum for one in the Bronx.

BULLETINS OF THE OREGON STATE BOARD OF HEALTH.

WE are in receipt of four pamphlets from the Oregon State Board of Health, published as bulletins and concerning themselves respectively with Smallpox in Oregon, Hints upon School Hygiene, the Prevention of Typhoid Fever, and the Prevention and Cure of Consumption. Our object in calling attention to these publications is not only for the intrinsic interest which they have for professional men, but also to bring to notice the excellent missionary work which such

statements of fact are likely to accomplish, not only in the special community concerned but in the country at large. The campaign of education which has received renewed stimulus of late in connection with certain prevalent diseases, notably tuberculosis and typhoid fever, should certainly be extended, and there is no better means of accomplishing this end than through the publication by persons in authority of plain statements which may be read and appreciated by the laity.

Among many interesting statistics regarding the prevalence of smallpox in the state, and its relation to vaccination, the following incident is significant: In an epidemic of 29 cases there were 9 deaths, a mortality of over 30%. Of these 29 cases 12 were unvaccinated, 9 of whom died, a mortality of 75%. Of the vaccinated cases not one died, and none were at any time dangerously ill. In the pamphlet on school hygiene much good and sound advice is given upon many points relating to school life, all of which is calculated to be of interest to parents without unduly exciting them as to the dangers to be met with in schools. Suggestions on the prevention of typhoid fever and of consumption are similar to those with which we are now perfectly familiar. Their wide dissemination is certainly to be desired. If knowledge is power, and there is undoubted truth in the aphorism, there can be no question that, as the people come to know the nature of prevalent and fatal diseases, they will on the one hand take rational methods of precaution, and on the other not be unduly alarmed when such diseases appear.

AWARD OF THE WARREN TRIENNIAL PRIZE.

The Warren Triennial Prize of $500 in the gift of the Massachusetts General Hospital has just been awarded to Prof. Max Borst, Professor in the University of Wurzburg, Germany.

This prize was founded by the late Dr. J. Mason Warren in memory of his father, and his will provides that the accumulated interest of the fund shall be awarded every three years to the best dissertation, considered worthy of the premium, on some subject in physiology, surgery or pathological anatomy; the arbitrators being the physicians and surgeons of the Massachusetts General Hospital. The dissertations must be submitted anonymously.

The title of Professor Borst's dissertation is "Neue Experimente zur Frage nach der Regenerationsfahigkeit des Gehirns," in which the regeneration of medullated nerve fibers in the central nervous system after trauma is conclusively demonstrated.

Professor Borst is a pathologist of established reputation and is the author of an extensive work upon the pathology of tumors, recently published.

The number of dissertations submitted was larger than ever before. They came from widely distant parts of Europe as well as from America. The widespread interest thus shown in the prize, as well as the great merit of many of the dissertations, is gratifying.

MEDICAL NOTES.

Decennial of Discovery of Roentgen Rays. — The tenth anniversary of the discovery of the Roentgen rays is to be celebrated in Berlin in 1905. Professor von Bergmann will preside at the congress and exposition which it is proposed to hold.

Examination for Director of Pathological Laboratories, Bellevue Hospital. — It is announced that a civil service examination will be held June 7 for the position of director of pathological laboratories in Bellevue and allied hospital in New York. The salary of this position is $5,000 a year, and its incumbent is required to devote all his time to the work of the laboratory and is not permitted to hold a position in a medical school.

Manila Mortality Statistics.—The monthly report of the Board of Health for the Philippine Islands gives the following death statistics for January of this year:

Convulsions of children, 272; pulmonary tuberculosis, 78; eclampsia, nonpuerperal, 47; chronic bronchitis, 46; congenital debility, 40; acute bronchitis, 34; diarrhea and enteritis, 31; meningitis, 25; beri-beri, 25; dysentery, 18; malarial fevers, 13; endocarditis, acute, 12; pneumonia, 11; Bright's disease, 8; bubonic plague, 7; cerebral hemorrhage, 6; puerperal septicemia, 5; typhoid fever, 5; Asiatic cholera, 3; tetanus, 4; leprosy, 3.

Of the above mentioned causes and deaths the following occurred in infants prior to the completion of the first year of life: Convulsions of children, 272; eclampsia, nonpuerperal, 47; chronic bronchitis, 32; congenital debility, 40; acute bronchitis, 32; diarrhea and enteritis, 24; meningitis, 15; dysentery, 1; pneumonia, 1;

tetanus, 4. Of the 796 deaths occurring among inhabitants of the city, 475 or 59.6%, occurred in children less than twelve months of age.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, May 25, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 68, scarlatina 19, typhoid fever 5, measles 129, smallpox 0.

A CENTENARIAN. — Mary Canney, reputed to be about one hundred and one years old, died in Woburn, Mass., recently.

OPENING OF THE COREY HILL HOSPITAL. — The Corey Hill Hospital will be opened Wednesday, June 1, and guests will be received at the building from three until six o'clock. This is a private institution erected under the auspices of certain physicians in Boston.

SURGICAL OUT-PATIENT DEPARTMENTS, BOSTON CITY HOSPITAL. — New buildings for the surgical out-patient department and three new wards are opened to-day. The trustees of the hospital have sent out invitations for the ceremonies in the afternoon. To-day is also the fortieth anniversary of the dedication of the hospital.

MORTALITY RATE OF DIPHTHERIA. — In the annual report of the Board of Health of Worcester, Mass., the mortality statistics for diphtheria are given as 3.84 for 1903, as contrasted with upwards of 8 in 1897 and 1898. In general there has been a constant decrease in the number of deaths from this disease, with a record for 1903 which is nearly two points better than any preceding year of which the statistics are given.

EPIDEMIC OF CEREBRO-SPINAL MENINGITIS IN CONNECTICUT. — A recent bulletin of the Connecticut State Board of Health discusses the question of an epidemic of cerebro-spinal meningitis in that state. During the first three months of the present year but six cases were reported. In April the disease assumed an epidemic character and 43 cases were reported in Hartford alone, with 20 deaths. Since April 1 reports of its presence have been received from various towns, with a total of 76 cases.

NEW YORK.

PREVALENCE OF MENINGITIS. — Within the last three weeks there has been a very great increase in the number of cases of cerebro-spinal meningitis in the city, with a large number of deaths, said to have been one hundred and fifty, in a space of two weeks. Measures are being taken by the health department to check, if possible, the spread of the disease.

RECEPTION HOSPITAL FOR THE INSANE. — It is gratifying to learn that Governor Odell has approved the bill passed by the Legislature authorizing the City of New York to acquire a site and to lease it to the state for the establishment thereon of a reception hospital for the insane, and authorizing the State Commission in Lunacy to erect such a hospital. It was generally understood that the governor had decided to veto this bill, fearing that it carried with it an appropriation of $300,000. It is stated, however, that recently Dr. Samuel B. Ward of Albany labored with the governor for an hour, explaining the necessity of a detention psychopathic hospital in New York, and assuring him that the purport of the bill was simply to authorize the city to acquire a site.

BEQUEST TO MANHATTAN EYE AND EAR HOSPITAL. — At a meeting of the board of directors of the Manhattan Eye and Ear Hospital held May 17 it was announced that a gift of $40,000, pledged by Edward R. Thomas, had saved the institution the loss of $125,000 in donations conditionally promised for a new building. The $125,000 was not to be given unless a total of $165,000 could be raised. Last year the Thomas family gave $50,000 to the same hospital to endow a ward, to be known as the Samuel Thomas Memorial Ward, and this latest gift from Mr. Thomas is a personal memorial to his father, the late General Thomas. The Manhattan Eye and Ear Hospital is to be removed from its present location on Park Avenue, near the Grand Central Railroad Depot, and steps will immediately be taken to purchase a plot of land for the new building. The site selected is in East 59th Street, within a block of the projected laboratories of the Rockefeller Institute for Medical Research.

Obituary.

A TRIBUTE TO BENJAMIN H. HARTWELL, M.D.

BY THE MASSACHUSETTS MEDICO-LEGAL SOCIETY.

THE Massachusetts Medico-Legal Society, recognizing the deplorable loss which Forensic Medicine has suffered in this Commonwealth through the death of the late Benjamin H. Hartwell, M.D., of Ayer, one of the original members

and the fourth president of this Society, desires to record, in this permanent form, its tribute to Dr. Hartwell's character and its estimate of the rare traits which endeared him to his fellows.

We recall the stern conscientiousness which animated his conduct of life and was a controlling characteristic. We remember how amply he exemplified the statutory qualifications of "ability, discretion and learning" which led to his selection from among all his professional neighbors in the Fourth Middlesex District, fitting him to discharge acceptably the responsible functions of a medical examiner, and which from 1877 to his death retained him as a conspicuous exponent of the trustworthy servant of the Commonwealth. We remember with gratitude the earnest, cordial, dignified manner in which he lent himself to the promotion of every good cause. Loyalty to duty was to him a passion and an inspiration. Simple honesty, his mental frankness and intellectual humility, dominated him. Fidelity to his memory and what it represents is the truest evidence that he has not lived in vain.

Correspondence.

SANITARIUM viz. SANATORIUM.

ARLINGTON HEIGHTS, May 18.

MR. EDITOR: We are frequently asked, "What is the difference between Sanitarium and Sanatorium?" Gould's dictionary of medicine gives the following definitions: "*Sanitarium*, — A health station — a place or institution where the conditions are such as especially to promote health and vigor. The word is often incorrectly employed for Sanatorium, which is a hospital or place for curing those who are sick. A Sanitarium may be used for a Sanatorium, but it is not necessarily the same thing." Also, "*Sanatorium*, — An establishment for the treatment of the sick; especially a private hospital." In England and on the Continent, sanatorium is largely used to designate a hospital for the treatment of consumptive patients. And in this country the word has been seized upon for the same purpose, and is rapidly becoming associated in the public mind with "retreats" for cases of tuberculosis. So prevalent is this idea becoming that a large institution in New York State, which for half a century has been designated a Sanatorium, has found it advisable to drop the name and substitute the word, "Retreat."

This state of affairs is unfortunate, for while sanatorium rightly includes the treatment of consumptive cases, it by no means excludes other diseases.

The word "hospital" is so entirely associated with the idea of acute and surgical illness, with bedridden patients and red tape, that its use is rightly restricted to this kind of work. "Asylum" has come to be entirely given over to places caring for the insane; and in the minds of many, "retreat" conveys the similar idea when attached to a private institution. Various private places have endeavored to surmount this difficulty by substituting fancy names ending in "hurst" or "croft" or "hall"; none of these, however, convey any idea of the end sought. If, then, we relegate the word "Sanatorium" to the institution for consumptives, what are we to do for a word to convey the idea of an institution where, amid congenial, semi-homelike surroundings, the chronic sufferer — nervous, rheumatic, cardiac, dyspeptic, etc. — can secure that environment and scientific treatment which his case demands?

ARTHUR HALLAM RING.

RECORD OF MORTALITY

Deaths reported, 3,695; under five years of age, 982; principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 917; acute lung diseases 674, consumption 411, scarlet fever 51, whooping cough 8, cerebro-spinal meningitis 102, smallpox 8, erysipelas 13, puerperal fever 23, measles 59, typhoid fever 61, diarrheal diseases 102, diphtheria and croup 76, influenza 3.

From whooping-cough, New York 1, Philadelphia 3, Baltimore 1, Pittsburg 1, Boston 1, Springfield 1. From smallpox, Philadelphia 5, Baltimore 1, Pittsburg 2. From cerebro-spinal meningitis, New York 97, Philadelphia 1, Baltimore 1, Lynn 1, Somerville 1. From erysipelas, New York 4, Chicago 2, Philadelphia 2, Baltimore 1, Boston 1, Worcester 1, Lynn 1, Somerville 1. From typhoid fever, New York 10, Chicago 6, Philadelphia 25, Baltimore 3, Pittsburg 12, Providence 1, Boston 2, Lynn 1, Chelsea 1. In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending April 30, the death-rate was 16.3. Deaths reported 4,785; acute diseases of the respiratory organs (London) 100, whooping cough 213, diphtheria 49, measles 155, smallpox 8, scarlet fever 40.

The death-rate ranged from 7.5 in Reading to 25.9 in Wallasey; London 15.6, West Ham 15.2, Brighton 19.0, Southampton 13.4, Plymouth 21.0, Bristol 16.0, Birmingham 19.4, Leicester 12.1, Nottingham 15.7, Liverpool 21.8, Bolton 17.8, Manchester 20.9, Salford 18.2, Bradford 20.7, Leeds 17.0, Hull 17.0, Cardiff 13.3, Rhondda 16.6, Wigan 20.8, Marthyr Tydfil 12.9, Whillesden 8.3, Warrington, 20.9.

METEOROLOGICAL RECORD.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING MAY 21, 1904.

J. J. SNYDER, passed assistant surgeon. Detached from the "Kearsarge" and ordered to the "Maine."

W. H. BUCHER, surgeon. Detached from the Naval Station, Cavite, P. I., and ordered to the Naval Hospital, Yokokama, Japan.

E. THOMPSON, surgeon. Commissioned surgeon, with the rank of lieutenant commander, from March 3, 1903.

F. M. FURLONG, passed assistant surgeon. Detached from duty with the marine battalion on the "Dixie" and ordered home and to await orders.

C. ST. J. BUTLER, passed assistant surgeon. Commissioned a passed assistant surgeon with the rank of lieutenant, from October 26, 1903.

R. O. MARCOUR, assistant surgeon. Detached from duty with the marine battalion on the "Dixie" and ordered to the "Hancock."

P. S. ROSSITER, assistant surgeon. Detached from the naval recruiting station, Baltimore, Md., and ordered to the naval station, Honolulu, H. I., sailing from San Francisco, Cal., via steamer "Abarenda," June 4.

W. D. OWENS, assistant surgeon. Appointed assistant surgeon with rank of lieutenant, junior grade, from May 17, 1904.

F. E. SELLERS, acting assistant surgeon. Appointed acting assistant surgeon from May 17, 1904.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MAY 19, 1904.

CARTER, H. R., surgeon. To report at Washington, D. C., for special temporary duty. May 13, 1904.

WOODWARD, R. M., surgeon. Granted leave of absence for three months from June 14. May 13, 1904.

EAGER, J. M., passed assistant surgeon. Reassigned to duty at the port of Naples, Italy, effective March 25, 1904. May 14, 1904.

FRANCIS, EDWARD, assistant surgeon. To proceed to Martinsburg, W. Va., for special temporary duty. May 11, 1904.

BURKHALTER, J. T., assistant surgeon. Ten days' extension of leave of absence, granted by bureau telegram of May 9, 1904, revoked. May 17, 1904.

ALEXANDER, E., acting assistant surgeon. Granted leave of absence for seven days from May 19. May 17, 1904.

KENNARD, K. S., acting assistant surgeon. Granted leave of absence for fourteen days from May 22. May 17, 1904.

WALKER, R. T., acting assistant surgeon. Granted leave of absence for four days from May 31. May 19, 1904.

WALKLEY, W. S., acting assistant surgeon. Granted leave of absence for nine days from May 24. May 19, 1904.

RODMAN, J. C., acting assistant surgeon. Granted leave of absence for four days from May 24. May 18, 1904.

CARLTON, C. G., pharmacist. Granted leave of absence for thirty days from June 1. May 12, 1904.

BIERMAN, C. H., pharmacist. Granted leave of absence on account of sickness, for one day (May 9). May 13, 1904.

VAN NESS, G. I., Jr., pharmacist. Granted leave of absence for thirty days from June 1. May 17, 1904.

BOARDS CONVENED.

Board convened to meet at Baltimore, Md., May 18, 1904, for the physical examination of cadets in the Revenue Cutter Service. Detail for the Board: Surgeon H. R. Carter, chairman; Assistant Surgeon C. W. Wille, recorder.

Board convened to meet at Stapleton, N. Y., May 18, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon Preston H. Bailhache, chairman; Passed Assistant Surgeon A. C. Smith, recorder.

Board convened to meet at Washington, D. C., May 18, 1904, for the physical examination of applicants for appointment in the Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus, recorder.

RECENT DEATHS.

CHARLES WARREN WHITE, M.D., M.M.S.S., died in Fairhaven, May 15, 1904, aged forty-four years.

THOMAS J. FITZMAURICE, M.D., of Paterson, N. J., died on May 20, from cancer of the liver. He was thirty-five years of age, and was graduated from Bellevue Hospital Medical College, New York, in 1891. At the time of his death he was a member of the Paterson board of aldermen.

SOCIETY NOTICES.

AMERICAN DERMATOLOGICAL ASSOCIATION. — The twenty-eighth annual meeting of the American Dermatological Association will be held at Niagara Falls, June 2 and 3, at the International Hotel.

CHARLES J. WHITE, M.D., Secretary.

ASSOCIATION FOR THE STUDY AND CONTROL OF TUBERCULOSIS. — A meeting will take place in Atlantic City on Monday evening, June 6, at 8 o'clock, in the Public School Building, for the organization of the National Association for the Study and Prevention of Tuberculosis. A Constitution and By-Laws will be submitted by the committee in charge.

BOOKS AND PAMPHLETS RECEIVED.

Fifth Annual Report of the State Board of Insanity of the Commonwealth of Massachusetts for the year ending September 30, 1903.

The Hayfield Mower and Scythe of Progress. By the Mower-Man. Vol. I, Nos. 1 to 26. Boston: The Hayfield Mower, 1904.

The Mothers' Manual. A Month by Month Guide for Young Mothers. By Emelyn Lincoln Coolidge, M.D. Illustrated. New York: A. S. Barnes & Company, 1904.

Adolescence. Its Psychology and its Relations to Physiology, Anthropology, Sociology, Sex, Crime, Religion and Education. By G. Stanley Hall, Ph.D., LL.D. Vols. I and II. Illustrated. New York: D. Appleton & Co., 1904.

The Closure of Laparotomy Wounds as practised in Germany and Austria. Including Detailed Methods and Views communicated by over Fifty Leading Surgeons. Edited and translated by Walter H. Swaffield, F.R.C.S. Ed., M.D. Ed. Philadelphia: P. Blakiston's Son & Co., 1904.

A System of Practical Surgery. By Prof. E. von Bergmann, M.D., Prof. P. von Bruns, M.D., and Prof. J. von Mikulicz, M.D. Vol. II. Translated and edited by William T. Bull, M.D., and Carlton P. Flint, M.D. Illustrated. New York and Philadelphia: Lea Brothers & Co., 1904.

Original Articles.

A STUDY OF CERTAIN CASES OF SARCOMA OF THE LONG BONES FROM THE MASSACHUSETTS GENERAL HOSPITAL CLINIC.

BY CHARLES L. SCUDDER, M.D., BOSTON,
Surgeon to the Massachusetts General Hospital.

The final results in this series of cases under the care of certain members of the surgical staff represent all those patients who could be traced or whose records were complete after several years. Most of these cases came to the hospital after having had the disease for some months, and in whom there was no doubt as to the diagnosis. This group of cases is made up of unselected instances of sarcoma of the long bones. I have avoided speaking of any of the cases which are well to-day as "cured cases," no matter how long a time may have elapsed since the operation for the removal of the disease, for it has seemed to me hardly accurate to place a time limit within which any case may be regarded as cured, for it is common knowledge that metastases occur after many months or several years. There is one case recorded in which metastases became evident even five years following the operation.

I was led to a study of these cases because of the findings offered by several authors (König, Kramer, Mikulicz, Wiesinger) in demonstration of the proposition that there is a group of malignant tumors of bone which should be treated by excision and preservation of the extremity, rather than by amputation. There is no doubt that the sarcomata of bone are of varying degrees of malignancy. Should these differences in malignancy influence surgical treatment?

In this series of cases there were five giant-cell sarcomata.[1] All of these are at present in good health, three years and four months, three years and two months, three years and two months, six years, fifteen years, respectively, after operation. In one of these cases the sarcoma was in the upper third of the humerus and an amputation was done at the shoulder joint. In two of the cases the sarcoma was in the tibia. In one of these resection was done and in one amputation of the thigh. In one of these cases the lower end of the ulna was involved. In this case resection was done. In one case the lower end of the radius was involved and amputation above the elbow was done.

In the remaining ten cases the disease was located in the lower end of the femur once, and this case died with metastases in the lungs about thirteen months after the operation. The disease was in the tibia four times. In three of these amputation was done, in one a partial operation.

Of the three amputated cases, one was in good health two years and five months after the operation; a second was in good health three years and six months after the operation; and a third died with lung metastasis one year and three months following the operation. The case of partial operation is living, five years and three months having elapsed since the operation. There is local recurrence in the wound and the general health is poor.

The sarcoma was located four times in the humerus. In all these cases amputation at the shoulder was done. One of the cases did not reply. In one case there was a recurrence in the axilla ten months after operation. In another case death occurred from metastasis in the lung two years and four months following operation. In still another, death occurred from metastases in the lung.

In one of these ten cases the sarcoma was in the forearm. Amputation of the upper arm was done. A local recurrence took place in the stump and an amputation at the shoulder joint was done. This patient was well four years after operation and died then of acute pneumonia.

To summarize this group of cases:

There were *six amputations at the shoulder joint* for sarcoma of the humerus. There was no reply from one case. There was recurrence in the axilla in one case. There was one case of giant-cell sarcoma, in apparent health three years and four months after the operation. There were metastases in the lungs in two cases and probably in a third.

There were *four amputations of the thigh* for sarcoma of the tibia. One giant-cell sarcoma, in good health six years after the operation. One lived two years and five months and was drowned. One is living three years and six months, in good health. One died of metastases in the lungs.

There was *one amputation at the hip joint* for disease in the lower end of the femur. This patient died thirteen months after the operation.

There were *two resections*,— one of the tibia, one of the ulna; each a case of giant-cell sarcoma. Each is at present well,— one three years and two months after the operation and the other also three years and two months after the operation. There was *one partial operation* upon the tibia. This case is in fair health five years after the operation, although a probable recurrence is present in the leg; there was *one amputation above the elbow* in perfect health fifteen years later.

In case fourteen the small metastatic foci discovered at autopsy were not only not detected in the very careful examination of the patient previous to operation, but they were not even suspected; death probably was due to shock and not to these metastases. Cases six, eight and thirteen all died with lung metastases, thirteen, fifteen and twenty-eight months, respectively, after operation. Case fifteen is said to have died of acute pneumonia; it is not known by autopsy whether or not there was lung sarcoma in this case; it was thought at the time, by the attending physician, to be a simple acute pneumonia. There were no metastases in the giant-cell sarcoma cases.

[1] The microscopical preparations from four of these cases have been recently examined, with special reference to this paper, by Dr. J. H. Wright, Director of the laboratory of the Massachusetts General Hospital.

Dr. Wright states that they all have essentially the same histological structure; that they are all typical examples of that definite form of sarcoma with giant cells, which is the typical giant-cell sarcoma of the textbooks, and which may be readily differentiated histologically from other forms of sarcoma with giant cells.

Cases one, two, four, five, six, eight and ten gave a history of trauma to the part in which the new growth subsequently developed; in other words, seven out of fifteen cases gave a history of trauma preceding the appearance of the tumor. The etiological relationship between trauma and the development of sarcoma is an interesting one, but not yet satisfactorily demonstrated.

That there is a difference in the malignancy of the sarcomata of bone has for some time been recognized (König). The giant-cell sarcoma is less malignant than the round- and spindle-cell sarcomata. The series of cases here recorded illustrates this anew. In view of this fact the very important question arises, Is it wise for the surgeon to treat the giant-cell sarcoma of the long bones by an operation less extensive than has formerly been adopted in this type of malignant disease? Hitherto, as illustrated in a number of the cases of this series, the surgeon has removed the extremity well above the disease, making no distinction in his treatment between the giant-cell sarcoma and the more malignant spindle- and round-cell sarcoma. From a study of the facts, emphasized by Kramer[2] in a paper upon the treatment of sarcoma of the hollow bones, and a paper by Jenckel,[3] who studied the sarcoma of the femur, and from the cases reported by Bloodgood, from Halstead's clinic,[4] and from the series of cases here reported from the Massachusetts General Hospital clinic, it seems to me that if the giant-cell sarcoma of a long bone is limited to the bone and is localized in the bone, involving only a small area, a resection or partial operation is justifiable, *vide* Greenough's case; but if the soft parts are in any way involved, or the disease in the bone is extensive and of long duration, that then an amputation is the best treatment; an amputation in the continuity of the bone, if the lower end of the diaphysis is involved, or an amputation at the joint above the disease, if the disease is high in the shaft. Exarticulation at the joint above the disease, at the shoulder or at the hip, is indicated only in those cases in which the disease cannot otherwise be completely removed. I should limit the excision or partial operation to a considerably narrower class than it is limited by Bloodgood. It is true that it has been pointed out that local recurrences after the conservative treatment can be satisfactorily handled. There appears also to be no increase in the likelihood of metastases following local recurrence. A careful study of the evidence presented does not, however, make me enthusiastic for the employment of the partial operation, excepting in the most carefully selected cases. It is always to be kept in mind that metastases may exist, and in the large proportion of late cases coming to the hospital clinic do already exist in the lung, only to make themselves known some time after operation. Exploratory incisions for diagnostic purposes in this group of cases is to be avoided. It is possible that metastases have been occasioned by these exploratory incisions. The x-ray is of great value in diagnosis, particularly early in the development of the disease, and in those cases in which no positive diagnosis has been made. The value of the x-ray in the diagnosis of bone lesions has been especially studied by Dr. E. A. Codman. [See Johns Hopkin Bulletin May, 1903.] The cases of this group are here presented in detail:

[3] Deutsche Zeitschrift f. Chirurgie, 1902, Band 7, xiv, p. 66.
[4] Bulletin of the Johns Hopkins Hospital, May, 1903, p. 134.

CASE I. Woman. Tumor of upper arm, probably malignant. Amputation at the shoulder joint. Recovery. Result three and one-third years after operation.

R. B., fifty-nine years old. Service of Dr. S. J. Mixter. Four months ago, after a fall, she noticed a weakness and limitation of motion of the right arm, which have increased gradually. Three months ago she first saw a swelling of the upper arm, which has increased a little since that time.

Examination finds, at the junction of the middle and upper thirds of the right humerus, a hard fusiform swelling of the bone. The movements of the forearm are limited. The x-ray shows a fusiform swelling of the bone and a thinning of the cortex by pressure of the tumor from within.

Operation. — Amputation at the shoulder joint.

Pathological Report by Dr. Jas. Homer Wright:

Diagnosis. — Myelogenous round-celled sarcoma.

The shaft of the humerus is the situation of a tumor growth, largely replacing the bone so that fracture has occurred. The tumor growth is situated in the upper half of the shaft of the bone and involves a length of the bone about 8 cm. The bone, over a great part of the area involved in the tumor, is somewhat greater in diameter than normal. On sawing through the bone and the tumor in a longitudinal direction, the following appearances are noted: Occupying the marrow cavity of the bone and to a great extent replacing the cortical bone is a tissue which is partly grayish to reddish, translucent and partly dark red in color. The tumor, on section, has a fusiform or oblong outline and measures in the longitudinal direction 8 cm. as before stated. The central portion of the tumor is softer than the periphery, and dark red to blackish, and moist in appearance as from hemorrhage. In consistency the tumor mass is generally soft and somewhat elastic, but not diffluent. It is also somewhat fleshy. It contains no bony spicules. Throughout the greater portion of its length, it pushes before it the remains of the cortical portion of the bone and the periosteum. The cortical bone in this situation is very much thinned, being represented, over a greater portion of the length of the tumor, as spicules, or thin plates, beneath the periosteum. At the upper extremity of the growth the marrow cavity is invaded without distortion of the outward appearances of the bone for a length of a few millimeters. The upper extremity of the growth reaches to about 3 cm. of the anatomical neck. The growth generally can be well separated and differentiated from the marrow and from the cortical bone. It can also be sharply differentiated from the spongy bone, which abuts upon it near the surgical neck at the upper extremity of the growth.

Microscopical Examination. — Sections of the tissue hardened in Zenker's fluid and afterward decalcified. The tumor tissue consists of closely packed, medium-sized polyhedral cells with a moderate amount of cytoplasm. The polyhedral shape of the cells seems to be due to mutual pressure, and it seems possible that in the fresh state they were spherical. There is little or no stroma. Here and there among the cells are spaces more

or less completely lined with thin cells, resembling endothelium. The nuclei of the tumor cells vary somewhat in size, are generally oval in shape and do not contain a large amount of chromatin. The nuclear membrane is very thin and not prominent. The cells are clearly not plasma cells and not like the cells described by J. H. Wright in a case of so-called "Multiple Myeloma."[5]

The thin and more or less perfect shell of bone investing the tumor seems to be, not the remains of the original bone, but a new formed bone.

End Result. — Three years and four months after the operation the patient replies to inquiry, "I am used up by rheumatism and pleurisy for a year." Friends of the patient write that her general health is excellent. There is no recurrence of the disease.

Case II. Child; girl. Injured knee; tumor of upper end of the tibia; malignant disease suspected. Partial operation at two different times. Recovery. Well after three years.

L. T., service of Dr. W. M. Conant; sixteen years old. One year ago she fell downstairs striking the left knee. Two months ago she noticed a small hard swelling just below the left knee, over the tibia. There has been tenderness in this region for eight months; the swelling has increased very slowly. She has lost no weight, but rather gained in weight.

Examination. — Well-developed and well-nourished girl. Anteriorly just below the knee is a swelling of the tibia 3 by 2 inches in size. This swelling is tender. The overlying skin is normal in appearance. Two small glands are felt in the groin.

Operation. — At operation the external layer of bone over the tibia was found to be a mere shell. Beneath the bone was a cavity the size of an egg. The softened bone was chiselled away, the material within was curetted out, the cavity remaining was wiped dry and painted with tincture of iodine and packed with iodoform gauze. The pathologist reported giant-celled sarcoma.

One month later a second curetting was done and the material removed at this time was reported to show no evidence of malignant disease. One year later the wound is reported as entirely closed for six months previously, with no evidence of malignant disease. She has some little pain at the seat of the wound.

Pathological Report by Dr. W. F. Whitney:

Diagnosis. — Typical giant-celled sarcoma.

A few small bits of bone and soft tissue received for examination.

Microscopical examination shows typical giant-celled sarcoma.

End Result. — Three years and two months after the first operation and three years and one month after the second operation the general health is good, and there is no trouble with the wound. She considers herself well.

Case III. Young adult; woman. Tumor of the lower end of the ulna. Excision of tumor. Recovery. No recurrence three years and two months after operation.

M. C., twenty-four years old. Patient of Dr. R. B. Greenough, service of Dr. J. C. Warren. For three months there has been soreness in the wrist. On the ulna side of the right wrist is a hard swelling. There is no redness of the skin. Over the swelling there is some tenderness on deep palpation. The bone feels thickened for a distance of 2 or 3 inches. The x-ray shows a disease of the head of the ulna. There is a suggestion of fluctuation over the swelling.

Operation. — An excision of the tumor was done. There has been no recurrence of this growth, three years and two months after operation.

Pathological Report by Dr. James Homer Wright:

Diagnosis. — Typical giant-celled sarcoma.

A portion of the ulna about 5 cm. long, including its lower extremity, received for examination. The lower extremity is about twice the normal size and is the seat of a neoplasm which largely replaces the substance of the bone, but does not extend beyond the periosteum. It extends only a very short distance into the shaft.

Microscopical examination shows typical giant-celled sarcoma.

End Result. — There has been no recurrence after three years and two months. The patient is in good health.

Case IV. Young adult; man. Injury to knee; tumor of head of the tibia; malignant growth. Amputation of thigh. Recovery; at present general health good, six years after operation.

R. O., twenty-four years old. Service of Dr. S. J. Mixter. Sixteen months ago he fell while running upstairs and struck his knee right. Three or four months later pain appeared in the knee. Six months ago he fell on the same knee. The knee was incased in plaster of Paris. Since then the pain has been getting worse.

Examination. — There is a swelling on the outer side of the head of the tibia about 2 inches in diameter. This swelling is hard and bone-like. Just above the tumor there is a semi-fluctuating spot. A button of bone was removed from the tibia and a red, soft, pulsating mass was discovered inside a thin shell of bone. The diagnosis was made of a giant-celled sarcoma. Patient was discharged untreated as he refused amputation. He received the Coley treatment for three weeks.

Amputation on account of the great vascularity of the tumor and because its growth was apparently not controlled by the toxins.

Pathological Report by Dr. J. H. Wright:

Diagnosis. — Giant-celled sarcoma.

Microscopical examination of a section of the neoplasm shows typical giant-celled sarcoma like that of an epulis.

End Result. — Six years after operation general health is good. There is no trouble with the stump wound. Has had some pain in hip and back when lying a long time at night. Has had this aching for a long time; otherwise perfectly well.

Case V. Man. Tumor lower end of the radius. Curetting and cauterization; then amputation above the elbow. Well fifteen years later.

C. D. S., thirty-three years old. Service of Dr. C. B. Porter. One month previously wrenched his hand, which swelled considerably and was painful for a few days. For two weeks past the hand continued swollen and more pain has been felt, sufficient to keep him awake.

Examination finds a small diffused swelling of the lower end of the radius, near the wrist. The swelling is tender to touch. There was an indistinct sense of fluctuation and pulsation of the swelling. The swelling was aspirated. Nothing was obtained from the aspirating needle.

Operation 1. — Whole lower end of the radius was occupied by a semi-solid mass of vascular medullary tissue. Whole cavity was curetted out and cauterized

[5] "Contribution to the Science of Medicine dedicated by his Pupils to William Henry Welch upon the Twenty-fifth Anniversary of his Doctorate and Volume IX of the Johns Hopkins Hospital Reports."

with the actual cautery and packed with iodoform gauze.

Operation II. — Amputation two days later above the elbow joint.

Pathological Report by Dr. W. F. Whitney:

Soft, slightly translucent medullary looking masses. Microscopical examination showed it made up of a mass of large oval cells with a slight fibrillated or granular intercellular substance between them, and large multinucleated giant-cells.

Diagnosis. — Myelogenous giant-cell sarcoma.

End Result. — The patient is alive and perfectly well fifteen years after operation.

CASE VI. A young adult. Injury to knee; tumor of femur, close to knee joint. Amputation at hip joint. Recovery.

J. C., nineteen years old. Service of Dr. J. C. Warren. Three months ago he stepped in a hole and wrenched his knee. After this he had slight pain in the knee, in the morning, on attempting to straighten the leg. He was gradually unable to completely straighten the leg and for two weeks past he could just bend the leg to a right angle. He has been on crutches for six weeks.

Examination. — The left leg is bent at a right angle. Upon attempting to passively extend the leg he complains of pain. There is a swelling over the external condyle of the femur. The skin over this swelling is slightly blue, tender, and there is a sense of fluctuation. There are a few glands to be felt in the left groin. The tumor is regarded as malignant.

Operation. — Amputation at the hip joint. Recovered from the operation and returned to his home.

Pathological Report by Dr. W. F. Whitney:

Diagnosis. — Osteo-sarcoma originating in the trabeculæ of the bone.

Fragments removed from a hemorrhagic new growth apparently originating in the neighborhood of the condyles of the femur and just above the knee posteriorly.

Microscopic examination showed the trabeculæ of bone almost entirely decalcified and replaced by a growth of irregular round cells, many of them of large size and occasionally distinctly spindle shaped. There was extensive hemorrhagic areas among these which seem to have originated in the medullary cavity of the bone and infiltrated this new growth, which, in places, was very necrotic. The cells of this new growth have neither the characteristic shape of cartilage, nor of bone corpuscles, but in places it seems as if they originated in a proliferation of the bone corpuscles.

The lymph nodes removed from the groin showed nothing but a proliferation of the endothelium of the lymph spaces to account for their increased size.

The End Result. — This boy could not be found after careful inquiry.

CASE VII. Child; a boy. Tumor of the head of the tibia. Amputation of the thigh. Recovery. Accidental death two years and five months after operation.

R. L. T., fifteen years old. Service of Dr. John Homans. Three months ago there was tenderness below the right knee over the tibia. A tumor developed at this point. For two months he has been unable to walk upon his leg. He has lost considerable flesh.

Examination found a well-developed but somewhat emaciated boy. A globular swelling is seen just below the head of the right tibia; the circumference of the right leg at the seat of the tumer is 12¾ inches; the left leg 11¼ inches. The tumor is soft, elastic, and the skin is not adherent to it. Tumor is apparently of the bone; tumor extends back toward the popliteal space but is most prominent in front at the head of the fibula. The surface temperature of the tumor is considerably increased. The glands of the right groin are slightly enlarged.

Operation. — Amputation of the thigh just above the knee. A bit of the tumor removed before the amputation was examined and found to be a large, round-celled sarcoma.

Pathological Report by Dr. W. F. Whitney:

Diagnosis.— Round-celled sarcoma, probably of periosteal origin.

A piece removed by the Mixter punch, showing the growth to be composed of a solid mass of large round cells with a little intercellular substance, here and there; buried in the growth were spiculæ of bone, evidently extensively destroyed.

End Result. — This boy wore an artificial leg, had no trouble from the stump and was always well after the operation. He lived two years and five months after the operation and then was drowned.

CASE VIII. Young adult; man. Fracture of leg below the knee; tumor at seat of fracture; malignant. Amputation of thigh. Recovery; lived one year and three months.

J. D., thirty-three years old. Service of Dr. F. B. Harrington. Three and one-half years ago the left leg was broken just below the knee. He was then laid up for three or four months. Six months later he noticed a lump over the left tibia anteriorly, which has been growing slowly ever since. There is not much pain. Eight weeks ago this swelling was incised by a country doctor, and the bony mass scraped. The wound has never healed. There is considerable discharge and hemorrhage from this wound.

Examination. — Well-developed and well-nourished. The leg is considerable enlarged just below the knee. The tibia is increased in size. There is a large ulcerating surface which bleeds easily, at the center of this swelling. The skin is considerably discolored. The skin is infiltrated with firm nodules in the immediate vicinity of the ulcerated part. No enlarged glands can be felt in either groin or along the iliac vessels.

Operation. — Amputation of thigh.

Pathological Report by Dr. William F. Whitney:

A soft, grayish growth filling a cavity which it had apparently excavated in head of the tibia, breaking through the articulating surface and infiltrating the tissues about the joint. Spindle-celled sarcoma.

End Result. — He lived one year and three months. He died with " the disease " in the other thigh and leg. He had much pain for six months previous to his death.

CASE IX. Young adult; woman. Tumor of the leg below the knee; malignant. Amputation of the thigh. Recovery; good health at present.

K. M., twenty-six years old. Service of Dr. A. T. Cabot. Five months ago she first noticed a swelling of the left leg extending from the knee to the ankle. Four months ago the upper third of the tibia began to enlarge. There was great pain of a grinding character, particularly at night. One month ago she was obliged to give up work because of the pain and loss of sleep. A bit of the growth removed from the head of the tibia was found to be sarcomatous.

Examination. — The upper third of the right tibia is uniformly enlarged; there is no fluid in the knee joint; there is no glandular enlargement. The x-ray shows a bony thickening of the upper end of the tibia. The center of the tumor is of great density.

Operation. — Amputation above the condyles of the femur.

Pathological Report by Dr. W. F. Whitney:

Diagnosis. — Osteo-sarcoma.

The head of the tibia invaded by a new growth which had increased it to about the size of the fist. The section showed a very dense bone replacing the spongy tissue and filling the medullary cavity for the distance of several centimeters.

Between it and the medullary cavity was a zone of grayish, opaque tissue of distinctly different character from the medulla and composed microscopically of a mass of large round cells with a little intercellular substance.

Enlargement of the bone was chiefly caused by an irregular deposit of new bone. On the outside of the outer surface was a zone of the same soft grayish tissue seen in the medulla and composed of the same structure.

End Result. — Three years and six months after the operation the patient is in good health, with no local trouble.

Case X. Adult; male. Fracture of leg; injury to seat of fracture. Tumor at seat of fracture; malignant. Partial operation; recovery; general health good.

M. B., fifty years old. Service of Dr. J. W. Elliot. Nine years ago the left leg was broken at the junction of the lower and middle thirds by the kick of a horse. Four years ago he was kicked by a horse in the same place and has been unable to put any weight upon the leg for some time. One year and a half ago he noticed a swelling over the site of the old fracture; this swelling increased slightly, was moderately tender, but not painful. A little less than a year ago the surface of the swelling ulcerated. The glands in the groin have been tender and somewhat enlarged; he has had some pain at night in the leg.

Examination. — Marked thickening of the left leg in the lower third. The skin over this area is bluish in color. At the center of this bluish and discolored area is an ulcerating and fungus mass about the size of a silver dollar. The glands in the groin are not particularly enlarged.

Operation. — An elliptical area of skin surrounding the disease was incised and granulation tissue was removed with the curette; bits of diseased bone and old granulation tissue were found in the depths of the wound; the diseased parts were removed with the bone chisel and curette; the wound was cleansed with peroxide and corrosive. The diagnosis of osteoid sarcoma was made.

Pathological Report by Dr. James Homer Wright:

Diagnosis. — Osteoid sarcoma.

The sections of the tissue received for examination Aug. 31, 1898, show a sarcomatous neoplasm identical with that in the specimen described below.

Specimen received Sept. 4, 1901. The tibia in its lower third is greatly thickened and is the seat of a tumor growth occupying the narrow cavity over a length of perhaps 8 or 9 cm. This tumor growth extends into the shaft of the bone and involves the skin on the anterior aspect of the leg where there is considerable ulceration.

The tumor growth consists of a firm, grayish, translucent tissue in parts of which a few fine, bone-like spicules are perceptible to the touch. At the periphery of the tumor, where it impinges upon the thickened bone, the tumor tissue occupies rounded depressions, with smooth walls, in the bone.

Microscopical examination of hardened sections shows that the new growth consists essentially of a tissue that at first sight resembles spongy bone. A large part of the tissue consists of closely packed cells, which cells are divided into larger and smaller groups by columns and trabeculæ of a tissue very suggestive of the trabeculæ of spongy bone and regarded as a form of osteoid tissue. These trabeculæ are composed of a fibrillary substance staining with eosin in which well separated, elongated, vesicular nuclei are distributed. With Mallory's connective tissue stain these trabeculæ take a deep blue coloration and are seen to consist mostly of fibrillary substance. In one of the sections the tissue of the trabeculæ is seen to become continuous with a small mass of bone. The other constituent of the tumor lying between the trabeculæ consists of closely packed cells. These cells contain elongated faintly staining vesicular nuclei of good size and a very small amount of cytoplasm, which is seen with difficulty as a more or less reticular substance between the nuclei. The nuclei show a marked tendency to be arranged with their long axes parallel to one another.

End Result. — Five years after operation the wound was still open. The general health was good except for a sore upon the leg. During the past three months — that is, three years since the first operation — he has had more or less trouble with the wound and is not feeling well. Patient will not consent to amputation.

Case XI. Young adult. Tumor of humerus, thought to be malignant. Amputation at the shoulder joint; recovery.

L. S., sixteen years old. Service of Dr. J. C. Warren. One year ago the patient first noticed a swelling of the right arm above the elbow. Six weeks ago this swelling began to be painful. The swelling has grown steadily larger.

Examination finds the entire humerus uniformly much enlarged. There are glands in the axilla.

Operation. — Amputation at the shoulder joint. The mass of new growth is found to infiltrate the muscles without a sharp boundary line. The periosteum is very much thickened. The medullary cavity is involved by the new growth. The axillary glands are also involved.

Pathological Report by Dr. W. F. Whitney:

Diagnosis. — Large round-celled sarcoma.

A spindle-shaped growth surrounding the humerus at its middle and about 6 cm. in diameter. It is of a grayish, slightly opaque, homogeneous surface and infiltrates the muscles without a sharp boundary line. The shaft of the bone is roughened but not destroyed, and in places shows a distinct periosteal thickening. In the medullary cavity is a similar new growth. The axillary lymph glands are also infected.

Microscopic examination shows it to be a large, round-celled sarcoma.

End Result. — No reply received after careful inquiry.

Case XII. An adult. Swelling of the whole upper extremity, thought to be a periostitis. Amputation at the shoulder joint; recovery.

J. I. C., thirty-three years old. Service of Dr. H. H. A. Beach. Sharp shooting pains in the limbs for many years. Three months ago this pain was most marked in the right upper extremity. The pain was sharp, localized at different times in the elbow, forearm and upper arm. Four weeks ago the arm began to swell; there were soreness and tenderness.

Examination finds the whole upper extremity swollen. There is marked tenderness on the inner side of the arm above the elbow. The superficial veins are prominent over the arm. The disease is thought to be a periostitis. There is limitation of motion at the elbow-joint due to the swelling of the upper arm.

Operation. — Amputation at the shoulder joint. Axillary vein involved in malignant thrombus. Pronounced malignant by the pathologist. Recurrence in the axilla after a little over a month. The Coley serum was used without benefit after the operation.

Pathological Report. — Pronounced malignant by the pathologist. The axillary vein was filled with a thrombus which was thought by the pathologist to be malignant. No glands were found enlarged in the axilla.

End Result. — In ten months recurrence in axilla.

CASE XIII. Woman. Tumor of the upper arm. Partial operation; Coley treatment; amputation at the shoulder joint; recovery. Died three months ater from lung metastases.

C. O., thirty-eight years old. Service of Dr. F. B. Harrington. Sixteen months ago she had pain in the right arm. Six months later she was operated upon for tumor of the soft parts and later the humerus was curetted. An x-ray was taken then and the patient told that she had malignant bone disease, and a radical operation was advised. This was refused and she was treated in New York by the Coley serum. She now has great pain at night, which keeps her awake. The swelling of the arm is slowly increasing.

Examination finds, upon the outer aspect of the upper arm, a little below the head of the humerus, a hard, firm swelling, not tender, not movable, and apparently connected with the bone. The x-ray shows a thickening of the bone like a periostitis.

Operation.— Amputation at the shoulder joint. One year after the amputation re-entered the hospital for a short time, with some trouble with the chest. Two years after the operation re-entered the hospital for recurrence in the stump.

Microscopical examination of this specimen showed a spindle-celled sarcoma.

A partial operation was done. The patient died three months later, evidently from metastases in the lung and stomach.

Pathological Report by Dr. James Homer Wright:

Diagnosis. — Periosteal fibro-sarcoma with metastasis in a regionary lymphatic gland.

Dissection shows a tumor involving the periosteum of the humerus and the insertion of the deltoid.

This tumor consists of an elongated mass continuous with the periosteum, about 6 cm. in length and 2½ cm. in greatest width. It is not sharply defined from the surrounding muscular tissue. It has been partly separated from the bone by the surgeon. On section through the tumor in a longitudinal direction, it is seen to consist of a grayish, translucent, gristle-like, fibrillated tissue fading out into the muscular tissue like scar tissue. Where it has been in apposition with the bone the tumor tissue becomes softer and reddish in color. The denuded bone surface is somewhat irregular, but presents no necrosis nor evident invasion by the neoplasm. At the lower extremity of the growth and just outside of the periosteum is a sharply outlined nodule about 7 mm. in greatest diameter and composed partly of a dark red and partly of a grayish translucent tissue.

The shaft of the bone contains normal marrow.

Microscopical examination of sections of the growth, hardened in Zenker's fluid, shows the neoplasm to consist of cells and a relatively large amount of connective tissue. The cells vary considerably in size and shape and very atypical in appearance. In places the cells are very numerous and form more or less well defined islands in the midst of the connective tissue. In other places the cells are scattered throughout the connective tissue. The connective tissue itself, in places, forms the most prominent feature of the growth and is very dense and coarse.

Sections of two small lymphatic glands, presumably from the axilla, show in one of them a small secondary tumor, identical, in structure, with that of the growth on the bone.

End Result. — About three months after the operation she died. The wound appeared healed and normal. There were evidences of trouble with the lungs and stomach, suggesting very strongly that metastases had occurred in these situations.

CASE XIV. A boy. Tumor of the shoulder region; malignant. Amputation at the left shoulder joint; died.

A. L., fifteen years old. Service of Dr. C. B. Porter. A tumor of the shoulder was first noticed two years ago. This has grown slowly and painlessly.

Examination finds a poorly-nourished, anemic boy; he has lost flesh and strength during the past two years. The region of the left shoulder is occupied by a large, round, smooth mass which completely obliterates all the outlines of the shoulder joint. The overlying skin is white and the superficial veins are enlarged. The mass involves not only the shoulder and the scapula but also the tissues below and above the clavicle. The circulation of the left arm is poor; there is slight numbness of the left upper arm and forearm.

Operation.— Amputation at the left shoulder.

Pathological Report by Dr. W. F. Whitney:

Diagnosis. — Osteo-sarcoma (round celled).

A lobulated dense new growth, which had entirely replaced the scapula and upper part of the humerus. On section, a portion of it was soft, rather myxomatous looking, while the rest was made up of an osteoid tissue with little islands of cartilage here and there. The mass measured 18 by 21 by 24 cm. and weighed 7,000 gm.

The autopsy, by Dr. J. H. Wright, showed a small metastasis in each lung.

CASE XV. Woman. Tumor of lower end of the radius and ulna. Amputation of the forearm. Recurrence one year and a half later in the stump. Amputation at the shoulder joint. Recovery. Lived six years after the first operation. Died of acute pneumonia.

T. A. P., sixty-seven years old. Service of Dr. J. W. Elliot. Two years and a half ago there was pain in the thumb. Two months later the wrist began to swell and throb. To-day there is a tumor involving the ends of the radius and ulna. The pathologist, Dr. Mallory, pronounces it to be osteo-sarcoma.

Operation No. I. — Amputation above the elbow joint.

A year and a half after the first pain the arm began to swell again and has slightly increased in size.

Examination finds a well-preserved old woman. The stump of the amputated arm is the size of a large cocoanut. The skin over the stump is tense, tender, and the surface temperature is increased. The skin is ulcerated in two places; there are no glands in the axilla or above the clavicle.

Operation No. II. — Amputation at the shoulder joint, two years after the first operation.

Pathological Report. — There is unfortunately no complete descriptive pathological report. Dr. F. B. Mallory reported, after an examination of the first specimen only, that the tumor was an undoubted osteo-sarcoma.

End Result. — The patient lived six years after the first operation. She then died of acute pneumonia.

DISINFECTION OF THE CLINICAL THERMOMETER.

BY FRANCIS P. DENNY, M.D., BROOKLINE, MASS.

In a letter to the Philadelphia *Medical Journal*, Dec. 15, 1903, Dr. W. H. Dyer called attention to a method of disinfecting the clinical thermometer by putting a few drops of formalin in the thermometer case. As this convenient method has not received the recognition that it deserves it has seemed well to again call attention to it, and report the results of some tests of its efficiency.

If two or three drops of formalin (40% solution of formaldehyde) are put in the thermometer case, they are taken up by the absorbent cotton usually kept at the end of the case, which will remain moist for a number of days. Formaldehyde gas is freely given off from the formalin, but is confined in the air-tight chamber of the case. If the formalin has been freshly added the surface of the thermometer when taken out of the case is often covered with minute sweat-like drops of fluid, showing the high humidity. The small size of the chamber, the high humidity, and the high temperature if the thermometer is carried in the vest pocket, furnish conditions very favorable for the disinfectant action of formaldehyde.

The tests which are here reported show that the disinfectant action of the formalin remains active for several weeks or as long as the pungent, irritating odor of the gas is marked. In practice it is well to add the formalin about every two weeks or oftener if the odor seems at all weak, and the cap should be kept on the case when the thermometer is being used in order to prevent evaporation. The thermometer should be washed in water both before and after using. If by mistake the thermometer is put directly into the patient's mouth, the taste is somewhat unpleasant but no serious effects result.

Where the thermometer has been used for a patient known to have a contagious disease it is best to disinfect it outside the case, or at least fresh formalin should be added and the thermometer exposed to the gas a longer time than usual (several hours) before being used again. This method should not be employed when it is desired to use the same thermometer within a few minutes for another patient; for example, in hospitals and dispensaries, or when a physician is attending two patients in the same family. Under such circumstances disinfectant solutions should be used.

Tests. — The organisms used and the number of tests made with each were as follows: *Staphylococcus pyogenes aureus* 4, P. *typhosus* 3, B. *subtilis* (spores) 3, B. *diphtheriæ* (pure) 4, mixed cultures from throats of diphtheria patients 8; and in 3 tests the thermometer was infected by putting it for a moment in the mouth of a healthy person.

When cultures were used a few drops of an emulsion of the growth were put on a sterile glass slide and a clinical thermometer, or a glass rod of similar size, was rubbed in this. When partially dried the thermometer was put into the case with the infected end uppermost — that is, away from the moist cotton — so that the disinfection would have to be gaseous rather than from the direct action of the solution. For a control a second thermometer was similarly infected and

put in a case in which there was no formalin. Both cases were then put in the vest pocket. The exposure to the gas varied from five to twenty minutes; in most cases it was between ten and fifteen minutes. On being removed from the case the thermometer was emersed in a tube of bouillon and rinsed, in order to remove any traces of the disinfectant that might have been carried over from the case. The thermometer was next rubbed over the surface of a serum or agar tube, and then dropped into a fresh bouillon tube. The control thermometers were similarly treated, and all the tubes were then incubated.

All the controls showed growth. Of the exposed thermometers three showed growth, these having all been exposed in cases in which the formalin had been added several weeks before, and where the odor of the gas was very faint. That the absence of growth in the other cultures was not due to the presence of a small amount of the disinfectant which had been carried over from the thermometer case, was shown by the fact that there was growth in them when the same cultures were inoculated from the controls.

The following table shows in detail the tests which were made and the results obtained:

Test No.	Bacteria used in Test.	Minutes Exposed.	Result.	Remarks Formalin in the Thermometer case.
1	B. Diphtheriæ (pure)	17	—	3 weeks
2	" "	15	—	3 "
3	" "	15	—	3½ "
4	" "	12	—	Faint odor
5	" (mixed)	10	—	10 days
6	" "	10	—	2 weeks
7	" "	10	—	2 "
8	" "	15	—	4 "
9	" "	12	—	4½ "
10	" "	12	—	Fresh
11	" "	10	—	Faint odor
12	" "	5	—	Fresh
13	Staph. py. aureus	15	—	2 weeks
14	" " "	15	—	2 "
15	" " "	10	—	Fresh
16	" " "	10	—	2 weeks
17	B. Typhosus	15	—	4½ "
18	"	15	—	Fresh
19	"	10	—	1 week
20	B. Subtilis (spores)	10	—	Fresh
21	" "	12	—	?
22	" "	15	—	Faint odor
23	Secretions of mouth	20	—	2 weeks
24	" " "	15	—	2 "
25	" " "	15	—	2 "

The convenience as well as the efficiency of this method should secure it more general use by medical practitioners. The time consumed in mixing disinfectant solutions is so great and their action so slow, that most physicians merely rinse their thermometers in water except when they have used them for a contagious case. The fact that contagious diseases cannot be diagnosed in their earliest stages, and also that apparently healthy persons may harbor in their mouths the organisms of diphtheria, influenza, pneumonia, tuberculosis, and probably also of syphilis and other transmissible diseases, shows the importance of disinfecting each time after use.

By this method the thermometer is always disinfected after it is used with no loss of time to the physician except the time it takes once in two weeks to add three drops of formalin to the case.

Clinical Department.

A SECOND CASE OF PUERPERAL ECLAMPSIA SUCCESSFULLY TREATED BY RENAL DECAPSULATION.[1]

BY GEORGE M. EDEBOHLS, M.D., NEW YORK.

A YEAR ago I had the honor of presenting for your consideration a report of the first case of renal decapsulation for puerperal eclampsia. The account of this first case, as published in the New York *Medical Journal* of June 6, 1903, may be epitomized as follows: Primipara, aged twenty-three. Typhoid fever during the fourth month of pregnancy. Symptoms of nephritis first noted during the seventh month. Uremia and eclamptic seizures near the end of eighth month. Five severe convulsions within sixteen hours, followed by forced delivery during fifth convulsion. Freedom from convulsions for forty-six hours after delivery. Then return of convulsions, six severe convulsions, not counting minor manifestations, occurring in eighteen hours. Decapsulation of both kidneys. No further convulsions, and rapid restoration of complete health.

I may add that I have seen the patient within the present month (May, 1904), and that she enjoys perfect health, with urine free from albumin and casts, fifteen months after operation.

In presenting the case I concluded with the following remarks: "The practical deduction from the happy result obtained is that we possess in renal decapsulation an additional potent resource in the treatment of puerperal eclampsia of renal origin." Personally, I should not hesitate to apply it again in a similar instance. I would even go further and propose a trial of renal decapsulation in puerperal convulsions of nephritic origin occurring prior to the beginning of labor. The mother would certainly be benefited, and the occurrence of premature delivery or the necessity of inducing it might possibly be averted.

On the first day of the present year the opportunity presented and was embraced of performing renal decapsulation for puerperal eclampsia upon the undelivered woman. The result is recorded in the following history of the case:

On Jan. 1, 1904, I was asked by Dr. N. R. Dann to aid him in a case of puerperal convulsions. The patient, W. N., a primipara of twenty, was married on Feb. 2, 1903, menstruated last on April 4, 1903, and expected to be confined on Jan. 9, 1904. Preg-

[1] Read before the American Gynecological Society, Boston, May 24, 1904.

nancy progressed smoothly until the occurrence of vulvar pruritus in November, 1903. Examination of the urine made by Dr. Dann at the date last named gave normal results, neither albumin nor sugar being present. On Dec. 20, 1903, the patient complained of specks before the eyes and dizziness. The urine was again examined and found to contain a trace of albumin. On Dec. 28, 1903, edema of the feet, puffiness of the eyelids, beginning coma, and total blindness supervened. The dropsy increased, the coma deepened, and the patient remained blind until Jan. 1, 1904, on which day at 10 A.M. the first convulsive twitching occurred. An hour later I saw the patient with Dr. Dann who had exhausted all the usual resources in attempts to dispel or lessen the uremia.

The patient's mental condition varied between stupid semi-consciousness and muttering active delirium. She was totally blind, with labored breathing, full, soft pulse, and temperature but slightly above the normal. The abdomen was of unusually large size even for a nine months' gestation; the dimensions of the patient were suggestive of hydramnios or twins. The lower extremities, the abdominal walls, and the back were dropsical in the extreme, while the upper extremities and face were only slightly edematous. Fetal movements, though not vigorous, could be plainly felt, and the fetal heart sounds were clear, distinct and regular. The cervix was tightly closed and there was not the slightest indication of beginning labor. During the twenty-four hours preceding my first visit the patient had voided in all 360 cc. of urine containing four tenths of one per cent of urea, making a total output of only 1.44 gm. of urea in twenty-four hours. During our examination a second general twitching occurred.

Renal decapsulation was offered the family and friends of the comatose patient as the most certain, prompt and efficacious measure to increase the urea output and thus to avert impending death from uremia. The offer was accepted, and hurried preparations were at once made for operation at the home of the patient.

The operation was performed on Jan. 1, 1904, at 11.30 A.M., Dr. Thomas L. Bennett administering chloroform, and Drs. W. G. Vincent and S. W. Adams assisting. On account of the enormous size of the abdomen, and of the danger of injuring the fetus by pressure, the lateral decubitus was the only position available. The left kidney was first operated upon, the patient lying on her right side. The extreme dropsy of the back, by increasing the depth of the wounds, and the convulsive twitchings of the patient even under chloroform, made the work rather more difficult than usual. The left kidney was increased in volume to about 50% above the normal. The capsule proper was found thick, strong, and loosely gathered or wrapped around the kidney. It was so loose indeed as to be slightly corrugated, and it could be pinched up in folds. There was no bleeding, not even oozing, from the kidney surface on stripping off the capsule, although the hemorrhage in cutting through the abdominal parietes had been unusually free. This hemorrhage, by the way, was purposely encouraged, and was only checked when it was judged that a sufficient amount of blood had been lost to confer on the patient the benefits of a moderate venesection. The capsule was separated from the kidney over the entire surface of the latter and was excised in toto. The kidney surface, after removal of the capsule, presented everywhere a dirty-gray, turbid, sluggish and stagnant appearance, the entire organ being choked with inflammatory exudate.

After completion of operation upon the left kidney the patient was turned upon her left side, the right lumbar region was rendered aseptic, and incision was made down upon the right kidney. The right kidney and its capsule were found in identical condition with that recorded for the left kidney, except that the right kidney was not quite as large as the left. Operation upon the right side was easier than on the left, the right kidney being readily delivered well into the wound, while the left kidney which could not be so delivered had proved more difficult of access. The operation upon the left kidney required fifteen, that upon the right fourteen minutes. Altogether, including the time required for washings and posturings, the patient was under the anesthetic for forty-five minutes. At the conclusion of operation the patient was returned to bed in good condition. The operative diagnosis was right and left acute or subacute parenchymatous nephritis.

During the twenty-four hours following operation there was almost complete suppression of urine, only 30 cc. of gelatinous, semi-solid, coffee-colored urine being obtained by catheter. Notwithstanding this, the patient's condition changed visibly for the better. During the same twenty-four hours of suppression following operation, the general restlessness and delirium disappeared, there were no further twitchings or convulsions, sight was restored following four days of total blindness, and the patient was able to recognize those around her. At the end of twenty-four hours after operation the urine began to flow freely, 1,000 cc. being drawn by catheter and a great deal more being voided into bed during the second twenty-four hours following operation, while the improvement of the patient's general symptoms became more and more marked and her condition no longer gave rise to immediate anxiety.

The next event of importance was the spontaneous commencement of labor forty-eight hours after operation. The beginning of cervical dilatation at 10 A.M. of Jan. 3, 1904, was marked by a petty convulsion quickly controlled by chloroform. At 10.30 A.M. and at 11 A.M. two further slight twitchings, the last in the history of the case, occurred. They were regarded as the response of the nervous system, still very susceptible by reason of uremic intoxication, to the ushering in of the parturient act. They gave rise to no anxiety as the patient's condition was otherwise satisfactory. At 1 P.M., the fetal heart sounds having all along remained distinct, and the cervix having spontaneously dilated to a sufficient degree, the forceps were applied to the presenting head, and a male child weighing 2,640 cc. was delivered. The partly asphyxiated child was revived by assiduous work on the part of Dr. Dann. An examination of the woman now showed a second head presenting. The fetal heart sounds remained clear. After a short period of rest for the mother and a little time granted for spontaneous birth, it was thought advisable in the interests of the second child to deliver. The forceps were applied to the head of the second child, and delivery was effected at about 3 P.M. The second child, of the same sex and weight as the first, was born alive but breathed only a few times after its birth, all efforts at resuscitation failing. The two placentæ were next delivered, after which the uterus contracted firmly and satisfactorily. The dressings of the lumbar wounds, which had become disarranged during labor and as a consequence of the immense shrinkage in size of the abdomen, were changed and the patient was allowed a much needed rest. She slept a natural sleep for the greater part of the twenty-four hours after delivery and awoke a changed, bright woman, in full possession of all her faculties.

The further progress of the case was uneventful. There was no recurrence of twitchings or of any unfavorable symptom, and the remaining edema rapidly disappeared. During the four or five days immediately following delivery a perfect deluge of urine, loaded with casts of all kinds and containing albumin in quantities varying between 0.05 and 0.6%, came down from the kidneys. The urine, mixed with blood and the lochial discharges, was not in favorable condition for satisfactory examination. Much of the urine also was lost with the fecal discharges which were abundant and frequent for some days. The exact daily amount of urine, therefore, could not be determined with anything like precision. Three days after operation, from Jan. 5 to 6, the amount of urine voided in twenty-four hours, as estimated by the nurse, was not less than 6,800 cc. One uncontaminated specimen of no less than 1,680 cc., obtained at a single catheterization on Jan. 6, was submitted to careful analysis with the following result: Specific gravity, 1,016; total solids in this one voiding, 62.63 gm.; urea, 1.3%; total urea, in one voiding, 21.84 gm.; albumin, 0.6%; numerous hyaline, epitheliated, fine and coarse granular casts, many of the latter with fat droplets; a few waxy, epithelial, blood and mixed casts; numerous isolated red blood cells; moderately frequent leucocytes. Numerous renal cells.

The output of solids and of urea during the first days after operation was simply enormous. Presuming that the specific gravity and the urea per cent above noted for a single voiding apply to the entire quantity estimated to have been passed during the third day after operation, we have an output for the third twenty-four hours after operation of no less than 253.5 gm. of solids and of 88.4 gm. of urea. By the end of a week after operation the daily excretion of solids and urea had gradually returned to about the normal. Owing to the presence of the lochial discharges, and to unwillingness to draw all of the urine by catheter, a full and valid twenty-four-hour specimen of urine was not obtained for examination until Jan. 14. Prior examinations of single voidings obtained by catheter showed a steady diminution from day to day of the amount of albumin and of the number and variety of casts. Examination of a full twenty-four-hour specimen, made Jan. 14, 1904, gave the following result: Total quantity of urine, 5,000 cc.; specific gravity, 1,011; total solids, 128.15 gm.; urea, 0.3%; total urea, 15 gm.; albumin, a marked trace; sugar, none; casts: occasional hyaline and granular, rarely a waxy; red and white cells, due to contamination with lochia.

On Jan. 31, 1904, the total amount of urine was 1,700 cc.; specific gravity, 1,015; total solids, 59.42 gm.; total urea, 11.9 gm.; albumin, a faint trace; rarely a hyaline cast; a few mucous cylindroids; no renal elements; still some lochial cells. An examination, made April 9, 1904, showed the urine to be practically normal; no albumin, no casts, a few mucous cylindroids, no renal elements.

The progress of improvement in the patient's general condition kept pace with that of the urine. At no time after delivery was there any cause for anxiety. The puerperium ran a normal course. Both lumbar incisions healed by primary union throughout, in spite of much unavoidable disturbance of the dressings during labor and immediately afterward. Three weeks after operation the patient left her bed and a week later resumed her duties in life.

Last report, May 14, 1904, four and a half months after operation. Patient has nursed her child continuously from its birth to date of report. Mother and child are enjoying most excellent health; the child weighs 9½ kg. Examination of the mother's urine gives the following results: Total quantity voided in twenty-four hours, 1,950 cc.; specific gravity, 1,012; total solids, 54.52 gm.; total urea, 21.45 gm.; no albumin; an occasional hyaline cast.

The case just narrated speaks for itself. Further comment appears unnecessary, and further valid deductions cannot be drawn from a single case. One fact stands forth prominently as absolutely proven and firmly established by the case, namely, that renal decapsulation can arrest the progress of uremia and of puerperal convulsions of renal origin *in the undelivered woman*. The deduction is self-evident. The production of abortion and the induction of premature labor, with all that those procedures imply for mother and child, need not henceforth be our only ultimate resources in the treatment of puerperal eclampsia.

A CASE OF TUBERCULOUS CONTAGION.

BY SARAH ELLEN PALMER, M.D., BOSTON,

Surgeon to the New England Hospital for Women and Children; Assistant Surgeon to the Women's Charity Club Hospital; Physician and Surgeon to the Pope Dispensary.

A. N., single; thirty-five. Came to my office in November of 1901, complaining of an uneasiness in the left axilla. I found the axillary glands slightly enlarged, and a faint line of redness and tenderness extending from a small abrasion on the wrist to be lost in the glands. The glands increased steadily in size, and at the instance of her family she consulted Dr. William Osler of Baltimore. He agreed with me that extirpation of the glands was the only treatment indicated, and early in February, I dissected out the axillary space. The more superficial glands, owing to the long delay, were about to break down and the deeper lymphatics were much engorged. Pathological report showed the glands to be tuberculous. Neither at the time nor subsequently has the patient shown evidence of general infection, and we are ready to hope that the tuberculous condition was limited to local manifestation. Investigation showed that my patient employed as maid a poor girl who had tuberculous glands in the neck which were suppurating. The wound was dressed daily, no special care being taken. This was the only direct exposure known.

After talking to Dr. Theobald Smith, I am confirmed in my idea that contagion is possible in just such a case as this reported, and that an unusual strain of bacteria might, though rarely, exist in a suppurating, tuberculous gland and thus communicate tuberculosis to others.

Dr. Osler of Baltimore, in a recent article on "Home Treatment of Tuberculosis," gives details of a plan in the city to investigate by house to house visits of trained workers the homes of the poor. They teach methods of precaution where tuberculosis is found in the family. Dr. John Russell of New York, in his School for Consumptives at the Post-Graduate Clinic of that city, has a plan of instructing the sick which is detailed in the reports of that Institution. In other cities the subject of prevention is agitated, as by the Society for the Relief and Control of Tuberculosis in Boston. It is, I believe, to the destruction of the sputa that attention is paid

most especially. In this instance reported, one of the most prominent physicians of Boston assured my patient that there was no danger to the other members of the family, although he knew the suppurating glands to be tuberculous. The belief in immunity from such a condition is evidently prevalent, because I am sure that infection from suppurating glands is rare. It is in the hope of adding an especial caution to the teachers of preventive methods, that this case is offered.

Medical Progress.

THE PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., AND HAYWARD W. CUSHING, M.D.

(Concluded from No. 21, p. 570.)

TREATMENT OF EMBOLISM OF THE LIMBS BY IMMEDIATE AND PROLONGED MASSAGE.

M. PIERRE MERKLEN[25] has recently called attention to the treatment of embolism of the arteries of the limbs by massage, a method suggested to him by Prof. Paul Berger who thus successfully treated embolism of the posterior tibial artery. When an artery is obliterated by an embolus a proximal clot forms and extends as far as the nearest branch given off by the artery; a distal clot also forms which is more extensive. If it extends very far it helps to prevent the establishment of the collateral circulation. Hence the indication is to break up the embolus or to drive it towards the periphery and to prevent the formation of the secondary clots. This result may be achieved spontaneously. M. Merklen related the case of a man suffering from mitral regurgitation which had existed for twenty-two years. He was suddenly seized with severe pain in one of the lower limbs which became cold and anesthetic up to a distance of several centimeters above the knee. The pulsations of the dorsalis pedis artery were absent but those of the femoral artery were retained. For nearly two hours M. Merklen and a colleague, relieving one another so as to avoid interruption of the process, practiced energetic petrissage of the femoral, popliteal and posterior tibia arteries until the patient declared that he was relieved. The limb was then wrapped up in cotton-wool. On the following day the relief had remained permanent and heat and sensibility had returned to the limb. The circulation evidently was re-established, although there were numbness and formication and the pulsation of the dorsalis pedis could not be felt until several months later. The patient regained complete power in the limb. Probably the massage acted by breaking up as well as by moving the embolus which was driven towards the periphery to a point where arterial obstruction did not, thanks to the collateral circulation, interfere with the nutrition of the limb.

[25] Lancet, Nov. 28, 1903.

TREATMENT OF FACIAL PARALYSIS BY NERVE TRANSPLANTATION.

Dr. Hackenbruch,[26] Wiesbaden, reported the results of an implantation operation in which he had united the spinal accessory nerve into the facial. The patient was a girl, eight years of age, in whom facial paralysis had existed for seven and three-fourths years. He implanted two thirds of the spinal accessory nerve into a cleft in the facial. Improvement was noticed at the end of four and one-half months. After a period of nine months the angle of the mouth could be voluntarily drawn outward. He also reported a subsequent case in which he had implanted, on account of infantile spinal paralysis, one third of the tibial nerve into the paralyzed peroneus nerve. At the end of three months there was some improvement. This was particularly noticed as regards position of the foot. An additional case was reported by Körte, Berlin, who showed a patient in whom, one and one-half years before, he performed an anastomosis between the facial nerve and the hypoglossal. The result showed that the muscles of the cheek and the angle of the mouth were distinctly mobile. The orbicularis oculi could be moved feebly while the frontal muscles were without motion. It was stated that the accessory nerve was a better nerve to graft than the hypoglossal. Dollinger, Budapest, called attention to the danger of dividing the accessory nerve before it passes through the sternomastoid muscle causing an incurable paralysis and atrophy of that muscle. He recommends making the division of the nerve as distal as possible and then turning it upward to unite it with the facial.

REPLACEMENT OF THE RADIAL DIAPHYSIS BY IVORY.

K. Vogel,[27] Bonn, claims to have successfully replaced the diaphysis of the radius in a case of traumatic necrosis of that bone. The patient, a little girl, was injured by a fall. The diaphysis as a sequestrum was removed subperiosteally and was replaced by an ivory rod which was fitted into the epiphysis at either end. The result is stated as quite satisfactory. The child uses the hand as before and plays like other children. Pronation and supination are somewhat restricted. The other motions of the hand are normal. Radiographic examination after one year showed considerable proliferation from the periosteum and from the epiphyses. The slight functional disturbance had then entirely subsided. The author considers that the experience has thus been found a success.

THE SEMI-LUNAR CARTILAGES OF THE KNEE.

F. F. Burghard, in an interesting article,[28] while discussing the modern treatment of several injuries thus speaks of the dislocation of the semilunar cartilages in the knee. The symptoms occur when the cartilage is bruised, torn, free, or

[26] German Surgical Congress, 1903.
[27] Deutsche med. Wochenschrift, B. xxix, Heft 46.
[28] Lancet, Dec. 19, 1903, p. 1703.

even when the synovial membrane alone is nipped between the articular ends of the bones. The writer does not consider the treatment by apparatus, pads, etc., of any especial value. He recommends conservative treatment if the patient is seen after the first injury and outlines his method of treatment. For the recurrent cases he proposes operation. After opening the joint he removes as much as possible of the injured semilunar cartilage. He discards the method of suturing. He in addition emphasizes the importance of trimming away the hypertrophied synovial fringes which hang into the joint cavity, especially in the region of the ligamentum mucosum and alaria, which may be caught between the bones and cause a return of symptoms after the removal of the cartilage. Careful search should be made for these, especially behind the ligamentum patillæ, before the joint is closed. The after treatment is also considered important, for the capsule of the joint is often relaxed and the thigh muscles atrophied. Hence a regular course of massage and exercise should be employed till these conditions are relieved. When relief is not obtained after the above methods it is generally due to the fact that an osteo-arthritis is present which has progressed in spite of the operative treatment.

REMOVAL OF AN OPEN SAFETY-PIN FROM A CHILD'S ESOPHAGUS.

Dr. A. H. Traver [29] has published an interesting case in which an open safety-pin was removed from the esophagus of an infant, nine months old. The pin was plainly seen, open, by radioscopic examination, located about half-way down the esophagus, the point toward the mouth. Its position prevented its being extracted through the mouth. The difficulty was overcome in the following manner: The child was chloroformed and placed on a table, underneath which a Roentgen ray tube had been placed, so that the pin could be seen without difficulty. While thus keeping watch of the pin, a whalebone bougie, also plainly visible, was passed down the esophagus till it came in contact with the safety-pin. Then by means of the bougie, the pin was carefully pushed down into the stomach and was seen to fall into the cardiac end. The bougie was then withdrawn. The child was now taken to the operating room, the abdomen opened in the median line, the pin located and removed through an incision one-fourth of an inch long in the stomach wall. This incision was closed with Lembert sutures and the abdomen sutured. The wound was dressed in the usual way. The child made an uneventful recovery and left the hospital on the seventh day.

POINTS IN THE TECHNIC OF MURPHY BUTTON ANASTOMOSIS.

O. Neuweiler [30] mentions the following details of technic which he considers important in the use of this surgical device: (1) The purse-string suture should not be inserted too far back from the margin of the intestine, so that a redundant mass of intestinal wall is not gathered into the cavity of the buttons around the cylinders; (2) contrarywise, also, the purse-string suture should not be too close to the margin of the intestine, so that when the button halves are apposed, the thread pulls out and permits the bowel to slip away from the grasp of the button; (3) in cases of circular anastomosis (end-to-end anastomosis) care must be taken that the mesentery is well grasped by the suture and drawn into the button, so that only serous membrane is against serous membrane; (4) a mucous membrane which bulges into the wound should be resected before the suture is passed and after the buttons are united and masses of tissue in the way should be carefully removed; (5) the pushing of the buttons together should be done not by a single powerful pressure, but gradually and cautiously. The fingers should not press too vigorously at the mouth of the ring, so that the intestine will slip off it, or so that the purse-string suture is torn out; (6) in all cases in which an absolutely uniform apposition of the serous surfaces, each to each, has not been obtained, a supporting safety suture should be carried out to prevent late accidents.

DANGERS OF THE TRENDELENBURG POSTURE.

Professor Kraske at the 1903 meeting of the German Surgical Congress,[31] while acknowledging the value of this position, comments on its dangers under certain circumstances. Twice during operations for suprapubic cystotomy there had been a fatal increase of existing myocarditis. In neither case was chloroform used and the loss of blood was not excessive. He considers that the increased hydrostatic pressure resulting from the posture caused a flow of blood from the inferior vena cava sufficient to result in acute fatal dilatation of the feeble heart. He also has observed intestinal obstruction apparently as a result of this position also in two cases. These were not patients notably fat. He, therefore, recommends that the position should be used with caution and for a short time in cases where serious disease of the myocardium is present or when it is believed that the omentum, mesentery and appendices of the cloaca are notably fat. During the discussion which followed, Trendelenburg doubted the correctness of Kraske's conclusions in regard to the cardiac cases. He admitted the possibility of intestinal obstruction, although stating that he had never seen such a result follow. He reported gastric hemorrhage following the use of the position. Konig at Berlin spoke warningly against this position in cases of abscess. Kümmel differed from Kraske in regard to the above mentioned ill effects. He claims never to have seen ill results from the use of the position, and did not believe that intestinal obstruction could follow.

THE TREATMENT OF GRANULATING WOUNDS.

Under this title H. Wagner of Breslau describes what he terms his "open air" treatment.[32] He claims that by this method a clean granulating surface the size of the palm of the hand can be covered with epidermis in eight to ten days. He has not observed during five years' experience any trouble from infection. He thinks that the danger of infection from air is slight, and quotes several authorities in support of this opinion. He claims that the usual moist and ointment dressings macerate and destroy the new forming epidermal cells. Also that they retain under the dressing the secretion of the glands in the deep layers of the skin. His method briefly is to daily clean the edges and surrounding skin with ether and then place the wound so that no clothing touches it. The dryer the room the more marked is the effect on the wound. He even, in suitable weather, places his patient out of doors. At night the wound is covered by powder, iodoform, or dermatol, or lime and starch and a bandage. The kind of powder is considered immaterial. He states that in spite of the dry bandage each morning the wound is moist. The secondary slough disappears, the granulations grow rapidly and the epidermis closes in daily from the edges, often several millimeters. He has no trouble, he claims, from retention of wound discharge under crust formation and infection. He thinks that the conditions of dryness inhibit the growth of bacteria. He would not conduct this open treatment, however, in wards where erysipelas or acute infectious patients were treated. For the exact details the reader is referred to the writer's original article which contains some interesting clinical observations of cases treated by ointment dressings and moist bandaging.

SEVERE BURNS.

M. M. Dieterichs[33] reports the results of an investigation for the purpose of learning the cause of the chemical conditions in very extensive and severe burns, especially the toxic changes in the blood. He reports to have found such substances in the blood of severely burned animals and in greatest abundance during the first five to ten hours. Agglutinine appeared somewhat later than lysine. For the full details of the conditions of the experimentation and the results the reader is referred to the original article.

In the second part of the report the writer applies the results of his work to the practical treatment of these cases and concludes that the conditions which call for relief are:

First. That the blood pressure should be raised preferably by the use of normal salt solution by rectum or by intravenous infusion. By this also the toxins are excreted by the kidneys.

Second. The deficiency of oxygen and the resulting destruction of the red blood globules must be relieved by a liberal use of oxygen.

Third. An excessive loss of bodily heat must be prevented.

As local treatment of the burn Dieterichs strongly recommends the aseptic dry treatment, avoiding as far as possible the use of drugs.

THE TREATMENT OF BURNS BY THE DRY METHOD.

Dr. M. Sattler in an interesting article has recently discussed this subject.[34] He calls attention to the fact that the chief symptom calling for relief in these cases (after "shock") is pain, and that most methods of treatment fail to relieve it. That treatment to be satisfactory must prevent infection, relieve pain, favor and hasten the removal of necrotic tissue and cicatrization of granulation tissue. The writer contrasts what he terms the "dry bandage" treatment with the other usual methods. He states that of 33 cases treated by water bath and other methods, 9 died, while of 29 cases by the "dry" method, no deaths occurred. In a later series there was a mortality of 8.8%. This dry method has been advocated at times by Lustgarten, Mosetig-Morrhof, Bardeleben, Eichhoff, and others. It was claimed to produce a dry slough and to hinder decomposition. Many observers claimed that the iodoform treatment of Morrhof in 1887 had a pronounced effect in quieting pain and preventing infection. Substitutes for iodoform were aristol, bismuth subnitrate, dermatol, xeroform and thiol. Dr. Sattler's method, briefly stated (for details the reader is referred to the original article), is to thoroughly clean the burnt area, open the blebs and remove all tags of epidermis with sterile scissors. The gelatinous exudation under the epidermis is wiped off with dry compresses. The surface surrounding the burn is then thoroughly cleaned. The affected area is thus made as far as possible aseptic. The injured surface is now covered with a thick layer of xeroform and after being thickly sprinkled with powder is covered with a covering of sterile gauze over which a layer of sterile cotton is fastened with a bandage. This bandage is changed generally after four to six days; in cases of much wound discharge oftener. In order to avoid pain and bleeding the patient is put in a bath when the bandage is removed and the dressing renewed. By this method it is claimed that infection is prevented, the necrotic areas are thrown off rapidly, that granulations form rapidly and defects are rapidly closed so that subsequent cicatricial contraction is prevented. The hypertropic growth of granulation tissue and profuse exhausting suppuration are avoided or essentially limited. If exuberant granulation tissue does form it is controlled with silver nitrate or a thermocautery. Strict attention is also paid to the function of the heart, kidneys and expectoration. This treatment has been now employed in one hundred cases to the exclusion of other methods. When contrasted with other methods such as ointment dressings, etc., on the same patient the result as regarded rapidity of healing, absence from pain, and the

[32] Centbl. f. Chir., 1903, Bd. xxx, 1361.
[33] Russisches Arch. f. Chir., 1903, Russian.
[34] Wiener Med. Presse, 1903, Bd. xliv, s. 2262.

character of subsequent scar formation was so markedly in favor of the "dry method" that finally other methods were discarded. The xeroform and powder dressing has a marked power in controlling pain which generally ceases shortly after the dressing is applied. The sloughs are separated in a shorter time, the granulation growth is more rapid and vigorous and the lesions cover in with epidermis quickly. The scars show no tendency to contraction. The xeroform is non-toxic. It diminishes the wound secretion thus avoiding frequent change of dressing. The histories of several cases of severe burns are published with the article illustrating the author's method, and showing his results.

ANTISEPTIC DRESSINGS.

Nœtzel [35] concludes from experimental research that the secretions of a wound are drawn up into a moist dressing better than into a dry one. Virulent anthrax bacilli placed on an artificial wound in rabbits were absorbed into these dressings and infection of the animals was prevented. Both the moist and the dry proved equally effective in this respect, but the germs were drawn up into the outer layers of the moist gauze while they were found only in the layers closest to the wound in the dry dressings.

THE ANTISEPTIC ACTION OF IODOFORM.

Dr. B. Heile [36] asks, Why does iodoform prove a good antiseptic in the clinic, and in the laboratory lag behind all other antiseptics in virtue? Heile's investigations show that when mixed with tissue juices in the *absence* of oxygen iodoform becomes decomposed in three to five days, and that it now kills both staphylo- and streptococci, while under the same circumstance neither the tissue juices nor the iodoform alone have any effect. Of the body juices, that from the liver decomposes iodoform most powerfully, that from the brain or from fat least powerfully. Granulation tissue acts similarly to juices from organs, and tuberculous granulation tissue seems to have the most intense decomposing power. The degree of decompositon was found by the quantitative test for iodine. Corresponding to the antiseptic action of iodoform is the degree in which iodine is set free. The antiseptic action is, however, not due to the free iodine, since iodine is set free in the presence of oxygen, and iodoform is no longer an antiseptic when oxygen is present. Further, iodine, in the form of tincture or in solutions of KI or NaI, of much greater concentration than can be obtained by the decomposition of iodoform, is not antiseptic.

The author thinks it most probable that the decomposition of iodoform sets free di-iod-acetylene (CHI-CHI). This is very powerfully bactericidal, and is rendered inert by oxidization. These experimental findings correspond with clinical experience. Iodoform has much value in cavities, but none in superficial wounds. In internal organs, viz., liver and kidneys, iodoform is most powerfully decomposed, so powerfully, in fact, that it sometimes acts not merely as an antiseptic, but as a caustic.

The author concludes that iodoform is truly one of our best, if not the best, of our antiseptics.

MODIFICATION OF EYE OF SURGICAL NEEDLE.

The slipping of thread and unthreading of needle during the suturing of wounds is often a source of great annoyance to the operating surgeon. To obviate this difficulty Dr. Marsh [37] has modified the eye of the surgical needle in such a way that this slipping of the thread is prevented. This he has accomplished by narrowing the eye end of the usual oval-shaped eye to a point. During suturing the traction on the thread forces it into this narrow portion of the eye by which it is grasped and slipping prevented.

OPERATIVE TREATMENT OF EXSTROPHY OF THE BLADDER.

E. Orloff [38] in a comprehensive monograph has included all the cases he has been able to find in which Maydl's method of transplanting the ureters has been employed with or without modifications. The total number of cases included is 61, which list includes 5 from his own records. Three of his patients died shortly after operation. He reports excellent results in two others. He also reviews other operative methods to date giving the results.

A NEW CYSTOTOMY OPERATION.

R. Frank [39] recommends a novel procedure, particularly applicable to old people with thick abdominal walls in whom a median cystotomy would be attended with considerable risk on account of possible complications. The operation is practically a perineal cystotomy and the main points are as follows: A transverse perineal incision is made and the rectum separated from the prostate, the blunt dissection being carried back until the posterior bladder wall, the seminal vesicles and Douglas' pouch are exposed. The section of exposed bladder wall is now incised in the median line, and the interior of the viscus explored. The author has used this method in two cases of vesical calculus, and in one of papilloma of the bladder, with good results. The operation requires more skilled technic than the median section, but the author thinks that is compensated by the simplicity of the after-treatment, more favorable drainage and cutting short the period of healing. The patients need to be kept in bed about eight to ten days, but during this time they may change their position, and from the beginning lie on the side.

THE PATENCY OF THE VAS DEFERENS AFTER SECTION, RESECTION AND SUTURE.

H. Vulliet has attempted to demonstrate that the vas deferens after resection can be sutured so that its canal is patent.[40] First this was ac-

[37] Journal of American Medical Association, vol. xli, p. 1413.
[38] Revue de Gynecologie, Paris, vol. vii, no. 5.
[39] Archiv. f. klin. Chirurgie, vol. 71, no. 2.
[40] Centbl. f. Chir., 1904, vol. xxxi, p. 36.

complished in dogs successfully. The suture was very fine. The diameter of the vas was not more than 2 mm. and that of the canal ½ mm. The wall was, however, rather thick which made it possible to suture it without the needle penetrating the canal. As just stated the needle and suture must be very small. In four operations the duct was shown histologically to be open and the canal lined with normal epithelium in three. Dr. Möhrlen in Lusanne also succeeded in finding live spermatozoa in the ejaculated seminal fluid in two dogs in whom the vaso deferentia had been resected and sutured, thus adding the physiological to the histological proof that this restoration of the duct is possible.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

The nineteenth annual meeting was held at Washington, May 10, 1904.

The meeting was called to order by the President, Dr. Wm. T. Councilman, of Boston.

The first feature of the program was the delivery of the president's address. In this, Dr. Councilman reviewed the condition of the association and called particular attention to the disadvantages resulting from the limitations upon membership. He asked that careful consideration be given to the question of increasing the number of members, and suggested, as one means whereby the end might be accomplished without detriment to the work of the society, that a class of associate members be established from which future members should be chosen, and that active membership be limited to twenty years; at the end of that period members to be transferred to the roll of honorary membership. This would about cover the average active period of a man's professional life and provide regularly a sufficient number of vacancies to accommodate the desirable portion of those on the waiting list.

THE INFLUENCE OF SUPRA-RENAL EXTRACT UPON ABSORPTION AND ELIMINATION; WITH DEMONSTRATIONS. DRS. S. J. MELTZER AND JOHN AUER.

Dr. Meltzer explained the experimental work whereby it was shown that the action of certain drugs was very much retarded when they were given in association with supra-renal extract. It was shown that this action was not a matter of chemical neutralization but due to biological changes. If small doses of adrenalin be injected into a frog, it becomes paralyzed in a few moments, but this is not a muscular paralysis since stimulation of the sciatic nerve causes the muscle to contract in a normal manner. If the effect of the adrenalin be allowed to wear off now, and strychnia given, even in more than the usually fatal dose, it produces no effect or only after a long period of delay.

In order to determine whether this was really a matter of delayed absorption experiments were made with a substance which is ordinarily very rapidly taken up by the tissues. If fluorescin be injected subcutaneously into a rabbit the conjunctivæ and mucous membranes very quickly take on the characteristic yellow stain and the Ehrlich's line appears in the pupil. If, however, such an animal be previously given adrenalin the coloring effects do not appear for a much greater length of time. As this coloring matter has first to be absorbed into the blood and then eliminated through the tissues of the organs, this may not have been purely a matter of delayed absorption but rather one of delayed elimination. By carefully timing, on a series of animals, the appearance of the color in the serum and later in the tissues it was demonstrated that both absorption and elimination are delayed by the adrenalin. These differences were most strikingly shown in the tissues of the kidney; the studies upon the urine were not so distinctive because even a minute portion of the fluorescin colors the fluids of the body intensely.

An effort was then made to determine whether transudation would also be delayed by adrenalin. For this purpose salt solution was introduced into the peritoneal cavity where, as we know, it ordinarily changes very rapidly with the blood, and fluorescin was injected into the vessels. Specimens were shown demonstrating that the fluid from the peritoneal cavity of the control animals contained more coloring matter after eight minutes than that from the adrenalin injected animal after sixteen minutes.

The work seemed to show that the use of adrenalin delays the absorption, elimination and transudation of other substances introduced in the body. The principal practical conclusion drawn was that in certain cases toxic materials introduced into the tissues might be delayed in their action by the use of adrenalin.

Discussion. — Dr. W. Gilman Thompson said that in his use of adrenalin therapeutically he had not observed that it had any effect whatever upon the kidneys and that it might do so experimentally because of the large dose or its continuous employment, but he doubted if it would do so in therapeutic doses.

Dr. H. A. Hare said that his conception of the action of adrenalin had been that it was quite brief in its effect and he was surprised to hear that it could prolong the effect of other remedies. He also called attention to the belief that the local application of adrenalin, through the ischemia produced, seemed to increase the danger of infection.

Dr. Meltzer, in closing, said that the popular conception of the action of adrenalin, as expressed by Dr. Hare, had its origin in a knowledge of its action on the blood pressure only. In some experiments he had been able to watch its effect upon the blood vessels for several hours. The effect upon non-striated muscle was much longer than that upon the striated muscles. He explained the delayed absorption and transudation by the theory that there exists a ring of contractile tissue around the pores of the capillary endothelium, and that the varying size of this ring, under the stimulus of the adrenalin, determines the rapidity with which other substances may pass through the pores.

POLYURIA IN TYPHOID FEVER. DRS. F. H. FUSSELL, H. S. CARMANY AND HUDSON.

Dr. Tyson reviewed the literature of typhoid fever to show the general opinion that as a rule the quantity of urine passed during the first week or ten days of this disease is usually diminished, that after the second week the quantity increases and that during convalescence it is almost invariably copious and of low specific gravity. Some authorities were quoted to show that polyuria occurs in a small percentage of cases and that, rarely, the amount passed may be as great as 10,000 cm.

The case which he reported was that of a married man aged forty, admitted to the hospital on about the eighth day of his typhoid fever with a temperature of 103°. On the day after admission his polyuria began and continued during the height of the fever. The

largest amount passed during one day was 7,200 cm. The amount of urea excreted was constantly normal in percentage. The polyuria lasted, to a greater or less degree, for a month, and during this period he was nervous and extremely thirsty. The patient has been under observation for a year since his recovery from typhoid and presents no evidences of organic kidney disease or diabetes.

Discussion. — DR. DOCK called attention to some work which had been done in regard to the retention of waters in fever, at the result of which the rule has been laid down that at first there is an actual retention of fluid in the body but that after defervescence the amount secreted increases until there may be a polyuria. He had been interested in noticing the effect of cold baths in typhoid upon the excretion of urine, and had found that where these were used there was not much retention during the fever. He therefore believed that the theory of treating fevers by "washing out" is to a certain extent possible. Dr. Withington inquired as to the nervous condition of the patient preceding the onset of polyuria, and Drs. Cabot and Osler both asked as to the connection between the polyuria and the typhoid, Dr. Osler pointing out the fact that in certain conditions, such as tuberculous peritonitis and retroperitoneal tumors, polyuria frequently occurred as the result of local irritation.

DR. W. S. THAYER remarked that the quantity of water the patient is drinking might play an important part in these cases, and spoke of some observations made by Dr. Cushing of Cleveland in this connection. He pointed out that typhoid fever patients probably do not always get as much water as they desire in spite of the liberal attitude of the physician in charge. Dr. Cushing has been carrying a rubber tube from the water tank to the bedside and attaching it so that the patient may suck water from it whenever he desires. He has found that these patients drink enormous quantities of water and pass large quantities of urine, and he is also under the impression that this is a beneficial feature in their treatment.

CASES OF VENOUS THROMBOSIS OCCURRING IN THE COURSE OF TYPHOID FEVER. DR. W. S. THAYER.

DR. THAYER presented an analysis of 42 cases of venous thrombosis occurring in the course of typhoid fever. Thirty-nine were instances of venous thrombosis that occurred among the 1,463 cases of typhoid treated in the Johns Hopkins Hospital; two were instances of this complication which were admitted during the period of convalescence and one was a man who had suffered from double iliac thrombosis coming on during typhoid fever but who entered the hospital for treatment two years later. In 5 of the 39 cases occurring in the hospital there was a fatal result; mortality 12.3%. In two instances the thrombus was the primary cause of death. As to the distribution of the lesions, the thrombus occurred in the lower extremities in 40 instances; in the upper extremity in one instance; and in the pulmonary artery in one instance. The vessel occluded was located on the left side of the body in 26 cases; on the right side in 5 cases; on both sides in 9 cases; no record in 2 cases. The particular vessels affected were: the femoral vein in 21 instances; the popliteal vein in 5 instances; the iliac vein in 5 instances; the internal saphenous in 3; the veins of the calf alone in 5; the axillary vein in 1; the pulmonary artery in 1; and the pulmonary artery and common iliac in 1.

In 36 of the 39 cases the development of the thrombosis was associated with fever. In 11 cases it was associated with chills. The first definite symptom of thrombosis in every instance was pain. In all of the cases there was swelling of the affected part and in some instances there was redness over the affected vessel. In 16 cases the thrombotic mass was felt as a palpable cord. Leucocytosis was almost always present and its extent depended, in part at least, upon the extent of the lesion, the highest count noted being 25,000 and the average count above 10,000. A study of the prognostic features showed that venous thrombosis in the lower extremity is always a serious complication of typhoid fever, and although the immediate danger is not great the after results are often grave; the affected extremity is often considerably and permanently enlarged, there is marked varicosity and usually more or less permanent disability when the femoral or iliac veins are affected. Thrombosis of the veins of the calf is less severe.

Discussion. — DR. PEABODY referred to the belief that the coagulability of the blood is increased by the presence of an increased amount of calcium salts in the blood and to the possibility that this could be overcome and thrombosis prevented by the administration of sodium citrate.

DR. STENGEL said that he had had a number of experiences with the appearance of the general symptoms produced by the thrombus before the local symptoms were noted. He had seen two cases of thrombosis of the pulmonary artery.

DR. WELCH called attention to the accumulating evidence in support of the old theory that the thrombosis in these cases originates from a primary inflammation of the walls of the vein — an infective phlebitis. This theory was once supposed to have been overthrown by Virchow, but the recent work of the French school, in particular, tends to show that although the question is by no means settled the inflammatory theory must be reconsidered. One of his assistants, Dr. Longcope, had recently gone carefully over these pathological specimens in his laboratory and demonstrated the presence of bacteria in over 70% of the cases.

DR. PRINCE said that, in this connection, he would like to report a case of typhoid that began with phlebitis of the veins of the leg. The patient was one who had previously suffered a number of attacks of phlebitis and presented the history of a gouty diathesis.

DR. CAREY referred to the marked disproportion between the general systemic symptoms and the local condition. He recalled one case where the local trouble did not seem to be very great but where the chills were as violent as in the vicious types of malaria. He believed, however, that most of these cases recovered entirely from the local edema.

DR. THOMPSON differed with Dr. Carey as to the ultimate results.

He had eight cases under observation for from six to ten years and in no one was there anything like complete recovery. All of them are weak and show dyspnœa after any exertion.

DR. TYSON questioned whether the pain which was such a marked feature of the thrombosis might not be due to the sudden vascular obstruction, and explained in the same way as that which accompanies angina pectoris.

DR. OSLER called attention to the difference in clinical picture between the hard, swollen, painful leg of phlegmasia albadolens and the condition described as occurring in typhoid. He said that he did not believe that the average experience with this condition would show quite such hopeless results as appeared in the report. He had known of a number of cases in private practice that had shown complete recovery and thought that the hospital had simply had an experience of an unfortunate series of cases.

CLINICAL STUDIES IN ARTERIO-SCLEROSIS. DR. ALFRED STENGEL.

The author had carefully studied the blood in a series of these cases. In measuring the blood pressure he used Stanton's apparatus in preference to the Riva-Rocci because it is devised to estimate both the diastolic and systolic curves. He does not believe that there is always high pressure where there is arterio-sclerosis. He had observed that the diastolic pressure is always high but the systolic pressure is not necessarily so; the mean pressure is generally high. He found a marked contrast between the appearance of the patient and the condition of the blood. In spite of the very marked anemia of the advanced cases there is often a high blood count and high percentage of hemoglobin. He had also noted that one of the first signs of arterio-sclerosis was a sustained first sound of the heart, and this prolongation was considered an important point in determining the early development of arterio-sclerosis.

Discussion. — DR. KINNICUTT asked whether the cases of low blood pressure that Dr. Stengel had encountered were in what might be called senile arterio-sclerosis, and said that his own observations had been that the blood pressure in senile arterio-sclerosis has been rather lower than that seen in pathological sclerosis.

DR. COHEN called attention to the fact that many elements enter into the production of high or low blood pressure, and that as only the net results are expressed by the measurements it is impossible to say whether the changes from normal are due to alterations in the vessel wall, the innervation or the cardiac force. He agreed with Dr. Stengel in the observation regarding the prolongation of the first cardiac sound and added that the sound is often impure in character.

DR. STENGEL replied to Dr. Kinnicutt that the cases of low pressure he had referred to were in pathological and not senile sclerosis.

AN INVESTIGATION OF THE EFFECTS OF CARDIAC STIMULANTS, ESPECIALLY STRYCHNINE, ON THE BLOOD PRESSURE IN FEBRILE CONDITIONS. DR. R. C. CABOT.

The cases included in this study were all febrile: 31 of typhoid, 4 of pneumonia and 15 with various diagnoses. In 32 instances the strychnia was given by mouth; in 18, subcutaneously. The records were kept for days and sometimes weeks before and after the drug was given. The measurements were taken with the Stanton modification of the Riva-Rocci instrument. The observations extended over eight months and included over 5,000 measurements.

Dr. CABOT's conclusions are, that strychnia does not raise or in any way affect the maximum or minimum blood pressure when given in the usual manner and

Discussion. — DR. STENGEL confirmed these observations and said that in some of his own work he had noticed that while this drug and others, even emotion, might cause a slight rise in the systolic pressure there was little or no influence exerted upon the diastolic pressure.

DR. HARE said he considered this paper of considerable value to the general profession as they had within the past few years come to look upon strychnia as a cardiac stimulant and to use it with the same energy that had formerly applied to the use of digitalis. Personally, he had been convinced that it not only did not act as a stimulant in fevers but that it sometimes retarded the patient's advance.

A SUPPOSED CAUSE OF HIGH TENSION PULSE IN NEPHRITIS. DR. W. H. THOMSON.

DR. THOMSON offered the following conclusions:

(1) High tension pulse occurs too early in nephritis to be due to any other cause than the presence in the blood of a general vaso-constricting agent, similar in its properties to adrenalin.

(2) Such an agent would also produce constriction of the renal vessels and general shrinkage of the kidneys, causing interference with the excretion of urea.

(3) Prolonged presence of such an agent in the blood would lead ultimately to endarteritis with degeneration of the vascular walls and to cardiac changes.

(4) Acute cardiac dilatation may occur from the effects of such a general vaso-constricting agent in the circulation before extensive alterations in the blood vessels have taken place.

(5) Aconite is the best vaso-dilator in nephritis, much more effective than the nitrites.

Discussion. — DR. PEABODY said that experience had taught him that aconite would materially increase the urea output even in cases where the arterial tension is abnormally low. The reason for this he could not give.

POISONING BY ILLUMINATING GAS. DR. W. G. THOMPSON.

DR. THOMPSON'S investigation was undertaken to determine the cause of death and of certain symptoms that are characteristic of poisoning by illuminating gas. The series of cases included 90, of which 17 were fatal. In New York there were 288 fatal cases in 1901, and probably 2,000 cases of gas poisoning occur there annually. This is due to the prevalent use of the gas stove and to the ignorance of the foreign population coming into the city. He described the effects upon the blood, and looked on carbon monoxide as the particularly poisonous element. He believed its action upon the nervous system is more important than the changes produced in the blood. A leucocytosis that lasts for many days is one of the features. The character of the fever is varied. A subnormal temperature may exist for hours and then be followed by a fever that persists high for a week or more. One case of hyper-pyrexia — 110° — reported. The nervous symptoms are varied and inconstant. They consist of tremors, anesthesia, rigidity, opisthotonos, headache, coma, mental disturbance, etc. Peripheral neuritis, sclerosis and changes in the brain and cord may follow as sequelæ.

The most satisfactory form of treatment had been phlebotomy and infusion of salt solution.

Discussion. — DR. STENGEL called attention to some experimental work that had shown that the transfusion of defibrinated blood had saved animals poisoned by coal gas even when venesection and infusion with salt solution had failed.

DRS. WEIR MITCHELL and SOLIS COHEN each called attention to the varying composition of illuminating gas in different cities, and even in a given city at different times. The last-named speaker and DR. PEABODY spoke of the difficulties in the way of procuring and using defibrinated blood.

DR. THOMPSON said, in conclusion, that these cases must be treated promptly, and salt solution is more convenient than defibrinated blood.

AN ANTITOXIN FOR SNAKE VENOM. A PERSONAL COMMUNICATION FROM DR. NOGUCHI TO DR. MITCHELL.

DR. S. WEIR MITCHELL read to the society a letter just received from Dr. Noguchi detailing the results of experimental work which he had been conducting under the auspices of the Carnegie Institute, in the

laboratories at Copenhagen. Dr. Mitchell explained that Dr. Noguchi had engaged upon this work with Dr. Flexner at the University of Pennsylvania two years ago, and having demonstrated his fitness to conduct such a scientific investigation and having outlined his plan of work the Institute had, at Dr. Mitchell's request, decided to provide him with the means.

The report of his studies was eminently satisfactory. He believes he has succeeded in preparing a certain antidote to the venom of the rattlesnake. The antitoxin will not operate against the toxins of other varieties of snakes, and he questions the work of others who have claimed to have discovered a universal antitoxin.

AFTERNOON SESSION. TUESDAY, MAY 10, 1904.

ABDOMINAL PAIN FROM UNSUSPECTED IRRITATION OF THE INTERNAL INGUINAL RING. DR. CHAS. G. STOCKTON.

The class of cases to which DR. STOCKTON referred presents the clinical picture of pain, generally located in the lower quadrant of the abdomen but occasionally in the upper as well, sometimes described as colicky, sometimes as misery, and, at others, as burning; there is rarely localized tenderness; occasionally there is a sense of abdominal uneasiness, a vague unrest, difficult to describe; at times the patient speaks of moderate disturbance of the intestine as though occasioned by intestinal flatus; generally these symptoms are relieved when the patient lies down, and, as a rule, exercise increases the distress; there is a marked tendency to recurrent attacks and the patient wanders from doctor to doctor, or becomes a drug fiend. The anatomical basis for these symptoms is to be found in a slightly over-patulous state of the internal hernial ring; not a condition so advanced as to admit of evident and easily recognized protrusion of the intestine or omentum, but one in which a slight bulging may be detected on palpation, when the patient undergoes abdominal strain such as is produced by coughing or bearing down. The sensation communicated to the finger is often quite unlike that of ordinary hernia. It is as though a very thin and almost unappreciable membrane presented at the opening with a sensation of elasticity as though a moderate gaseous pressure was operating behind it.

The symptoms presented so closely simulate serious abdominal conditions that many cases have come to unnecessary operation. The proper treatment is the application of a carefully fitted truss. The histories of twelve cases were given in detail.

Discussion. — DR. CAREY related the history of one case which had come to operation after the patient had become addicted to morphia and the mere trace of a hernial sac found and removed; the condition was relieved.

DR. PEABODY reported a case that had long been suspected of being appendicitis but was finally properly diagnosed and relieved by the use of a truss.

DR. BOND described a case simulating intestinal flatulence that was discovered to belong to this class.

DR. DOCK saw one in which the diagnosis was made, but, in addition, the man was supposed to have gallstones. The hernia was operated upon first and investigation of the gall bladder failed to disclose any trouble there. It was concluded that the colic in that region was simply reflex pain from the inguinal trouble.

THE MECHANISM OF EXOPHTHALMOS. DRS. W. G. MACCALLUM AND W. B. CORNELL.

An effort was made to determine experimentally the mechanism of exophthalmos by arranging an apparatus that would mark upon the smoked drum any movement of the eye, and then proceeding to alter the normal vascular and muscular conditions. It was shown that obstruction to the outflow of blood from the veins of the orbit produces at once exophthalmos which is relieved by the establishment of collateral circulation. This process is completed, however, so slowly that in the meantime the orbital tissue as well as the tissue of the face becomes very edematous, thus adding to the exophthalmus. Furthermore, entirely independent of any circulatory changes, there is an exophthalmos produced directly by the stimulation of the cervical sympathetic nerve. This protrusion is due to the peristaltic contraction of the orbital muscle tissue.

From these experiments no conclusions could be drawn as to the mechanism of exophthalmos in Grave's disease, but the possibilities are more closely defined.

DIABETES INSIPIDUS. DR. THOMAS FUTCHER.

DR. FUTCHER called attention to the fact that animal experiments have shown that polyuria follows lesions of a point in the floor of the fourth ventricle a little in front of the glycosuria center; also after injuries to various portions of the middle lobe of the cerebellum; and, after injuries to the posterior portion of the pons and the anterior part of the medulla. He divided the cases of diabetes insipidus clinically into two groups, the idiopathic cases, or those without evident cause and the secondary or symptomatic cases, those referable to some organic lesion or some known cause. Tumors of the medulla and floor of the fourth ventricle, basilar meningitis and cerebral hemorrhage are the commonest organic lesions causing the disease. He believed that cerebral syphilis is a cause in a much larger percentage of cases than has been generally suspected. A basilar syphilitic meningitis he considered to be frequently the lesion and looked upon a transitory bitemporal hemianopsia in a case of diabetes insipidus as strong evidence in favor of the disease being due to syphilis.

He stated that diabetes insipidus belongs to the rarest of the medical diseases. In fifteen years there have been but seven cases recorded in the Johns Hopkins Hospital and Dispensary out of a total of 403,535 patients. Five of these cases belonged to the symptomatic group, and of these four were undoubtedly syphilitic in origin. Thirst appeared to be the first symptom complained of in the majority of cases. In considering the treatment, Dr. Futcher stated that while it is very unsatisfactory as a rule, the cases which appear to do best are those of luetic origin; anti-luetic treatment almost invariably relieves the cerebral symptoms and occasionally causes a reduction in the thirst and polyuria.

Discussion. — DR. BAUMGARTEN asked if Dr. Futcher had observed any connection between diabetes insipidus and saccharine diabetes. He related the history of a case which first came under his observation twenty years ago as a young man with diabetes insipidus. A year or two later the disease took on the attributes of saccharine diabetes. There was never any suspicion or evidence of syphilis or cerebral disease in this case, and the patient eventually died of tuberculosis.

DR. THOMPSON related a case which was hereditary in character and in the treatment of which he had made careful estimations of the food and water taken and the amount of polyuria, and had shown that actually more fluid was excreted than was ingested.

DR. TYSON said that he had only seen six or seven cases in the whole course of his practice, but that in these he had been impressed by the fact that they were so largely relieved by potassium iodide.

Dr. Dock spoke of the prognostic differences of these cases and of the satisfaction with which he elicited the history of syphilis in any case, because he felt that the syphilitic cases were more favorable for treatment.

Dr. Jacobi thought that the frequency of diabetes insipidus is very much greater than hospital records would seem to imply, and gave as his reason the belief that the disease is quite frequent in childhood. He had seen it follow chorea minor, whooping cough, falls upon the occiput and probable cerebral tumors.

Dr. Futcher said that he did not wish to give the impression that the vast majority of cases of diabetes insipidus are due to lues, but merely that there are a greater number of cases due to that disease than has been generally supposed.

A CASE OF PROLONGED MALE HYSTERIA: WITH AUTOPSY. DRS. S. WEIR MITCHELL AND W. G. SPILLER.

Dr. Mitchell related in detail the clinical history of an hysterical man who had been under his observation more or less constantly for thirty years. He had watched it from the appearance of the first nervous symptoms to the development of peculiar muscular movements that were constant in character and uncontrollable by the patient except by the greatest effort on his part, or under the influence of hypnotism. The patient requested that after his death an autopsy should be performed under Dr. Mitchell's direction, and this was done, Dr. Spiller making a most careful examination of the brain and cord. Absolutely no lesion could be found.

Discussion. — Dr. Prince related the history of a similar case.

Dr. Putnam expressed the feeling that these continuous movements, which hysterical patients sometimes carry on, and the fact that they are carried on by dissociated centers and without signs of fatigue on the part of the patient are important, and that the so-called professional neuroses cause effects from much less motion than these hysterical patients are accustomed to carry out.

Dr. Wood said that in order to account for this thing it would seem reasonable to suppose that the nerve centers of organic life may take on some of the functions of the centers of inorganic life. He referred to the fact that the heart beats constantly for a period of many years, but leaves no record of its contractions, and suggested that perhaps, after all, it is not the muscular movement that leaves a cerebral record, but the volition thereto.

Dr. Mitchell thought that we might have expected to find some marked pathological evidence resulting from such long continued muscular actions, and in support of this view referred to the work of Dr. Hodge on the effects of fatigue upon the nerve cells.

SOME UNUSUAL FORMS OF ACUTE MYELITIS. DR. B. SACHS.

Dr. Sachs defined the term "acute myelitis" as a disease process causing a more or less rapid or a more or less complete destruction of the substance of the spinal cord at any given level, excluding, however, those forms which are due to large hemorrhages and to the breaking down of neoplasms.

The clinical histories of two very unusual cases were given, the first being a senile form of myelitis which had the characteristics of a spinal counterpart of the cerebral apoplexies which occur at that time of life, and the second was the record of a sudden development of myelitis in a young girl who presented the complication of multiple streptococcus abscesses.

(To be continued.)

Recent Literature.

Atlas of Operative Gynecology. By Dr. Oskar Schaeffer, Privatdocent of Obstetrics and Gynecology in the University of Heidelberg. Authorized translation from the German with editorial notes and additions. Edited by J. Clarence Webster, M.D. (Edinburgh), F.R.C.P.E., F.R.S.E., Professor of Obstetrics and Gynecology in Rush Medical College; Obstetrician and Gynecologist to the Presbyterian Hospital, Chicago. With 42 colored plates and many text illustrations. 138 pages. Philadelphia, New York, London: W. B. Saunders & Co. 1904.

This little book is a companion to the Atlas of Gynecology, by the same author and same publisher, which appeared in 1900.

The plates are carefully executed and show the steps of the operations clearly and the explanatory text is terse and satisfactory.

A noticeable feature of the operative technic is the use of double tenacula to bring the tissues into view, displacing the speculum almost entirely, in some of the operations as many as ten pairs being figured.

Although many of the operations are not those commonly practiced in this country, the book should prove of value to the medical student in making him familiar with the minutiæ of gynecological operating, an opportunity which is but scantily afforded him in most of the hospital clinics.

The Self Cure of Consumption. By Charles H. Stanley Davis, M.D., Ph.D. New York: E. B. Treat & Co. 1904.

This book adds another to the long list of those which have already appeared upon the treatment of tuberculosis, and barring some rather sweeping statements and inaccuracies, both typographical and otherwise, it will be of use in circulating knowledge about the disease and its treatment.

In Chapter VII the author declares that "without full and free exposure to outdoor air, regardless of all weather, no case of tuberculosis has been cured," a statement which can be disproved in many cases, while granting that the exceptions to this rule are decidedly in the minority.

The advocates of the use of tuberculin and of the x-ray as means of diagnosis will not agree to his sweeping condemnation of the former and his entire skepticism as to the efficacy of the latter in detecting pulmonary disease in its incipiency.

Inaccuracies like the statements of the altitude of the State Sanatorium at Rutland, the inexcusable mistake of using the word "sanitoria" in two places and several instances of vague and poorly expressed sentences suggest carelessness in preparation and the need of an intelligent proofreader before publishing a book which has a good deal that is useful in suggestion to the general reader.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 2, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

NEWER METHODS OF WATER PURIFICATION.

ONE of the most difficult problems presented to chemists, engineers, microscopists and others who are engaged in the study of public water systems is the prevention of the bad taste and foul odor which frequently prevail in the many water supplies throughout the country. In some instances the appearance of such foul tastes and odors is a matter of yearly visitation, and not infrequently is of such intensity as to induce very many to resort to the use of spring waters, some of which have been drawn from polluted sources, so that epidemics of disease have resulted from the use of waters, which, although clear and sparkling to the taste, yet were dangerously polluted.

The cause of the foul taste and odor is invariably found to exist in the presence of different sorts of algæ, which multiply rapidly in open reservoirs and ponds, and especially in ground waters which have been stored in such open reservoirs after pumping from the ground. This serious trouble has occurred in connection with many of the different water supplies of Massachusetts, notably at Springfield, Fitchburg, Brockton, Holyoke, Haverhill, Woburn, Waltham, Amherst, Orange, Concord and other places. At Newton, Brookline, Wellesley and Hyde Park the difficulty has been overcome by the introduction of covered reservoirs to exclude the light. But in the case of large, open reservoirs, this course is impracticable.

Within the past three years a series of experiments has been instituted by the Department of Agriculture at Washington, supplemented by the State Board of Health of Massachusetts, for the purpose of determining whether this condition might not be prevented. The report of Prof. George T. Moore and Karl F. Kellerman, published May 7, 1904, gives the results of these experiments, to the effect that extremely dilute solutions of sulphate of copper may be depended upon to accomplish the desired result of destroying objectionable algæ and preventing their reappearance. In addition to this valuable discovery is the possibility of employing the same agency, not only for the destruction of pathogenic organisms, but for the treatment of certain germ diseases. Dr. Salomon of New Orleans claims that by the administration of salts of copper, severe cases of typhoid fever became converted into a simple, benign fever, with recovery in ten or twelve days.[1]

The following summary of experimental investigations is published in the report of Professor Moore:

The disagreeable odors and tastes so often present in drinking water are due almost exclusively to algæ, although the economic importance of studying these plants has not been recognized until recent years.

These algal forms are widely distributed, and reservoirs in many states have been rendered unfit for use by their presence.

The methods now known for preventing or removing the odors and tastes caused by algæ have proved unsatisfactory, either because of prohibitive expense or failure to accomplish result.

It is, therefore, desirable that some new, cheap, harmless and effective method be devised for ridding reservoirs of these pests.

It has been found that copper sulphate in a dilution so great as to be colorless, tasteless and harmless to man, is sufficiently toxic to the algæ to destroy or prevent their appearance.

The mode of application makes this method applicable to reservoirs of all kinds, pleasure ponds and lakes, fish ponds, oyster beds, water-cress beds, etc. It is also probable that the method can be used for the destruction of mosquito larvæ.

At ordinary temperatures, 1 part of copper sulphate to 100,000 parts of water destroys typhoid and cholera germs in from three to four hours. The ease with which the sulphates can then be eliminated from the water seems to offer a practical method of sterilizing large bodies of water, when this becomes necessary.

The use of copper sulphate for the prevention of disease is regarded as incidental, and is not designed in any way to supplant efficient preventive measures now in use. It is believed, however, that up to this time no such satisfactory means of thoroughly, rapidly and cheaply sterilizing a reservoir has been known. Since the selective toxicity of copper sulphate renders it fatal to pathogenic forms peculiar

[1] New Orleans Medical and Surgical Journal, June, 1902.

to water, while the saprophytic or beneficial bacteria are unaffected, the method is particularly well adapted for this purpose.

Definite knowledge in regard to what organisms are present, the constitution of the water, its temperature, and other important facts are necessary before it is possible to determine the proper amount of copper sulphate to be added. A microscopical examination thus becomes as important as a bacteriological or chemical analysis.

No rule for determining the amount of copper sulphate to be added can be given. Each body of water must be treated in the light of its special conditions.[2]

In an editorial in the *Medical Record* of April 16,1904, we are surprised to find Professor Moore's announcement characterized in the most hasty manner as absurd " and contrary to all scientific views on the subject of water purification." But science is progressive, and the great discoveries of past centuries, the different applications of steam and electricity to locomotion and other purposes, the discoveries of medicine, anesthesia, and even vaccination have all been ridiculed in their turn. So far as Massachusetts is concerned, remarkable progress has been made in the study of its many public water supplies in the past twenty years. Its methods and discoveries have been adopted far and wide, since the state, through its board of health, has become recognized as a leader in scientific progress. The principles involved in the discovery of the normal chlorine of different regions, the covering of ground water reservoirs, the value of sand filtration, and other important matters connected with the study of water supplies, have proved to be of great value in securing to the people abundant supplies of pure water, and in reducing to a minimum epidemics of disease which in early years were of frequent occurrence.

The " simple, safe, effective and available " plan advised by the *Medical Record*, that of boiling the water, is applicable only to the individual taker, and is, consequently, utterly unheeded in the majority of instances. It cannot be applied to large bodies of water at the source or fountain head. Moreover, the foul tastes and odors for which a remedy was mainly sought by Professor Moore are but little influenced by the process of boiling. The dogmatic assertion of the *Record* that " simple drainage is always available for stagnant bodies of water of any sort," and that " scum can be easily disposed of by ordinary filtration," show a surprising lack of knowledge, both of chemical and engineering problems, " equalled only by the absurdity of the proposition."

The work of Professor Moore has passed the laboratory stage, and he reports several successful instances of the application of the copper treatment to large bodies of water, in proportions varying from 1 to 4,000,000 to 1 to 50,000,000. When we consider that millions of pounds of French vegetables, treated with quantities of the same substance in proportions vastly larger than those recommended by Professor Moore, are eaten without obvious harm to the consumer, the danger apprehended by the *Medical Record* fades out of sight.

[2] " A Method of Destroying or Preventing the Growth of Algæ and Certain Pathogenic Bacteria in Water Supplies," by Geo. T. Moore and Karl F. Kellerman. U. S. Dept. of Agriculture, Bureau of Plant Industry, Washington, May, 1904.

REPORT OF THE MASSACHUSETTS STATE BOARD OF INSANITY.

A PUBLIC document of perennial interest is the report of the State Board of Insanity, which has now completed its fifth year of service. The general activity which has been manifested during the past few years in the more adequate care and closer study of the insane is well exemplified in this yearly report, which shows unremitting activity on the part of those in charge in the attempt to solve the difficult problems which this class of dependents presents. A comparison of statistics for the last five years shows that there is an average annual increase of about four hundred individuals for whom public provision is required. This naturally leads to the complaint, which apparently can never be wholly allayed, of overcrowding in the public hospitals and asylums. At present there are in use 1,733 beds in corridors and day rooms, of which upwards of a thousand must be removed each morning to make sufficient space for patients during the day. The operation of the new State Care Act has furthermore led to the necessity of receiving at the state institutions about 650 insane inmates of almshouses. It, therefore, becomes at once apparent that there is imperative need of further accommodations, although the present situation will be in a measure mitigated by the liberal appropriation made by the last legislature. The board recommends that provision for the annual increase should be made in connection with existing institutions as follows: Hospitals for the acute curable class; industrial and home colonies for the quiet, harmless and able-bodied insane; infirmaries for the sick and feeble; buildings especially adapted for the care and treatment of chronic patients who are disturbed; farm houses for farm working patients; tuberculosis pavilions. In addition it

is recommended that separate houses be provided for nurses and private residences for superintendents.

On Oct. 1, 1903, the total number of insane in public institutions was 8,610. Adding to this number those in private institutions and certain others not counted in the original estimate, the total number is raised to 9,802, of whom 9,729 were permanent residents of the state. Interesting and important statements follow regarding the present status and the needs of the individual hospitals of the state, and statistics are also provided of smaller private institutions. The method of so-called farm care of the insane has apparently justified the hopes of its promulgators. One hundred and forty-four patients were so treated during the year, which was a gain of 26 over the preceding year. In general, this report affords information of the work being done throughout the state in this increasingly important department of medicine, and one may no longer doubt that the insane are receiving the care and attention and even the personal study and investigation which not many years since was certainly not the fact. It is to be hoped that this work, closely allied as it is in many respects to the other branches of medicine, may come into closer and closer relationship with the investigation of other forms of disease, and that a completer co-operation may exist between hospitals devoted to the insane and hospitals from which this class is excluded.

MENTAL DISEASE IN GENERAL HOSPITALS.

THE suggestion made in the preceding paragraph has been realized for many years in certain European hospitals, and is coming at last to be recognized as feasible in America. We refer especially to the possibility of a ward or wards in connection with general hospitals where insane patients may be studied and treated under the same conditions as those suffering from bodily disease of other character. A very interesting statement has recently been made in the May number of the *Albany Medical Annals* by Dr. J. Montgomery Mosher regarding the success of such an experiment at the Albany Hospital. Dr. Mosher describes the working of what is known as pavilion F of that hospital, which is devoted to the treatment of mental disease. He makes the comment that an illustration of the fellowship of mental and physical disease is given by the fact that twenty-four patients have been transferred to pavilion F from the other wards of the hospital. Certain patients, on account of the undesirability of forcible detention, are not received in this ward, but there are left, as a glance at the table of diseases shows, a large number of mental and quasi-mental conditions which might be treated with advantage not only, we believe, to the patients, but also to the hospital as a center of general medical effort. Naturally, these cases are largely of an acute sort, as are the other cases in the ordinary general hospital, and the element of observation and proper disposition must play an important part in the work of such a ward. Furthermore, this department of the Albany Hospital has been open to students of medicine under the same conditions as the other departments. The extraordinary neglect which the general subject of mental disease receives at the hands of the ordinary medical student is thereby in great measure obviated, and, even more important than this, the medical student is made to realize that diseases of the mind should be regarded as in the same general category with the diseases of the body.

We are glad to call attention to this progressive step on the part of the Albany Hospital. A similar plan was discussed some years ago in connection with the Boston City Hospital, but no definite action has, as yet, been taken. The example will, however, undoubtedly be followed by other prominent hospitals, and we may surely look forward to the time when this type of disease, as well as certain others which now are excluded in many institutions from the wards, will be given equal privileges with those diseases which apparently at the present time enjoy a special prerogative. A step in this direction has also recently been taken by New York in the approval by Governor Odell of a bill authorizing the city to establish a reception hospital for the insane. It is not our purpose, at this time, to discuss the relative merits of a system which will provide a separate hospital building for the observation of mental disease or the plan of devoting a ward in an already established institution to the same end. In general, however, we are inclined to think that the multiplication of institutions is undesirable, both for financial and scientific reasons, if arrangements in existing nstitutions may be made. The question is certainly one which must be seriously considered by all large communities in the very near future. The apparent success of the Albany experiment should at least serve as a stimulus to the more conservative.

ANNUAL REPORT OF THE SURGEON-GENERAL OF THE UNITED STATES.

The report of the Surgeon-general of the Public Health and Marine Hospital Service of the United States for the year 1903 is published in the same form as for previous years, with the exception that no transactions are included beyond the end of the fiscal year, thereby reducing somewhat the bulk of the annual report. Much of the matter heretofore published in the annual report is now presented in the several bulletins of the service, which also tends to reduce the size of the report. Naturally in a publication of this character a large part of the contents is concerned with statistical matter. That part which appeals rather to the general physician is the division of scientific research. This division of the service includes in its work a review of medical and scientific journals and careful indexing of all subjects concerning communicable diseases in relation to the public health. These references are naturally growing rapidly and should prove of positive value. It is clear from the perusal of these pages that there is much activity in various lines of original research, which is certainly one of the ends for which this department of the public service exists. The section of the report which is given the general heading of "miscellaneous division" includes various contributed articles and reports of autopsies, which is not only valuable as a report of unusual cases, but is again significant of the careful work which is now being done in the marine-hospital department. The report is embellished with a few excellent half tone microphotographs illustrating a case of *lipoma arborescens*.

MEDICAL NOTES.

Sir Henry Thompson's Memoirs and Fortune. — It is reported that Sir Henry Thompson, of London, left a fortune of £223,000, and some personal memoirs which are not to be published for ten years.

A Centenarian Life Insurance Policy Holder. — Charles Henry Booth died recently in Englewood, N. J., in his one hundred and first year. He took out a life insurance policy in the New York Mutual in 1843, and was supposed to be the oldest holder of a life insurance policy in the world.

Faculty Re-organization — University of Pennsylvania. — A plan for the re-organization of the Faculty has just been approved by the Board of Trustees, whereby the Faculty members ship has been extended to the Clinical Associated and Assistant Professors, to the Associates and Lecturers, and to limited representation from the subordinate staff. The scheme provides for an executive body or council, to be composed of the heads of the departments in the fundamental subjects and two representatives of the specialties. The plan will be put into effect Sept. 1, 1904.

Monument to Benjamin Rush. — The Rush monument committee of the American Medical Association announces that the projected monument to Benjamin Rush will be unveiled and dedicated June 11, on the grounds of the Naval Museum of Hygiene and Medical School in Washington. The introductory address will be made by the president of the American Medical Association; a eulogy of Rush will be given by Dr. J. C. Wilson, and the monument as a gift to the nation will be accepted by the President of the United States.

Dr. Charles A. Oliver Guest of the British Medical Association. — Dr. Charles A. Oliver of Philadelphia, Pa., has been chosen by the British Medical Association as its official guest from the United States for its seventy-second annual meeting, which is to take place in Oxford, England, in July. With him are associated Professor Hirschberg of Berlin, representing Germany, and Dr. Javal of Paris, representing France. During his stay Dr. Oliver will reside at Keble College as the personal guest of Mr. Robert Walter Doyne, the president of the ophthalmological section of the association and lecturer on ophthalmology at Oxford University.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, June 1, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 58, scarlatina 18, typhoid fever 7, measles 96, smallpox 0.

Death from Glanders. — A death from glanders is reported from Fall River, Mass.

Trauma as a Cause of Appendicitis. — A verdict for $4,000 damages was recently awarded by the Supreme Court, sitting in Boston, to the driver of a brewery wagon who was injured by collision with a car of the Elevated Railroad Company in August, 1890. The injured man had previously been in good health. There was

a blow upon the abdomen. In November, 1902, he was operated upon for appendicitis. The attending physician testified that the plaintiff had symptoms of appendicitis between the time of the accident and the time of the operation. The operating surgeon testified that trauma was a cause of appendicitis. For the defence there was expert surgical testimony that trauma was not recognized as a cause of appendicitis. The case apparently turned upon the question whether trauma was or was not a cause of appendicitis, and has an especial interest from that point of view.

NEW YORK.

A CENTENARIAN. — Carlos P. Scovill, the oldest ex-member of the legislature in New York State, died on April 27 at Lowville, N. Y., at the age of one hundred years. He was born in Collinsville, Lewis County, N. Y., on Feb. 26, 1804. Mr. Scovill served for some time in both the Assembly and State Senate, and afterwards as Surrogate Judge of Lewis County for eleven years.

PRESIDENT OF BOARD OF POLICE SURGEONS. — At a meeting of the Board of Police Surgeons held on May 23 Dr. Stephen G. Cook was elected president of the board for the eighteenth time. During the last municipal administration an innovation was made as regards the long prevailing custom of permitting the police surgeons to choose their own president, and General Greene, the police commissioner under Mayor Low, appointed Dr. Edward T. T. Marsh the chief executive of the board. The present commissioner, Mr. McAdoo, returned to the former practice and Dr. Cook was again elected president. It is announced that Dr. Marsh will shortly be retired on a pension.

Correspondence.

THE GAME OF QUARANTINE AS PLAYED AT NAPLES.

ROME, May 17, 1904.

MR. EDITOR: Before my vivid impressions of a recent experience fade, I am impelled to record a roughly outlined sketch, although I can do but scant justice to a scene in which were condensed more extraordinary and absurd incidents than are presented in the average comic opera.

Before going aboard a Messageries steamer at Alexandria which was bound for Marseilles via Naples, a few days ago, all passengers were required to sign a paper declaring upon honor that they had not visited certain ports on the Red Sea littoral (where the existence of bubonic plague was more than suspected) within ten days. This was truthfully done, in my own case at least, and the incident regarded as closed.

Next day, however, the ship was full of rumors of impending trouble with the quarantine authorities at Naples (of all places!), but reassured by past experience, and the well known laxity of the port officials, we settled down to the enjoyment of fine weather and a very fair sea boat. Three days later we came to anchor about a mile from the city and sat down to dinner while the (presumably) perfunctory sanitary inspection should be carried out.

The Naples contingent was looking forward with pleasurable anticipation to getting ashore at a seasonable hour and sleeping in comfortable beds, when a peremptory summons of "All table stewards on deck for quarantine inspection," left us to digest as best we could such portions of the meal as had been served. The worst had come, and gloomy predictions of long detention and inconveniences of all sorts were rife.

Half an hour later our waiters reappeared and the dinner ended far less cheerfully than it had begun; the tables were hastily cleared and all hands bidden to remain in the dining saloon, the doors of which were closed and guarded by quarantine officials of unsanitary aspect.

Presently we were herded on the upper deck, our numbers being loudly proclaimed as we filed up the gangway. Here we remained for quite a time, those of us who were near the staircase constantly peering over the railing and trying to see what was going on at the foot of the steps where three Italian officials were holding earnest council which lasted for what seemed an interminable period of time.

Suddenly they were joined by one of the ship's officers, who shouted: "But one hundred and seventy-seven and five, plus the insane English tourist, make a total of one hundred and eighty-three!" a statement which was instantly greeted with derisive laughter, and cries of "Bravo," "*Bien raisonne*" and "Quite right you are, old man," on the part of the passengers who, having failed thus far to extract much fun from the situation, now cut loose and entered into the spirit of the occasion which was almost unique, comprising as it did an attempt by the Neapolitan quarantine officials to be taken seriously, and to play the game for all it was worth. So general hilarity prevailed and we swarmed below again and awaited the next move.

There was apparently nothing doing, when I was casually informed by a fellow passenger (no announcement having been made) that it would be well to communicate with a solemn-looking person who was seated at one of the tables with official-looking papers spread out before him.

In answer to my inquiries he told me that such of us as intended disembarking at Naples must appeal before him to obtain their sanitary clearance papers, and at once proceeded, without question or delay, to furnish me with a document to which I shall refer later on. Soon the entire Neapolitan contingent was similarly equipped, the doors were thrown open and we were permitted to wander at will over the ship, but not to leave her until something further (nobody seemed to know just what) should be accomplished. At this junction about forty itinerant vendors of tortoise-shell and coral ornaments swarmed up the ship's side; but upon being asked if they "wished to acquire the bubonic plague" fled precipitately to their boats, the usual floating orchestras and singers, meanwhile, regaling all and sundry with "Santa Lucia," etc.

An hour passed when there suddenly appeared several reincarnations of Morgan and Kidd arrayed in particularly dirty yellow blouses reaching nearly to their boots. Some carried paste pots and pink labels, while others had bottles of disinfectants in the form of powders. What was done (if anything) with the latter I cannot say (if the bottles contained bichloride of mercury and they had swallowed it, I am confident that it would have been beneficial to the public health), but such of the buccaneers as carried the paste pots proceeded to affix the pink "etiquettes" (certificates of disinfection) to all the hand luggage.

At last we were free to depart? Not so, for one of the ship's officers rushed up and asked me, "What I supposed they said now, those idiots of sanitation?" and not waiting for a reply: "*Que toute la linge sale doit passer par l'éuve!*" 'But,' I objected, "everything is packed and each piece

is already certified." "That makes no difference — they are crazy — I have been here many times before, and have never seen anything like this — I beg you, for the love of God, to go and find something — an odd sock, an old undershirt, what you will, and deposit it on that commode at the foot of the stairway. Persuade your friends to do the same, or you will never get ashore, and we shall never get this sacred ship out of port!" I at once complied, but so far as I observed, with the exception of a young lady who tossed some sort of a garment from which hung a narrow blue ribbon near my personal offering to Hygeia and hastily withdrew, nobody paid the least attention to the order, and again we waited. Nobody's pulse or temperature had been taken, and aside from the names of the hotels where we intended staying, no questions had been asked. All at once a lot of children *from the steerage* were brought into the saloon for inspection. One of them had such a well-marked case of measles that a second year medical student could have diagnosed it correctly at a distance of twenty feet. This was the last straw, and the Latin element among us expostulated vigorously. One Frenchman made a speech in which the words "*terrible*," "*ignoble*" and "*effroyable*" were prominent. A lady of noteworthy pulchritude whom I tried to reassure by saying that it was only measles (a majority apparently thought it was a case of bubonic plague) immediately became quite hysterical — she had three children in Paris, and of course would carry it to them! But upon being told by a gallant fellow countryman that it was simply impossible that one so young could by any chance be "*mère de famille*," she calmed down, and smiled through her tears.

Meanwhile the children had been hustled out, the excitement gradually ceased, and at midnight a weary and angry crowd were landed in a tug. At the custom house the usual bribe produced the usual result. Nobody paid the slightest attention to our pink "etiquettes" or to the documents to which I have referred.

Mine informs me that "El Signor Smith e Signora are to be subjected to sanitary vigilance for the space of six days," and that "in accordance with the ordinance of Maritime Sanitation of Feb. 23, 1902, he must report himself to the health authorities of each commune that he may visit for a further period of ten days, or be denounced to the judiciary," etc. Something (surely it cannot be my New England conscience) tells me that I shall *not* report myself nor be "denounced" any more than I have been "subjected to sanitary vigilance." "What would you do," I asked the proprietor of my hotel, "if you had been served with a document like this?" His answer was a shrug and a motion to deposit it in the waste paper basket; but I reclaimed it and send it to you as documentary evidence,— a sort of "Exhibit A," — and remain,

Yours truly,

James A. Smith, M.D.

TECHNICAL TERMS MAY BE MISINTERPRETED.

The following correspondence, sent to us by a surgeon of the Boston Dispensary, explains itself:

To the Doctor at Dispensary: Please give this boy's hand attention as I think a bone is out of place.

Respectfully,

K. E. L., *Teacher, Public School.*

The note was endorsed by the surgeon: "There seems to have been a 'green stick' fracture of the metacarpal," and sent back to the teacher by the scholar. In due time it was brought back to the surgeon by the scholar with this addendum from the teacher: "I can't quite understand the chirography. Is that 'queer stick' or 'green stick'? In either case I am *happy* to say that the learned M.D. is mistaken as to the cause. Little 'Abie' loves his teacher and his teacher reciprocates to the extent of 'sparing the rod' in this particular case. All masculines are not exempt, however." K. E. L.

RECORD OF MORTALITY

For the Week ending Saturday, May 21, 1904.

Deaths reported, 3,481; under five years of age, 905; principal infectious diseases (smallpox, measles, scarlet fever, cerebro-spinal meningitis, diphtheria and croup, diarrhœal diseases, whooping cough, erysipelas, fevers and consumption) 927; acute lung diseases 556, consumption 444, scarlet fever 32, whooping cough 9, cerebro-spinal meningitis 87, smallpox 5, erysipelas 15, puerperal fever 13, measles 53, typhoid fever 54, diarrhœal diseases 132, diphtheria and croup 82, influenza 1.

From whooping cough, New York 5, Chicago 1, Philadelphia 1, Pittsburg 1, Lowell 1. From smallpox, Philadelphia 5. From cerebro-spinal meningitis, New York 82, Philadelphia 1. Boston 1, Lowell 1, Marlboro 2. From erysipelas, New York 4, Chicago 5, Philadelphia 2, Pittsburg 1, Boston 1, Lowell 1, Weymouth 1. From typhoid fever, New York 8, Chicago 5, Philadelphia 30, Baltimore 1, Pittsburg 6, Boston, Brockton, Medford and Newburyport 1 each.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending May 7, the death-rate was 14.9. Deaths reported 4,359; acute diseases of the respiratory organs (London) 83, whooping cough 195, diphtheria 51, measles 158, smallpox 5, scarlet fever 32.

The death-rate ranged from 43 in Smethwick, to 26.5 in St. Helens; London 14.9, West Ham 13.7, Brighton 12.4, Southampton 16.7, Plymouth 21.5, Bristol 13.1, Birmingham 17.0, Leicester 11.9, Nottingham 9.6, Liverpool 18.6, Bolton 13.9, Manchester 23.1, Salford 20.0, Bradford 16.3, Leeds 17.5, Hull 17.7, Cardiff 10.4, Rhondda 13.6, Wigan 19.1, Merthyr Tydfil 23.7, Reading 15.7, Wallasey 12.1.

METEOROLOGICAL RECORD.

For the week ending May 21, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING MAY 28, 1904.

C. D. LANGHORNE, passed assistant surgeon. Detached from the "Monongahela" and ordered to the "Denver."

H. L. BROWN, assistant surgeon. Detached from the "Lancaster" and ordered to the Naval Station, Guantanamo, Cuba, with additional duty on the "Monongahela."

J. H. IDEN, assistant surgeon. Ordered to the Naval Hospital, Philadelphia, Pa.

J. FLINT, assistant surgeon. Ordered to the Naval Hospital, Chelsea, Mass.

H. A. MAY, assistant surgeon. Ordered to the "Franklin."

E. EAGLING, pharmacist. Retired. Detached from the Naval Hospital, Yokohama, Japan, and granted leave abroad.

C. T. HIBBETT, surgeon. Detached from the "Franklin," June 1, and ordered to duty in charge of the Naval Hospital, Cavite, P. I., sailing from San Francisco, Cal., June 11.

A. R. WENTWORTH, surgeon. Ordered to the "Franklin," June 1.

P. A. LOVERING, surgeon. Detached from duty in charge of the Naval Hospital, Cavite, P. I., and ordered home to wait orders.

F. M. FURLONG, passed assistant surgeon. Ordered to the Naval Museum of Hygiene and Medical School, Washington, D. C., for temporary duty.

P. E. MCDONNOLD, assistant surgeon. Ordered to the Naval Museum of Hygiene and Medical School, Washington, D. C., for temporary duty.

J. L. BELKNAP, assistant surgeon. Ordered to the Naval Hospital, New York.

L. H. WHEELER, assistant surgeon. Ordered to the Naval Hospital, Chelsea, Mass.

E. EAGLING, pharmacist, having been examined by a retiring board and found incapacitated for active service, on account of disability incident thereto, is retired from active service, May 19, 1904, under the provisions of section 1453, revised statutes.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MAY 28, 1904.

CARTER, H. R., surgeon. Two days' leave of absence from May 26, 1904, under paragraph 189 of the regulations.

NYDEGGER, J. A., passed assistant surgeon. Granted leave of absence for fifteen days from May 6, 1904, on account of sickness. May 20, 1904.

CLARK, TALIAFERRO, passed assistant surgeon. To proceed to Duluth, Minn., for special temporary duty. May 20, 1904.

ANDERSON, J. F., passed assistant surgeon. To proceed to Hartford, Conn., for special temporary duty. May 20, 1904.

DUFFY, FRANCIS, acting assistant surgeon. Granted leave of absence for two days from May 25. May 23, 1904.

HOUGH, J. S., acting assistant surgeon. Granted leave of absence for thirty days. May 23, 1904.

HUNTER, W. R., acting assistant surgeon. Granted leave of absence for seven days from May 22. May 21, 1904.

WETMORE, W. O., acting assistant surgeon. Granted leave of absence for seven days from May 17, 1904, under paragraph 191 of the regulations.

HALL, L. P., pharmacist. To report to Chairman of Examining Board at Norfolk, Va., May 31, 1904, for examination to determine his fitness for promotion to the grade of pharmacist of the second class. May 23, 1904.

BOARDS CONVENED.

Board convened to meet at Washington, D. C., May 26, 1904, for the physical examination of candidates for admission into the Revenue Cutter Service. Detail for the board: Assistant Surgeon-general L. L. Williams, chairman; Assistant Surgeon-general W. J. Pettus, recorder.

Board convened to meet at Norfolk, Va., May 31, 1904, for the examination of Pharmacist L. P. Hall to determine his fitness for promotion to the grade of pharmacist of the second class. Detail for the board: Surgeon J. B. Stoner, chairman; Assistant Surgeon J. S. Boggess, recorder.

RECENT DEATHS.

THEODORE OSGOOD CORNISH, M.D., M.M.S.S., died in South Boston, May 23, 1904, aged eighty years.

EDWIN GAILLARD MASON, M.D., of New York, died at the home of his father, Dr. A. S. Mason, at Hagerstown, Md., on May 24. He was born at Hagerstown and was thirty-nine years of age. He was graduated from Bellevue Hospital Medical College in 1887, and practiced in New York throughout his professional career. For several years he was assistant professor of diseases of the nervous system at the New York Polyclinic Medical School and one of the editors of *Gaillard's Medical Journal*. Among the other positions that he held were those of vice-president of the New York County Medical Association and vice-president of the Southern Society of New York.

SOCIETY NOTICES.

AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. — The annual meeting of the American Gastro-Enterological Association will be held at Atlantic City, June 6 and 7, 1904.

AMERICAN OTOLOGICAL SOCIETY. — The thirty-seventh annual meeting of the American Otological Society will be held this year at the Hotel Chelsea, Atlantic City, N. J., on Monday and Tuesday, July 11 and 12, at 10 A.M.

FREDERICK L. JACK, M.D., Secretary.

CONFERENCE OF STATE AND PROVINCIAL BOARDS OF HEALTH OF NORTH AMERICA. — The nineteenth annual meeting of this organization will be held at Washington, D. C., Friday and Saturday, June 3 and 4.

GARDNER T. SWARTS, M.D., Secretary.

Providence, R. I.

APPOINTMENT.

Dr. Charles M. Green has been appointed Associate Professor of Obstetrics and Professor of Clinical Gynecology at the Medical School of Harvard University.

BOOKS AND PAMPHLETS RECEIVED.

The Therapeutics of Mineral Springs and Climates. By I. Burney Yeo, M.D., F.R.C.P. Chicago: W. T. Keener & Co., 1904.

The Practical Application of Cryoscopy to Medicine. By Henry W. Catteli, A.M., M.D. Reprint.

Annual Report of the Surgeon-General of the Public Health and Marine-Hospital Service of the United States. For the fiscal year 1903. Washington, 1904.

Transactions of the American Pediatric Society. Fifteenth Session. Held at Washington, D. C., May 12, 13 and 14, 1903.

The Extra Pharmacopœia of Martindale and Westcott. Revised by W. Harrison Martindale, Ph.D., F.C.S., and W. Wynn Westcott, M.B. Lond., D.P.H. Eleventh Edition. London: H. K. Lewis. 1904.

Radium, Radio-active Substances and Aluminum with Experimental Research of the Same. By Myron Metzenbaum, B.S., M.D. Reprint.

Specimen of Pseudarthrosis or False Joint of the Ulna. By Myron Metzenbaum, B.S., M.D. Reprint.

Malposition of the Head (Torticollis, Canted or Tilted Head), with resultant Ill-health, Spinal Curvature, etc., due to Eye-strain. By George M. Gould, M.D. Reprint.

Address.

PROGNOSIS; ITS THEORY AND PRACTICE.[1]

BY GEORGE DOCK, M.D., ANN ARBOR, MICH.

THE topic I have ventured to bring before you is "Prognosis; Its Theory and Practice." As a text, let me quote from the oldest work we have on this subject,[2] which, though old, still has the freshness and modernism that genius gives to human productions:

It appears to me [said the Father of Medicine] a most excellent thing for the physician to cultivate prognosis; for by foreseeing and foretelling, in the presence of the sick, the present, the past and the future, and explaining the omissions which patients have been guilty of, he will be the more readily believed to be acquainted with the circumstances of the sick; so that men will have confidence to entrust themselves to such a physician. And he will manage the cure best who has foreseen what is to happen from the present state of matters. For it is impossible to make all the sick well. This indeed would have been better than to be able to foretell what is going to happen; but since men die, some even before calling the physician, from the violence of the disease, and some die immediately after calling him, having lived perhaps only one day or a little longer, and before the physician could bring his art to counteract the disease, it therefore becomes necessary to know the nature of such affections, how far they are above the powers of the constitution. Thus a man will be the more esteemed to be a good physician, for he will be the better able to treat those aright who can be saved, from having long anticipated everything; and by seeing and announcing beforehand those who will live and those who will die, he will thus escape censure.

In this Hippocrates describes the essential importance of prognosis to the patient and the physician in relation to treatment. Besides this, prognosis is often important to relatives and dependents, not merely for reasons of sentiment, but in order to protect property and prevent unhappiness and destitution that would be as painful for the patient to contemplate as for the others to suffer. There is another aspect not present in the time of Hippocrates — giving the patient an opportunity to prepare himself for the anticipated life beyond the grave. In many cases, too, prognosis may have important bearings on political parties or for the commonwealth.

The patient very often ignores these needs. If he asks for anything, it is usually either the name of the disease or that of the medicine the physician intends to use. He really understands as little of the significance of the name as he does of the action of the drug, and is often more quickly satisfied in proportion as both answers are occult.[3] What really should interest him is, as clearly as his mental development permits, some idea of the changes in his body, anatomic and functional, their present seriousness, the chances of death, or of complete or partial recovery, with, in the latter case, the probability of temporary or permanent disability, near or remote, in some organs or functions.

Within the last century prognosis has lost some of its relative importance. Unlike etiology, diagnosis, prophylaxis and treatment, it has no special literature, and is only occasionally the subject of addresses or essays. But much of the so-called prognosis of the earlier periods was really diagnosis, as in Hippocrates' vivid description of empyema, and his remarks in regard to other diseases of the respiratory organs. It also seems a mistake to assume that practical prognosis was more accurate at any period than in later ages of equal enlightenment. While we may admit that great masters, like Hippocrates himself, Galen, Sydenham and Boerhaave, were remarkably accurate in their prognostications, there is no reason for thinking that the rank and file, following their rules without having their keenness of observation and precision of reasoning, were more accurate, or as accurate as physicians of a later period when the formal study of prognosis was neglected, but when other means of knowledge were greater than before. We must bear in mind a fundamental difference in methods. The older prognosis was based on the observation of symptoms alone, and consciously or unconsciously took the standpoint of humoral pathology or some equally imperfect theory. One charge against ancient prognosis is not as serious as some have thought, viz., that the prognosis was made without a definite diagnosis. Even now we sometimes have to be satisfied with a very imperfect diagnosis, and yet may make a very good prognosis, at least for the immediate future. But the older prognosis was almost wholly lacking in anatomic and totally without chemical basis. Realizing how far short of accuracy the diagnosis must have been in many cases, we can understand that prognosis must have failed almost as often. Moreover, in early medicine, most attention was paid to acute diseases, or the acute terminations of chronic diseases, so that the many important chronic diseases that now make so much of medical practice were comparatively neglected.

Whatever shortcomings medicine may have — and those who cultivate the subject most thoroughly feel the needs most deeply — it must be admitted that diagnosis is much more certain than ever before. Not only are we able to distinguish more quickly and more accurately many diseases long known, such as some of the acute fevers, malarial disease, tuberculosis, diphtheria and pneumonia, but we have learned

[3] Striking examples of the virtue of mysterious names are conspicuous in the practice of the popular sect of osteopaths. I could give many examples of the license with medical terms among these people, but as the evidence is derived wholly from patients I cite only one that can be vouched for by medical eye-witnesses. A hospital patient with typhoid fever, with the neck pain not infrequently felt in that disease, requested that his osteopathic physician be allowed to treat him. I was not unwilling, especially as the osteopath gave assurances that he would not attempt to treat the typhoid fever. Two internes "assisted" at the treatment. The osteopath, one of the *sang azul* of his class, after feeling the neck, announced that the transverse processes of three cervical vertebræ were displaced on one side. After some manipulation he pronounced the displacement relieved, though I was sorry to see that the pain was not much less than before.

the existence and the means of detecting many diseases formerly confused with others. As examples, let me name only a few, such as the diseases originating in the vermiform appendix and the gall bladder, diseases of the pancreas, many diseases of the blood, a large number of diseases of the nervous system and of the ductless glands, and many diseases caused by animal parasites, of which the sleeping sickness is the most striking example at present.

The older prognosis, far from being negligible, is really of fundamental importance. It gives the accumulated experience of ages that, untrammeled by detail, carefully noted broad and elementary features of disease. As gathered together in the aphorisms and prognostics of Hippocrates, and in the numerous commentaries on them — not always improving the original — it furnishes a fund of inestimable value, but like everything else in medical art, this knowledge is less useful when applied mechanically than when worked over in the crucible of personal experience, tested by other methods and transposed into current formulæ.

Older prognosis was possible to collect into fairly circumscribed space, but this is no longer true.[4] In proportion as diagnosis has become subdivided, specialized and enlarged, and as knowledge of morbid processes has become more complex, so prognosis has become more intricate. Older prognosis was based on broad, symptomatic lines, qualified in practice, we may be sure, by a consideration of the patient's constitution. The present basis is diagnosis, but of a different kind. It means not merely a recognition of the name of the disease, but a knowledge of the nature of the disease, still incomplete, but rapidly gaining in fullness and accuracy. In many cases we know the causes, and a good deal of the nature of the causes; in many more we know the seats of the disease, and the anatomic, chemical and functional changes that result directly and indirectly. It is by the study of the altered functions that we can make a prognosis and plan useful treatment without knowing the name of the disease. Clinical and anatomic investigations have been aided by experiments and observations on lower animals, without which our knowledge would have been much less certain than it is. Scores of technical methods have been devised for reactions and explorations; natural forces previously unknown, such as the x-rays, have quickly been pressed into service. Long and painstaking observations have thrown much light on complications and sequels, their nature and detection. From all these things the prognosis proceeds naturally in most cases, but here again an indispensable part is a just recognition of the patient's constitution. It is probably true that in this connection we unduly neglect some prognostic aids furnished by the patient, such as changes of the physiognomy. But, on the other hand, we have much more accurate methods of ascertaining the constitutional factor than were formerly available. Constitution is still a somewhat vague term, but we can speak of it here as the result of the functions of all the organs. While the method of representing these functions is still inadequate, we can safely assert that we have much more accurate means of determining the condition of the heart, arteries and veins and the force of the circulation than we had before; we have gone considerably beyond the recognition of the apoplectic habit in foretelling the danger of vascular disease. We can usually estimate fairly well the efficiency of the blood-forming organs; we can determine with reasonable accuracy the capacity for work of the stomach and intestines, as well as a few details of nutrition and metabolism; we are rapidly getting beyond the limitations of Falstaff's water doctor in fixing the anatomic and functional ability of the kidneys, and we are working toward methods of testing the functions of liver, muscles and nerves. When we have all these factors thoroughly investigated it is probable there will be little need of the *vis medicatrix naturæ*, now an essential part of prognosis.

In the conclusion resulting from these things there is no room for a supposititious clairvoyance, an intangible gift of prophecy, a hypothetic intuition that trained intelligence cannot equal or industry surpass. We have a positive foreknowledge, a prescience, a prognosis, corresponding in accuracy and usefulness to our diagnosis and often in advance of our treatment.

In the foregoing I have spoken of the theory. In the practical use of prognosis the first to profit by that function is the physician. With an accurate prognosis, based on exact and thorough examinations, knowledge of the natural course of the disease and of the patient, the physician foresees the course of the malady and is prepared for changes, emergencies and complications. He is thus enabled not only to preserve his imperturbability, so essential in carrying out necessary measures of treatment, but he can also prepare the patient to meet coming events in better physical and mental condition than otherwise, and, what is often of even greater importance, the self-confidence thus shown stimulates the efforts and the compliance of others concerned in the case.

It is not easy to say how much the patient should share this foreknowledge, and how it should be conveyed to him. In many cases the patient does not ask an opinion, and in many others, either because the present disease seems too slight or for other reasons, the physician does not proffer one. Yet it is good mental discipline to work out the prognosis in every case, as a complement to the diagnosis, and in many the results should be stated to the patient. Many things may conspire to make such statements act either favorably or unfavorably on the patient as on the physician.

Physicians, like other people, can often be classified as either optimists or pessimists. Not

[4] I have not attempted to include prognostic details, but would refer those interested to "Observations on Prognosis," by P. H. Pye Smith, Guy's Hospital Reports, vol. xliv, 1887, as one of the most comprehensive and suggestive articles in modern literature.

that these tendencies affect all parts of the individual's activities. One may be a perfect Pangloss in sociologic, political or climatic matters, and yet take a gloomy view of all his patients. (I am not speaking of those who, rarer in the profession than in some of its parasitic growths, habitually exaggerate the danger of their cases, making every angina a diphtheria, every erythema an erysipelas and every bronchitis a threatened pneumonia.) Another who is perpetually cast down by the failure of democratic government or the need of a stronger one, the immorality of the rich and the rule of the bosses, may meet every case with hope and cheer.

But the practice of prognosis should be cultivated as objectively as any other part of medicine. Not only the therapeutic indications suggested by it, but also the human ones, should be carried out without fear or timidity, without unnecessary harshness, but also without the false benevolence that often does more harm than brutal frankness or ignorance. Here, as in other departments of medicine, the welfare of the patient must be the touchstone by which the action proposed should be proved.

No disease should be looked on as insignificant. Nothing seems less becoming than to hear medical men speaking lightly of disease in general, or of any disease in particular. It is no consolation to the mother whose child has died of one of the rare complications of chickenpox to find that many physicians think that too trival to concern themselves with it. Nor does it increase confidence in the profession to have hysteria and neurasthenia considered imaginary and ridiculous evidences of perversity, while the impatience, not to say lack of scientific interest, sometimes shown toward other less well-defined neuroses, undoubtedly has some relation with the crowded ranks of followers of isms of all kinds.

In acute diseases the best general rule is still that of Hippocrates (Prognostics; 19, sect. II): "In acute disease it is not quite safe to prognosticate either death or recovery." A case of this kind, however, should not be considered likely to die unless from a complication, or from the effect of a pre-existing disease, though in certain diseases, such as scarlet fever and diphtheria, the danger of a sudden change and of death should be made known in the beginning. Of course, in cholera and plague, and even in cholera infantum, such information is rarely necessary. In some other acute diseases the study of prognosis prepares the physician not to be unduly elated by the remissions that are so reassuring to relatives. The temporary amelioration in meningitis and peritonitis, in which the patient seems almost free from symptoms, may be mentioned. Less disappointing, but still ominous, is the occasional lull in bronchopneumonia. But in the cases I have just mentioned it is rarely advisable to bring the unfavorable probabilities too strongly before the patient. In these we often need the effects of reassurance and of hope. For the latter, as we see it in medical practice, is not merely the "kind nurse of old age — hope — which," as Pindar says, "more than aught else steers the capricious will of mortal man"; in acute cases especially it is distinctly stimulating to physical and mental processes. Sir Dyce Duckworth,[5] speaking from a ripe experience, recently gave an address on "Hopefulness in Medicine," in which he emphasized this fact, and Niemeyer, equally successful in his career, at his medical promotion defended among others the thesis *medicus semper hilaris*. On the other hand, it is a serious error not to point out, after recovery from certain acute diseases, the possibility of sequels, sometimes months or years afterward, and the advantage of examinations at intervals for the purpose of detecting them before they become inveterate. The thorough examination of the urine at intervals after scarlet fever, of the lungs after pleurisy and all bronchitic diseases, of the heart and arteries after many infectious diseases, often has great practical value.

In chronic diseases there are few exceptions to the rule that the patient should be told the nature of his case as fully as possible. At least, in patients who can be made to understand, and who have a possibility of recovery, of definite improvement or of long duration, there are only individual exceptions. Patients with tuberculosis, heart disease, kidney disease, and disease of the alimentary tract cannot get the best possible results unless they understand why and how they should do certain things and why they should avoid others. Tact and patience and a knowledge of human nature are essential in this. The statements made should be as simple as possible, as brief as definiteness permits, without pathologic explanations. Better no statement than an unconsidered or an unintelligible one.

In talks of this kind we too often forget how different are the ideas of non-medical persons, even those who have studied physiology in the public schools, from our own, regarding the body, its functions and diseases. I am always interested in seeing how soon medical students lose the lay point of view, just as one forgets an unused foreign language, and how sometimes they never recover it. Yet unless they do, they lack valuable means of giving aid. Darwin has noticed how everyone who studies profoundly a subject often becomes unaware on what points the ignorant require information. Carlyle, as John Beattie Crozier tells us, imagined his stomach as some old teakettle, thickly encrusted with fur, and I have seen an otherwise intelligent man on the point of using strong sulphuric acid for a cough, because he found by experiment that oil of vitriol dissolved sputum more quickly than any other reagent he had tried. Nor is it enough to make the explanation. We must ascertain whether the statements are understood, and, if possible, whether they are accepted. How often, even with an intelligent individual, after we have stated the existence of a small tuberculous focus, and described the results of rational treatment, we

[5] Duckworth, Sir Dyce: Opening of University of Liverpool Medical School, British Medical Journal, Oct. 3, 1903.

find the patient shutting himself in a dark and close room, taking "lung cures," cough syrups and more or less medicated cod-liver oil; and how often, after demonstrating the sufficiency of dietetic treatment in a digestive disease, we find the patient taking bitters, digestive ferments, usually well neutralized by alcohol, antiseptics and other drugs less easy to classify. So time and patience must be devoted to this part of the work, and we should never be discouraged by failure. I am convinced that there is an improvement in the possibility of carrying out rational treatment, notwithstanding the insidious propaganda of useless or dangerous methods in and out of medical journals.

It is much easier to advise in cases that have a strong tendency to recovery than in those that have not, and there is room for difference of opinion and of practice in the latter, because the conditions vary with patients according to individuality and accidental factors. A number of aspects present themselves for consideration. In the first place, there is often an element of diagnostic or prognostic uncertainty, where the prospects are better than they seem. Sir Dyce Duckworth [6] has formulated universal experience in pointing out the advantages of the "cautious 'if,'" and if the alternative accepted is the hopeful one, much good can be accomplished in many cases. An interesting example is given by Kussmaul in his fascinating "Jugenderinnerungen." Having made a reputation as a zealous dissector, and having won over his confiding peasants to the many advantages of post-mortem examinations, he was asked by the father of a girl with advanced tuberculosis of the peritoneum to arrange for an autopsy on the daughter, when she died. Although Kussmaul, too, thought the daughter was lost, he retorted that he could not speak of an autopsy until the patient was dead. Notwithstanding many obstacles, the girl recovered. The tendency to take the less hopeful alternative is still shown in some cases of tuoerculous disease in stages not far advanced, though it is not so common, fortunately, as it was not many years ago, to see such patients given over either to a life of dissipation or of abject despair. The prognosis of valvular disease of the heart is also in a much more optimistic vein than it was fifty or even twenty-five years ago. However, in many cases the prognosis needs to be tested by a therapeutic "if" that is not as well recognized as it deserves. The physical conditions may seem hopeless, and yet if the action of the heart can be improved the case may assume a very different aspect. The advantages of trying were well illustrated by a case in which a woman with aortic and mitral insufficiency and moderately severe loss of compensation was given up as beyond treatment by her family physician. Not knowing this I told the relatives the impossibility of complete recovery, the danger of sudden death or more probably rapid failure at any time, but also the possibility of improvement and a fairly comfortable life for some time, all the more worth trying to realize, because the condition was not complicated by medicinal action, and the other important organs showed no serious alteration. The family physician then wrote me admitting that he had stated improvement was out of the question, and treatment not worth trying, although under subsequent treatment the patient lived two years and nine months.

In cases hopeless in a more certain degree than such as I have just mentioned, it too often happens that treatment is abandoned too early in the case. Patients with cancer of the stomach or other inoperable tumors, cirrhosis of the liver, and many other diseases are permitted to drag out their existence without relief. There are several reasons for this. Sometimes families, having been told the truth about such a patient, refuse all further medical aid, even when the conscientious physician who gives the information points out what can still be done.

Many physicians voluntarily discontinue attendance when they realize that the end is inevitable, with the feeling, doubtless, expressed by Sir William Temple. The latter said that "an honest physician is excused for leaving his patient when he finds the disease growing desperate, and can, by his attendance, expect only to receive his fees, without any hopes or appearance of deserving them." This, however, ignores the fact that in such cases the accomplished physician can often do more real good to the patient than in many cases that recover, while the opportunities for obviating despair, alleviating pain and soothing mental anguish, and for exhibiting thoughtfulness, gentleness, persistence and variety of resources, are more valuable to the physician than any fee. Even in acute cases it sometimes happens that the physician is either discharged or withdraws because the indications seem hopeless, and I have known of patients with pneumonia living for one or two days in this way, the family waiting for the end of a life that with greater effort might have been saved. Sir Francis Bacon described this tendency as one of the deficiencies of medicine, "so that Sylla and the triumvirs never proscribed so many men to die as physicians do." For, as he continued, "the office of a physician is not only to restore health, but to mitigate pain, and not only when such mitigation may conduce to recovery, but when it may serve to make a fair and easy passage."

Improvement in methods of treatment have an important relation to prognosis, in that many diseases, considered hopeless at one stage of knowledge, may in another offer many chances for recovery or alleviation. In this connection a critical knowledge of current medical literature is necessary, and a realization of the value of medical evidence. Few things can be more disastrous to the physician's mental development — never completed — than constant change of therapeutic method, but there are differences. One need not try every drug proposed for the treatment of typhoid fever or pneu-

[6] Duckworth, Sir Dyce: Address on Medicine, British Medical Journal, 1896, ii, p. 251.

monia, nor every new antipyretic or hypnotic. But the physician who does not inform himself quickly of the value of surgical treatment in various diseases as it is developed, in pelvic diseases, brain diseases, diseases of the appendix, biliary tract, stomach and pancreas, comes very near deserving the reputation of an unscrupulous practitioner. In these departments, too, mistakes are made and exaggerations are inevitable concomitants of progress, but the gain is often distinct and unmistakable, and often changes the prognosis from one extreme to the other.

It may seem that I have taken a too purely medical view of the practice of prognosis. Can we always act from the standpoint of simple diagnosis and prognosis, or must we not at times take into consideration the weakness, fears and prejudices of people? In trying to get the best light on this subject I have for many years noticed the opinions of patients and their relatives, as well as of non-medical writers, and it is instructive to learn how those who are not physicians approach the subject. Many physicians have been influenced by the views of Percival, from whose interesting work on Medical Ethics some of the best parts of the old Code of the Association were taken. Percival said:[7]

> A physician should not be forward to make gloomy prognostications, because they savor of empiricism, by magnifying the importance of his services in the treatment or cure of the disease. But he should not fail, on proper occasions, to give to the friends of the patient timely warning of danger, when it really occurs, and even to the patient himself, if absolutely necessary. This office, however, is so peculiarly alarming, when executed by him, that it ought to be declined whenever it can be assigned to any other person of sufficient judgment and delicacy, for the physician should be the hope and comfort to the sick; that by such cordials to the drooping spirit he may smooth the bed of death, revive expiring life and counteract the depressing influence of those maladies which rob the philosopher of fortitude and the Christian of consolation.

In general, this furnishes a useful guide to conduct, but nevertheless requires some examination. Part of it reminds one of the maxim of John Halle, who as far back as 1596 wrote:

> With one consent uniformlye
> Comfort the wounded man,
> But unto some good friend of hys
> Express all that you can.

In the first place, the truth is not always so alarming to the patient, painful as it often is to the physician. In fact, it seems to me this is one part of our duties that does not become less trying with increasing experience. To the sick man, whose thoughts have been turned toward the end longer than others suspect, intimation of a fatal end often brings no shock, but rather relief from the ending of a painful uncertainty. According to the rules of the Roman Catholic Church, a timely announcement should always be given, and those who have witnessed the last days of members of this faith can confirm the statement that good often follows, speaking merely from the medical standpoint, and rarely harm, while the same thing is true of many of other faiths or of no faith. Even where we have to give a fatal prognosis there are certain mollifying influences that can be introduced, aside from those that spring from a tender heart. A hope can be expressed based on the fallibility of human knowledge in general and medical knowledge in particular.

The rule in regard to giving the patient a good prognosis and the relatives a bad one, can often be followed, but is a very fallacious one on the whole. It is often more necessary to keep up the spirits of the relatives, especially those who have to nurse, than those of the patient, so that sometimes the rule can be reversed with advantage. Darwin[8] cites some interesting and instructive examples of this kind, from his father's practice, and Billroth[9] has expressed himself with much feeling in one of his letters. Moreover, the relatives informed, either from a feeling of compassion or otherwise, may not bring the patient to act on the information, and I have known of serious financial loss befalling a family because the relative entrusted with the task of breaking the news to the patient did not do this. Another risk is that the relatives may divulge the fatal prognosis in such a way as to put the physician in the light of a heartless deceiver, and thereby cause the patient to lose all confidence in him. On the whole, in cases where the patient should know the truth the physician is often the best one to state it, and he should see that this is done before it is too late.

Exceptions to the rule of candor may occur in the case of children, in women with no spiritual obligations or business responsibility, or in

[7] Medical Ethics: or a Code of Institutes and Precepts, adapted to the professional conduct of physicians and surgeons, with an appendix containing a discourse on hospital duties: also notes and illustrations, by Thomas Percival, M.D., Manchester, 1803, p. 31.

[8] The Life and Letters of Charles Darwin, edited by his son, Francis Darwin, New York, 1887, vol. i: "Called in to see a patient who had been given up to die by the family physician, Dr. Darwin took a different view of the matter and maintained that the man would recover. He was found quite wrong in all respects, and owned his error. He was convinced that he should never again be consulted by this family, and was much surprised at being called in after a few months by the widow. He asked a friend of the widow to find out why he was again consulted. The widow answered that she would never again see the odious old doctor who said from the first that her husband would die, while Dr. Darwin always maintained he would recover. In another case Dr. Darwin told a lady that her sick husband would certainly die. Some months afterward he saw the widow, who was a very sensible woman, and she said, 'You are a very young man, and allow me to advise you always to give, as long as you possibly can, hope to any near relative nursing a patient. You made me despair, and from that moment I lost strength.' 'My father,' continued Darwin, 'said that he had often since seen the paramount importance for the sake of the patient of keeping up the hope, and with it the strength, of the nurse in charge.'"

[9] Briefe von Theodor Billroth, 1902: Speaking of the slow decline of Professor Breisky, and of the attending physician telling the whole truth to the wife, he remarked: "I admit that under certain circumstances this is necessary: but here I do not think it is necessary. How can the poor wife, without a glimmer of hope, bear the weeks until the Liberator of all sorrows gently approaches the husband. We should give her courage, and the poor patient morphine. A hard task. But let us remember that every family physician is in this situation hundreds of times, and often has to see his incurable patients daily. If the young man suspected these mental tortures when he enthusiastically enters the temple of Æsculapius he would surely often turn back. To face the unveiled figure of Sais requires all the undaunted resignation that we slowly win in our profession."

exceptional cases in men. No general rule can be laid down, but that such exceptions occur can be confirmed probably by every physician. A striking example of this is quoted by Darwin.[10]

Of course, this part of the subject is closely related to the theory of ethics, and many writers on this subject have touched directly on the question of medical veracity with, as one might anticipate, diametric differences of opinion. Some moralists of the strict school of Kant and Fichte insist that any deviation from the absolute truth is wrong in medicine, as they assert that it would be wrong even for the purpose of saving the whole race. Others believe with Paulssen, who says: "There is not a physician in the world who does not give deceptive answers to his patients, who does not excite hopes that he does not share. He does not blame himself, nor do others, for everyone does the same." Johnson, "the stern old moralist," in his remarks on the subject, laid open a serious flaw in his own logic: "You have no business with consequences, you are to tell the truth." But surely the physician's chief interest is with the consequences, and if he thinks the patient can gain only by misrepresentation, it is just as proper for him to use it as it would be to give a medicine that in other cases might be quite improper. But the physician in such a dilemma would do well to bear in mind the next sentence in Johnson's *ipse dixit:* "You are not sure what effect your telling him that he is in danger may have. It may bring his distemper to a crisis, and that may cure him." Jonathan Dymond, as strict as any one in his morality, threw a gleam of stern humor into the discussion: "Persons frequently employ falsehoods to the sick man who cannot recover, lest it should discompose his mind. This is called kindness, though an earnest preparation for death may be at stake on their speaking the truth. There is a peculiar inconsistence sometimes exhibited on such occasions. The persons who will not discompose a sick man for his interest in futurity, will discompose him without scruple if he has not made his will."

This part of the discussion might be indefinitely prolonged, but I think we can never get far away from the principle I intimated in the beginning — that in practical prognosis we must individualize, just as we have to in therapeutics, with the patient's welfare ever the object of our activity.

Accidents that follow an unfavorable prognosis occasionally suggest a revision of methods. I have already alluded to the error formerly not uncommon in the treatment of tuberculous patients. More acute results sometimes follow a fatal prognosis, as in two of my patients who resorted to suicide. One was a man with far-advanced carcinoma of the stomach, to whom I recommended palliative treatment and advised against a useless effort at radical treatment. The patient left for his home, but threw himself from a fast train and was killed. In another patient, a man with a large kidney tumor, apparently with many adhesions, my surgical colleague and I advised against an operation. The patient went to another hospital, and apparently received similar advice, for he shot himself through the tumor, and died in a short time. From a broad biologic standpoint it does not, of course, make any difference whether an individual organism dies as either one of these, or as it would if left to its fate. But no matter how one may feel on the subject of suicide, I have always thought these men less fortunate than another patient with carcinoma of the stomach, also far advanced. To him, in advising against an operation, I added that if he could find a good surgeon who was willing to operate, he might submit. He underwent the operation at the hands of one of the most distinguished surgeons in the country, and died on the table. In such a case the result is often unfortunate, because it prevents operations on other and more promising cases, but for the man himself, fighting to the last, it seems to me one can have only respect.

This brings up a question on which a few words may be proper — the question of euthanasia. Every few months some one — usually not a physician — proposes that people with incurable diseases should be killed by some painless method. The plan offers so many opportunities for crime that it would be difficult to carry out, but aside from that it involves important principles. The difficulty of telling when the proper time had come would often be insuperable. Aside from examples of fortitude and other virtues exhibited by the dying, how much the world would have lost if a chronic invalid like Stevenson had the cord of his life snapped at one of the times when the *aes triplex* of his soul seemed battered through! To take a less selfish view, we can think of the "pictures of human patience, the visions of ripened character, which have been revelations and inspirations to generations of mankind" (Phillips Brooks), and see these repeated daily in sick rooms of all degrees, while the self-sacrifice and kindness developed in others at such times cannot but be of untold benefit to the race. To most physicians the suggestion of any planned shortening of life must be abhorrent. For countless generations they have been doing their utmost to lengthen life and lessen disease. They have shown how to prevent the plagues that formerly made life almost as bad as a perpetual illness for the survivors, and they have also shown how many deaths can still be prevented. On the other hand, they can, in most cases, so treat the dying man that the bitter anguish often associated with death is absent, that life is not only less painful but, actually longer, so that they will continue to follow the rule of the Father of Medicine, and "give no deadly medicine to any one, even if asked, nor suggest any such counsel."

[10] *Op. Cit.* "He was sent for by Mr. P., who said, 'From all that I have seen and heard of you I believe that you are the sort of man who will speak the truth, and if I ask you will tell me when I am dying. Now I much desire that you should attend me, if you will promise, whatever I may say, always to declare that I am not going to die.'"

Krompecher [1] has called attention to a peculiar superficial tumor of the skin, which he places in a class by itself because it is neither typical carcinoma nor typical adenoma. Clinically they appear as fungoid tumors or as ulcers occurring most frequently in the skin of the face or of the female breast. They may occur on other parts of the body, but never at the junction of mucous and epidermal surfaces. Histologically they originate from the Malpighian basal layer or its embriologic equivalents. These tumors have been observed and described by several authors, but Krompecher was the first to give a full description and recognize their peculiarities. Since the appearance of Krompecher's article, I have examined thirty-seven tumors of this variety occurring in thirty-five cases. The tissues were fixed in alcohol, formalin, solutions of mercury and Zenker's fluid and stained with various reagents. They were infiltrated with either paraffin or celloidin, and studied in serial sections in all cases except one in which only two sections of the tumor were obtained.

Because of the great similarity of these cases clinically, the chief features pertaining to their clinical course are summarized in the following table:

[1] Ziegler's Beitrage, 1900, xxxviii, 1.

CLINICAL NOTES.

Case I. The tumor became painful a year before the operation, and during the last three months was growing; at the time of the operation the surface was nodular, shining, elevated .5 cm. above the skin level and extending .5 cm. below, and caustic.

Case II. A slightly elevated tumor, having an ulcerated center and a slight depression around it.

Case III. Began as a papule, and after first removal by caustic three years ago grew more rapidly; was excised one year ago when it appeared as a fungoid ulcer 2 mm. above the skin level, having irregular raised edges.

Case IV. Began as a small nodule, which ulcerated and was removed after a few months. At the time of removal there was an ulcer with moist, crusted, raised floor and irregular, indurated edges.

Case V. A flat ulcer with irregular, indifferent edges and moist floor.

Case VI. Began as a papule, which ulcerated and grew slowly, involving the nose and cheek to the outer side; the base was seropurulent.

Case VII. Began as a pin-head-sized papule, which ulcerated and was twice removed. It now has a moist, grayish floor with raised indurated edges.

Case VIII. Began as a small "sore" and grew slowly till the present time, now being an irregular ulcer with raised and telangectatic edges.

Case IX. Began as a small papule, which soon ulcerated, then slowly extended over the surface. The floor is now covered with a thin, shiny epidermis, broken in many places, forming small ulcers. The border is nodular, infiltrated and 2 mm. thick.

Case X. The tumor had existed as a red spot for ten years; six months ago it began to grow. The tumor is firm, movable, superficial, elevated ½ cm. above skin level and has no line of demarcation. The summit is depressed and ulcerated, the surface being fungoid in appearance.

Case XI. Began as a small papule, which soon

For Case 8 I am indebted to Dr. Hugh E. Montgomery, and for cases 6, 9, 11, 12, 13, 33 and 34 to Dr. E. V. Brown.

ulcerated; when it reached the size of a nickel it was removed by a plaster.

Began as a small papule and soon ulcerated; it grew until now there is an ulcerated, cauliflower-like mass filling the orbit.

CASE XII. Beginning as a dark papule, which remained stationary for several years; it suddenly began to grow, and in six years from its appearance it had involved the entire orbital contents, producing an ulcerating fungoid mass.

CASE XIII. A small pimple was first noticed; this ulcerated and was cauterized two years after. At the time of operation there was present an ulcer with moist, scaly floor and indurated, raised borders, involving both eyelids and the outer canthus.

CASE XIV. Began as a small pimple and grew till time of operation; it never ulcerated nor caused pain.

CASE XV. Began as a small pimple and grew steadily. At the time of operation it appeared as a flat tumor with pebbly surface, ulcerated in small areas and in part covered with a thin, shining, bluish skin.

CASE XVI. Began as a small tender area, which was removed while no larger than a grain of corn. At the time of operation there was a bleeding and sloughing ulcer 1 cm. deep, the edges being hard and red.

CASE XVII. A small growth was present on the eyelid for several years; it then ulcerated and gradually grew in size.

CASE XVIII. A pimple was noticed in the external meatus, which broke down, forming a shallow, painless and slowly growing ulcer.

CASE XIX. At the time of operation there was a slightly nodular tumor, painless and with a small ulcer at its summit; the cut surface was caustic.

CASE XX. A slight swelling first appeared, which in two weeks broke down and would not heal. At the time of the operation the floor of the ulcer was covered with a serous exudate; the edges were raised and indurated. The lesion was painless. The cut surface was striated.

CASE XXI. There was a slowly growing, painless tumor for twelve years. Nine months ago the lip was struck, and the abrasion produced over the tumor refused to heal. At the time of the operation there was an ulcerating, papillomatous tumor.

CASE XXII. Began as a small pigmentation, painless and slowly growing. The surface was rough and covered with comedones. It was raised 1 mm. above the skin and freely movable with it.

First noticed as a small ulcer, which grew slowly and was attended by itching. The surface was depressed and granular; the edges were indifferent.

CASE XXIII. Began as a small, bluish pimple attended with pricking sensations. A year ago it was punctured and healed over. At the time of operation it was an elevated nodule, rough and telangectatic. The cut surface was cystic.

CASE XXIV. First noticed as a pin-head-sized, painless papule, bleeding easily when irritated. At the time of operation it was a flat nodular tumor elevated ½ cm., the surface covered with rough, pebbly growths, hair and dirty sebaceous material. The overlying skin was thin, shiny and tender.

CASE XXV. Began as a shot-like papule, which grew slowly for years. During the last six months it has ulcerated with a sticky secretion. At the time of operation there was a small, elevated, painless nodule, freely movable and ulcerated at the summit.

CASE XXVI. Scratched the ear on the limb of a tree. The wound healed but remained tender. Three months ago it broke down, forming a crater-like ulcer.

CASE XXVII. Began as a pimple, which grew slowly. Three months ago it became an ulcer with moist, granular floor and raised indurated edges.

CASE XXVIII. Began as a pimple, which, after being repeatedly shaved off, formed a shallow, bleeding ulcer, slowly increasing in size.

CASE XXIX. A small swelling had been present for twenty-four years, then it began to grow slowly. Sixteen years later it ulcerated, forming crusts, but was never painful. At the time of removal there was a clean, ulcerating surface along the margin of the lower lid, which was slightly indurated, the edges being irregular, but neither undermined nor elevated.

CASE XXX. Had existed for many years as a papillomatous growth without pain and with only slight increase in size.

Was first noticed as a hard nodule, which slowly increased in size without ulceration or pain. At the time of removal it was subcutaneous and movable with the skin, the summit soft and the base hard. The cut surface was caustic and calcareous.

CASE XXXI. First noticed as a small sore which would heal at times. It was never painful, but a week before removal presented prickling sensations. At the time of removal there was a thin, flat growth with an ulcer in the center, having an irregular, indifferent edge and a scale-covered floor. It was freely movable.

CASE XXXII. Three years ago two warts on the left cheek began to grow, soon ulcerated, and coalesced two years ago. They were slightly painful. At the time of removal there was an elevated, fungoid ulcer with a purulent floor and indurated telangectatic edges.

CASE XXXIII. Began as a small raised point which grew slowly and ulcerated later. The ulcer was shallow and moist with indifferent, irregular edges.

CASE XXXIV. Began as a small "sore" on the lower lid, finally involving both lids, the eyebrow and a portion of the cheek. The ulcer was grayish, purulent, fungoid mass with irregular raised edges.

CASE XXXV. Began as a small, painless, scaly wart and grew slowly for years, healing and ulcerating alternately. Six months ago it was treated with an electric needle, and a month ago with paste, which aggravated the condition. It is now an ulcer, ½ cm. deep, with a clean granular floor and irregular, slightly indurated, elevated edges.

As may be seen by a study of this table, some very interesting facts, associated with the clinical histories of these cases, are made apparent. Surgical intervention was sought, as a rule, only after the tumors had existed for a number of years; this is directly attributable to their seeming insignificance. The duration of the growths, which was obtained in all but four cases, varied from forty years to two months and averaged over eight years. The average age of the patients was fifty-one years. Recurrence was observed in eight cases, and in a few the time is so short since removal that no statement concerning the tumor would be of value. Where careful search for the involvement of the lymphatic glands was made, it was invariably wanting. The tumors are all small, and in all cases were located on the upper two thirds of the face. In four cases there were two tumors at the same time; in Case XXII the elevated tumor on the right ala had existed for a number of years before the ulcerated, depressed tumor, 1 cm. above and external to the angle of the mouth, developed. The structure of the growths in this case is somewhat differ-

ent, although they both belong to the class under consideration. In Case XXX the tumors were on opposite sides of the face, and in Case XXXII there were at first two separate growths, which later coalesced. In Case II, four years after the removal of the first tumor from the lower lid of the right eye, one correspondingly located appeared on the other side. Other observers have also noted their occurrence as multiple growths (Fordyce, Bowen, Brooke).

Krompecher distinguished six forms of these tumors according to whether they grow as anastomosing papillæ and cords, sheet-like folds, invaginations from the surface, styloid accumulations of cells or cylindrical-celled tubules, or as combinations of these. It has seemed to me, from my study, that insufficient notice has been given by Krompecher to the fact that most of the tumors of this variety are made up of rounded aggregations of cells possessing an elongated neck-like connection. The tumors showing a preponderance of such flask-like masses of cells, and most of the thirty-seven tumors studied do, I shall designate as "bulbous"; those which are not characterized by such formations correspond to the "cystic" or "styloid" varieties of Krompecher. The majority of the tumors are mixtures of these, although the styloid form is found sometimes quite pure.

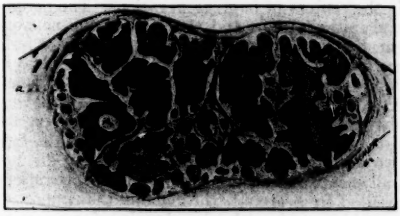

FIG. I. — The Bulbous variety, from Case XIV. The form taken by the groups of cells is well shown.
a. — Degenerative changes.

The Bulbous Form. — As an example of the bulbous form of superficial adenocarcinoma, the tumor in Case XIV will serve. The growth (Fig. 1) is entirely encapsulated with connective tissue; and the overlying epithelium, where present, is reduced to a few layers of flattened cells; the sudoriparous and sebaceous glands at the periphery, outside the capsule, show no changes except those of compression and displacement. The tumor cells are elliptical and small with very few mitotic figures. The stroma consists of a few narrow bands of mature fibrous tissue carrying blood vessels. Between these are solid masses of tumor cells, those at the periphery being perpendicular to the stroma. In a few places (*a*, Fig. 1) the cells have undergone degenerative changes and necrosis, and are represented by granular material and fragmented nuclei. In this variety the aggregations of tumor cells, as seen in serial sections, possess a rounded form with narrow, slender bridges uniting them to other collections.

Careful study of serial sections has demonstrated that these growths originate from more than one point of proliferation. Grouped islands of tumor cells, which appear separately in single sections, when studied in series, are found to be connected, each island directly or indirectly, with every other island of its group, all having a common point of origin. In most of these tumors, however, there is more than one point from which tumor cells arise, and the connected masses of tumor cells from one origin are separate from those of a different origin. Thus, in studying one half of a tumor from center to periphery, seven separate masses of tumor cells were found.

FIG. II. — The Cystic form, from Case I. The cyst-like cavities are formed by alterations in the stroma, chiefly due to circulatory disturbances.
a. — Swollen and degenerated (edematous?) connective tissue.
b. — Narrow parallel rows of tumor cells.

The "Cystic" Form. — In single sections from many of the growths the appearances are entirely different from those described for Case XIV, on account of the predominance of cavities instead of bulbous aggregations of tumor cells. When a freshly removed growth of this character is examined, the cavities are sometimes found to contain a turbid, slightly opalescent, thin gray fluid. The methods of fixation have evidently not preserved this fluid, for, as a rule, empty cyst-like spaces are found when these tumors are examined microscopically. One of the largest of these spaces measures 5 mm. across, but generally they are much smaller. These cavities usually possess a thin wall of epithelial cells; in some the lining is in part formed by swollen and degenerated connective tissue (*a*, Fig. II). The facts that the innermost row of epithelium lining these cavities is columnar, that many of them contain blood and some remnants of connective tissue, point to an origin through an interference with the circulation in the vessels of the stroma. Sometimes, in the study of serial sections, a mass of connective tissue is found almost surrounded by tumor cells and connected with the rest of

the stroma only by a narrow, compressed strand. The cavities are not always, therefore, as casual examination would indicate, spaces within the tumor cell masses, but, instead, are located in the stroma, which has entirely disappeared from many of them.

There may be found in both the bulbous and so-called "cystic" varieties collections of degenerated tumor cells, which simulate the above described cavities due to edema and other circulatory disturbances of the stroma. Even cursory examination demonstrates the difference between these. The cavities inside the tumor cell masses caused by degenerative processes always contain necrotic cells their lining, instead of being columnar cells, shows only a gradual transition of granular débris in the center to the well-preserved tumor cells; there is no sharp line of demarcation between the central cavity and the unchanged tumor cells. True retention cysts are also occasionally met with, formed from portions of sebaceous glands or their ducts, which have been enclosed by the growing tumor. In these the lines of demarcation between tumor cells and the enclosed mass of necrotic sebaceous cells and sebaceous material is distinct and sharp.

Another characteristic of the "cystic" form is the occurrence, as seen in single sections, of narrow, parallel rows of tumor cells (*b*. Fig. II), which may be at right angles, obliquely placed, or even parallel to the surface. They are very long in many sections, in one instance measuring 1 mm. Study of serial sections shows that these are sheets of epithelial cells and not cylinders, and that they anastomose. They are usually parallel at their beginning, but growing downward their direction becomes tortuous, and at their deepest parts they are greatly folded and compressed and not infrequently end as compact masses of cells, resembling the formations characterizing the bulbous variety.

FIG. III. — The Styloid form, from Case III. The compression of the tumor cells into aggregations with pointed processes characterizes this form. They are easily mistaken for fibro- and spindle-celled sarcoma.

The Styloid Form. — In eight cases (Cases III, V, IX, XVI, XVII, XXVIII, XXXIV, and one of the growths in Case XXII), the microscopical structure failed to answer to either of the forms described, and in two of these, in which the entire tumor was studied, nearly all the sections presented the following appearances (Fig. III, Case 3). In these cases a limiting capsule sharply demarking tumor cells from normal tissue, such as occurs in the bulbous and "cystic" varieties, is not found; in addition, the stroma is much more abundant and there are many evidences of an inflammatory process, such as infiltration of round cells, newly formed blood vessels and other appearances of cicatrizing granulation tissue. The tumor cells, instead of being aggregated into round masses, as in the first form, or enclosing cavities, as in the second, are grouped into irregular anastomosing and branching bands and styloid processes. The processes are very different from the sections of sheets of epithelial cells appearing as cords in single sections previously described, in that great variations in width occur in relatively short distances, and the cells are rarely perpendicular to the stroma. In these bands two epithelial cells may represent the width at one point, and on either side the band may suddenly widen to many cells or be reduced to a narrow thread of cells. Tumor cells with round and vesicular nuclei are found only in the centers of large aggregations. The peripheral epithelial cells and the cells of the network constituting the conspicuous feature of this form are spindle-shaped, and where they terminate in delicate processes are with difficulty differentiated from the nuclei of the stroma. It is very obvious that the inflammatory reaction on the part of the surrounding tissue, which in the first two varieties is represented by a fairly distinct wall encapsulating the tumor, has in this variety resulted in a growth throughout the tumor of branching and coalescing bands of connective tissue. The resulting compression of the epithelial cells and the consequent alteration in their shape explain why some growths of this form have been wrongly diagnosed as fibro- or spindle-celled sarcoma and as endothelioma.

It will be seen from the table that erosion occurred early in these eight cases when compared to the long duration of the growth. It is reasonable to suppose that the escape of the inflammatory exudate, the products of necrosis and degeneration as well as the serum and the formed elements of the blood accumulating in consequence of local disturbances of the circulation, interfered with the development of cysts. To what extent the penetration of the tumor by the surrounding granulation tissue was facilitated by the ulceration would be difficult to state. Absence of the protecting epithelium certainly afforded more exposure to irritants which promote the inflammatory process.

It was found by studying serial sections that preservation of one or the other of the types described did not prevail throughout the entire growth. Twelve of the tumors were almost

entirely of the bulbous form, seven of the cystic and six of the styloid. The remainder presented such admixtures that classification as distinct forms was not possible. The most frequent association obtained in growths showing both bulbous and "cystic" forms, the bulbous predominating. Cavities were never observed in the styloid form.

Excellent opportunity for examining the relationship between the tumor cells and the superficial epithelium was afforded by the study of entire growths in serial sections. In all but three cases the tumor cells were distinctly continuous with the Malpighian layer. In Case VIII the tumor arose from the neck of a sebaceous gland, and in Case XIII from a hair follicle; in the third case the relationship could not be determined because of the method of removal. In seven cases direct connection between tumor cells and sebaceous glands was also demonstrated, and in five with the outer layer of hair follicles. In twenty-three cases the epithelium appeared to give origin to tumor masses at more than one point.

However varied the origin, as shown by its connection with pre-existing and normal epithelium, the tumor cells invariably resemble the basal cells of the Malpighian layer with a single difference: they never contain pigment. The marked benignancy of these growths and the absence of pigment in the cells are in striking contrast to the great malignancy of the pigmented tumors which Abesser,[2] Larass,[3] Schalek [4] and others have recently insisted develop from the epithelium and are therefore carcinomas, instead of sarcomas as has been heretofore supposed.

The similarity of the tumor cells to the Malpighian layer is especially shown in the peripheral cells of the bulbous masses and in the thin partitions of "cysts." Slight modifications in shape and staining reaction are met with in the centers of the large aggregations of cells, but they are never sufficient to correspond to the alterations that occur in the successive layers of normal epithelium. Reference has been made to the marked alterations in the styloid form from compression.

The relatively few dividing nuclei always represent regular and typical phases. In Case V careful search failed to show any karyokinesis. The blood vessels are found in the stroma, which is scanty in the bulbous and "cystic" varieties and more abundant in the styloid form. Plasma cells and lymphocytes occur in the stroma in varying amounts. In the well-marked zone of granulation tissue around the cystic and bulbous forms they occur in numerous foci; mast cells are found scattered diffusely throughout most of the growths. In the styloid the stroma is more cellular than in the other forms. In the pars papillaris at the periphery of many of the growths the large amount of elastic tissue (Wiegert's stain) is too great to be accounted for from mechanical disturbances. This fibrous element is rarely found among the tumor cells.

There are good reasons for believing that diseases of the sebaceous glands are in some way related to the development of these tumors. The great size of these glands in the adjacent skin in many instances, the connections between tumor cells and sebaceous glands and their ducts, the origin in one case from a duct, and the occurrence of two separate growths on either side of the face in Case XXII, in which there was a well-marked acne vulgaris of several years' duration, are some of the reasons which support this view. Other investigators have observed this association. Great variations occur in the direction of the hair follicles and gland ducts at the margins of the growths; these structures are rarely found within the confines of the tumors and never in the styloid form. The superficial character of this last-named variety is shown by the invariable presence of sudoriparous glands below the tumor.

In a number of the tumors the so-called hyaline degeneration was present, chiefly as a terminal phase of the organization of granulation tissue. In a few instances mucoid degeneration was observed, and in Case XXX the growth on the left side of the face was extensively calcified. Hemosiderin was frequently found in all parts of the growths.

The tumors examined in eight cases were recurrent growths, and in one instance the primary tumor was also examined. Since recurrence may be considered as one step nearer malignancy, and these secondary growths are intermediate between those already described and the familiar carcinoma originating in stratified squamous epithelium, they were examined with special interest. The most important differences revealed by their study are the greater number of dividing nuclei, the disposition of the epithelium to form "pearls," a more marked inflammatory reaction and the lessened formation of a compact encapsulating zone of granulation tissue.

That tumors of this class are not as harmless as might be inferred from their small size and long duration and that great care should be exercised in their removal is evident from the history of Case XXXIV. The woman first noticed a papule where the bridge of her eyeglasses irritated the nose. This increased in size slowly, was diagnosed eczema and treated with x-rays. Under this treatment it almost disappeared. Growth began again four weeks after its discontinuance and various local applications were made. At the end of two years after it was first noticed, the ulcer involved most of the nose; the edges were irregular, indurated and slightly elevated, and it was removed with a cautery knife, the line of incision being close to the edge of the ulcer for fear of injury to the eyes. The tissue removed was studied in serial sections and the structure of the ulcer at the edge corresponded with that described for the bulbous form. There was then some treatment with the x-rays, another operation at the end of six months, recurrence in less than another month with involvement of the

[4] Journ. of Cutan. and Gen.-Urin. Dis., 1900, xviii, 145–153.

upper lip, the eyelids, forehead and cheeks and destruction of the soft tissues of the nose. The structure of the growth at that time was ordinary carcinoma of the squamous cell type, and the case was considered inoperable. The above account illustrates the truth of the statement by Fordyce [5] that these tumors are better left alone than carelessly treated. The histories of the other recurrent cases show that the temporizing treatment with local applications, no doubt the result of fear by operators of leaving unsightly scars, has been followed by recurrence and more rapid growth.

Two facts acquired considerable emphasis from a careful review of the literature pertaining to tumors presumably of this variety. The first of these concerns the long list of names which they have received, so numerous that even Krompecher hesitated to add a new one; the second, the almost universal tendency to consider them as closely related to carcinoma. The so-called "Rodent Ulcer" I regard as belonging to the styloid form of this class of tumors, but the term, even as a purely clinical one, is open to many objections. The name suggested by Krompecher, "drüsenartige oberflächenepithelkrebs," certainly carries with it no suggestion of an origin in the glands of the skin, although the development of these tumors from the basal layer of the epithelium, from hair follicles, or from the necks of the sebaceous glands, is definitely established. It has also been shown that the resemblance to glands is only apparent and chiefly due to disturbances of circulation in the stroma. The similarity to tubules, when single sections are examined, may be quite marked, and with much edema of the stroma pseudocysts develop. These tumors are not glandular, but gland-like; they are benign, superficial, and develop from the epithelium.

The usual conception of the development of a carcinoma of the skin includes proliferation of the epithelium and invasion of the deeper tissue. Both of these processes occur in the histogenesis of these tumors, and yet the majority of the clinical characteristics of carcinoma are certainly absent. Not even the loss of the protecting epithelium and ensuing irritation, ulceration, etc., are alone sufficient to effect their transformation into the familiar forms of cutaneous carcinoma. As before stated, in connection with recurrent cases, the evolution to carcinoma often takes place as a result of methods of treatment largely due, no doubt, to their location upon the face.

THE RELATION OF THE BURN TO THE BULLET HOLE AS EVIDENCE OF HOMICIDE vs. SUICIDE: REPORT OF THE NAGLE CASE.[1]

BY JAY PERKINS, M.D., PROVIDENCE, R. I.

ON the morning of the 14th of November, 1901, the body of James Nagle was found lying on his bed at his home in East Providence, R. I., with a bullet wound in the right side of the head, 1¼ inches above and a little anterior to the junction of the ear with the head. Singeing of the hair extended 1½ inches above the bullet wound, a little back of the ear and a little below the angle of the mouth, the beard being about a week's growth. The body was lying in a natural position on the bed, the arms at the sides, with a 32-calibre revolver between the right hand and the thigh. The tenement occupied by James Nagle and his wife, Rose, both French Canadians, was in a basement and consisted of a kitchen and sleeping room. Back of the house was a wood shed. Mrs. Nagle claimed that James came home the preceding night a little after eleven o'clock, drunk (Mr. and Mrs. Nagle were both frequently drunk and quarrelsome), and drove her out of the house. She was afraid to re-enter the house and spent most of the night in the wood shed, going to a window of their bedroom at intervals and looking in at her husband. At about four o'clock in the morning, hearing no noise and thinking he was asleep, she entered the house, but he was by the stove and drove her out with the poker. After hearing the five o'clock whistle, she again started to enter the house, and looking through the window of the sleeping room saw "some fire or something" and heard "an awful noise." Thinking that he had probably killed their dog she rushed into their bedroom and saw "Jimmy" with his two feet on the floor and his body across the bed. She placed his feet on the bed, laid him straight and pulled the blanket over him. At that time he was alive, but breathing very hard and lived for half an hour. She then went to a neighbor's and asked that he go for a doctor for Jimmy, and upon being asked what had happened to Jimmy she replied, "He is shot, for I heard such a noise."

At a little after five in the morning the Police Sergeant asked Dr. Allison, the medical examiner, to accompany him to Mr. Nagle's house. When they arrived there they found the body in a natural position on the right-hand side of the bed with a bullet wound as described above. At that time Mrs. Nagle stated that her husband had shot himself, and that she had found him lying across the bed with his feet on the floor and holding a revolver in his hand, and that she had placed him in the position in which he was then lying. On the pillow under his head was a blood spot three to five inches in diameter. No blood was found anywhere else on the bed. The fingers were relaxed, and though Mrs. Nagle tried to make them hold the revolver as she said she had found it they would not accommodate her. When asked where Jimmy got the revolver she said that she did not know, but later in the day she stated that he had traded a watch for it.

At this time the case was considered one of suicide, but later in the day it was learned that a woman said to be Mrs. Nagle had, a few days before, purchased at a hardware store in East Providence a revolver corresponding to the one found beside Mr. Nagle. After purchasing the revolver she asked the clerk to load it for her. This he refused to do, but he gave her five cartridges, not noticing whether she had selected a five or six chambered revolver. The revolver found beside Mr. Nagle had six chambers, one chamber being empty, one containing an empty shell and four containing cartridges. At the trial the identification of the woman purchasing the revolver as being Mrs. Nagle was not absolute, in that the one who purchased the revolver wore a thick veil so that the face could not be seen. Otherwise, the two corresponded, a special feature in the identification being the broken English with the French Canadian accent.

Mrs. Nagle was now charged with the murder and arrested and an autopsy was held. The bullet wound

[5] Journ. of Cut. and Gen.-Urin. Dis., 1902, xx, 147.

[1] Read at the Massachusetts Medico-Legal Society Meeting, Feb. 3, 1904.

and burn were as above described. In the autopsy report no mention was made as to powder marks or the character of the wound, but at the trial the medical examiner stated that there were some powder marks. There was a large opening through the skull, and the brain substance and pieces of bone and powder were scattered along the track of the bullet in the brain. The bullet was found lodged "in the cerebellum, just above the medulla oblongata."

Mrs. Lawson, who lived on the floor above the Nagle tenement, testified that as a regular thing "Jimmy came home and made a noise at night and that in the morning Mrs. Nagle made a noise and jawed him." On the night of Mr. Nagle's death she was awakened a number of times and heard quarreling in the tenement below. Most of the time she could distinguish only Mrs. Nagle's voice, and at about three or half-past three in the morning Mrs. Nagle "hollered out" two or three times "I'll kill you." At about quarter past five she heard "a short noise about like a revolver."

I did not see Mr. Nagle's body, but was called into the case by the Attorney-General, who sent me a copy of the autopsy report with a request that I should advise him from a medical standpoint. The report of the wound was very meagre, being only as stated above. I had observed in my work that when burning of the hair or clothing is present the bullet wound is not in the center of the burn, and so, in studying this case, one of the first things I did was to experiment with the revolver found beside Mr. Nagle's body, using the cartridges from the box from which those in the revolver were supposed to have come. I found that there was a uniformity of results, that the major part of the burn always corresponded with the hammer or "sight" side of the revolver. A perusal of medico-legal works at my command failed to show any reference to this with the exception of a small work by Reese. I then wrote to Dr. Draper in reference to these findings, and was pleased to receive an answer from him confirming my investigations and also giving me the reference to a paper read by Dr. Fish before this society and published in the BOSTON MEDICAL AND SURGICAL JOURNAL, Oct. 2, 1884, which treats the subject exhaustively, and shows that unless the revolver is held firmly, as in a vise, there is no exception to the rule as I found it.

At the first trial of this case, I therefore testified that with a bullet wound in the right temple, 1¼ inches above and a little in front of the upper part of the ear, with the hair singed 1½ inches above the wound, some back of the ear, and the beard singed down to the angle of the mouth, the bullet following a direct line to the lower part of the cerebellum just above the medulla oblongata, with fragments of bone and powder scattered along the passage of the bullet through the brain, the revolver was held at a distance of between four and six inches from the head, the barrel pointing in the direction taken by the bullet, with the sight side of the revolver in the direction of the more extensive part of the burn, that is, in front of the right ear, and the trigger side towards the top of the head. The revolver in question being a cheap, Fourth of July variety, and of very hard action, it was improbable that such a wound should have been self-inflicted by anyone, and for myself would have been impossible, while, with the body lying in a natural position on the right side of a low bed, this was precisely such a wound as would be produced by a person standing beside the head of the bed and shooting with the right hand at close range.

At the first trial the defence put in no medical testimony in contradiction of mine. A new trial was, however, obtained on technicalities, and at the second trial your President also appeared as an expert witness for the state and ably upheld the state's claim that the position of the revolver was as stated above, and that the wound was improbably, almost impossibly, suicidal. The defence, at this trial, had two medical witnesses, Dr. William H. Palmer, who had served for eighteen years as medical examiner in Providence and for some years preceding that as coroner, and Dr. Jerome B. Green. Both of these witnesses claimed that there was no such rule as stated above in reference to the relation of the burn and bullet wound, Dr. Palmer characterizing our statements as "fanciful." He stated that his experience and experiments, of which he said he had performed a good many, showed that there was no constant relation between the sight side of the revolver and the extension of the burn. He also stated that nothing could be told in reference to the position in which the revolver was held when the shot was fired, by the direction taken by the bullet through the brain, because of the possible deflection of the bullet. My testimony at the second trial was similar to that at the first, except that on further experimentation I changed the distance from the head at which the revolver was held to between three and six inches instead of four and six, because, with this revolver, it seemed as if I got more marked burning at four inches than at six. All of my work, however, makes me more firmly convinced than at first that in the relation of the burn to the bullet wound we have an accurate guide as to the position in which the revolver was held as regards the sight side of the revolver, this relation being more marked the farther the revolver is held from the object fired at until the point at which the burn fails to appear is reached.

At the second trial Rose Nagle was acquitted. It is the history of murder trials in Rhode Island that usually, when a second trial is obtained, the defendant is acquitted. In this case, the character of the man killed and the pitiful appearance of the defendant probably had as much to do with the acquittal as any lack of evidence on the part of the state.

Even the Attorney-General was moved by the defendant's appearance at the time he made his plea. She was partially blind, of small stature, and sat with her body somewhat doubled over and her feet on a box. In her hand she held a bunch of white pinks with a piece of newspaper wrapped about the stems, looking at them as if trying to derive some comfort from them. After the trial was over the Attorney-General remarked to the

counsel for the defence that he was moved to pity by the forlorn appearance of the defendant, and especially by the way she held the white pinks. An amused smile came over the face of the defendant's counsel, and, on being questioned as to the cause of it, he said that on his way to the court house in the morning he saw those pinks and, thinking that they would look well in the hands of the defendant, he bought a bunch, wrapped a piece of newspaper about the stems, put them in the hand of the defendant and instructed her as to the manner of holding them, which instructions she faithfully carried out.

Clinical Department.

A RÉSUMÉ OF THE RESULTS OF DR. F. B HARRINGTON'S SERVICE, MASSACHUSETTS GENERAL HOSPITAL, FROM JUNE 1 TO OCT. 1, 1902, AS SEEN IN THE FOLLOWING JUNE OR LATER.

BY E. A. CODMAN, M.D., BOSTON.

DISEASE.	Total number.	Number traced.	Perfect result.	Good result.	No improvement.	Bad result.	Died in hospital.	Died after leaving hospital.

Explanation. — The results were seen personally by Dr. E. A. Codman, with the exception of a few who replied by letter. Those cases which replied by letter, even if they reported that they were well, are not classed as "perfect" because they were not examined, for it is found that patients frequently consider themselves well when they have hernia or other undesirable after-results. The results of cases as seen at the time of discharge and not heard from later are not given, because such figures can easily be obtained from the annual report of the hospital.

Perfect results are not discussed in the remarks at the end because they are perfect and speak for themselves.

Good results include those cases which, while they showed some benefit from the operation, were nevertheless not completely relieved. In what respects these lacked perfection is explained in the remarks. It must, therefore, be understood in reading the following that with a few exceptions, only the cases in which some undesirable symptoms remain after the operations are spoken of.

REMARKS ON THE CASES IN WHICH THE RESULTS WERE NOT PERFECT.

APPENDICITIS.

General Peritonitis. — In the above table only the cases which died of undoubted peritonitis are included under this heading. As a matter of fact, some of the acute appendicitis (wound drained) might justly be considered general peritonitis, but it is felt that classing them as such might give a false impression.

Wound drained. — Of the seven good results three were not perfect because they had ventral hernia or weak scars; four reported themselves well by letter, but since they were not examined cannot be called perfect.

Wound closed. — The two cases which were not improved complained of the same pain which they had before the operation. Of the five good results, four complain of constipation and indefinite pain. One wrote that she was well, but was not examined.

HERNIA.

Inguinal. — One case, where a double operation had been done, died from pneumonia on the forty-fourth day; the wounds were healed. One of the "perfect" cases was the huge hernia which Dr. Harrington operated on, on "Mass. Med." day; another small hernia has, however, appeared on the other side. Of the six good results, four only reported by letter, and therefore cannot be called perfect (one of these speaks of "a thickening" about the testicle). The other two had good anatomical results, but indefinite pain in the region of the scar, and one has a small hydrocele; the bad result was a recurrence ten months later.

Ventral. — The case which was not improved broke her stitches just after the operation and had to be resutured in the ward. The two good results had small, weak areas in the scars.

The *femoral hernia* was not examined.

MISCELLANEOUS LAPAROTOMIES.

Fibroids. — Two of the three good results reported themselves well by letter; the other was a case of myomectomy (J. W. E.) who complained of slight pain in the right side and had a large separation of the recti.

Salpingitis. — Of the eight "good results" five reported by letter only. One of these, from whom huge hydro-salpinges had been removed, had "never been so well"; three of the other four have disagreeable symptoms from the artificial menopause. Of the three who were examined, one was symptomatically well, but had a pelvic tumor; one was anatomically well, but had irregular menstruation; the third had a ventral hernia requiring operation.

Ovarian Cysts. — Two report themselves by letter as perfectly well; the other five scarcely lack perfection, but have minor symptoms, *e. g.*, bulging of scar, irregular menstruation, or tenderness.

Gallstones. — The two cases of "good results" have still slight attacks of pain. One has a sinus. Both had cholecystostomy.

Carcinoma of Cervix Uteri (abdominal hysterectomy). — The one good result reports herself perfectly well and gaining weight. The one "no improvement" was well six months before the disease returned.

Chronic Intestinal Obstruction from *Carcinoma of the large Intestine.* — All four had temporary relief only; one is known to be dead.

Volvulus. — A small boy who has had many operations for idiopathic dilatation of colon is benefited but has two fecal fistulæ.

Adhesions. — One had to be operated on again the next year, since which he has been well.

GYNECOLOGICAL CASES.

Carcinoma of Cervix (curetted). — Three were made much more comfortable. One died six months later.

From *dilating and curetting* for endometritis, metrorrhagia, etc., two cases showed "no improvement." In one of these the symptoms were probably due to osteo-arthritis of the spine. The other by letter said, "The operation done me but very little good." Of the four "good results" a case of metrorrhagia was cured, but has other uterine symptoms of minor importance. The other three regard themselves as better, but still complain of various troubles.

From *D. and C. and ventral suspension or fixation*, one case was in much the same condition as before; the other somewhat improved.

Of the cases where *D. and C. cervix and perineum* alone were done, two reported good results by letter, one was symptomatically better, due probably to a careful diabetic diet which was first prescribed for her after the operation. The three others were improved in some respects, but still complained of one thing or another. Three were no better for the operation.

Cervix and perineum with ventral fixation was, as a rule, done for procidentia, or prolapse. One case had nothing to complain of; the other six, though greatly improved, still lacked perfection in some minor respect.

Unclassified Gynecological Cases. — The good result was from a curettement after miscarriage. The case not improved was a girl with venereal warts who returned the next year (the warts still present and ulcerated) with well developed secondary syphilitic eruption.

GENITO-URINARY CASES.

Prostatic Hypertrophy. — All four cases were very feeble subjects and had very large tumors. On one the Alexander operation was done; the tumor was an adeno-fibroma weighing 100 gms.; this patient died at once. From another case an adeno-fibroma weighing 105 gms. was removed through a suprapubic opening with an écraseur; this patient's health was greatly improved; he has no hemorrhages, but is still obliged to use a catheter. A third case on whom Dr. Mixter did a Bottini operation reports that he has been "as well as ever he was in his life" since the day of his operation. This case is not considered perfect because he was not examined. The fourth case, marked "no improvement," refused operation in Dr. Harrington's service and returned later in another service, when a suprapubic cystotomy (M. H. R.) was done, through which "nearly all the urine still comes."

The results of the *strictures, hydroceles and miscellaneous genito-urinary cases* are only of individual interest.

HEAD CASES.

Depressed Fracture. — One reported himself well by letter. A boy who had a depressed fracture with hemorrhage from the middle meningeal and lateral sinus is well, except for a spastic condition of the left leg and arm.

A case thought to have been *fracture of the base* is in an insane aslyum.

A case operated on for *traumatic epilepsy* by introducing gutta-percha tissue between the scar and the brain was not improved.

BONE AND JOINT DISEASES.

Perfect Results. — One each of tuberculosis of patella (excision of sequestrated patella and drainage of joint; R. B. G.); "mice" in knee joint; displacement of semilunar cartilage; chronic synovitis of knee; septic punctured wound of knee; excision of shoulder for tuberculosis; excision of tubercular sequestra from humerus; partial excision of inflamed deltoid bursa; excision septic bursa of olecranon; excision of necrosed bone in amputation stump; excision (J. W. E.) muscle callous of quadriceps extensor.

Good Results. — One each of: excision of knee (the leg itself is said to be well but patient is too feeble to use it); excision of metatarsal and proximal phalanx of the great toe for tuberculosis — had a small sinus which has recently been excised and has healed; caries of ilium, — wound has healed, but patient still has pain; reduction of dislocated semilunar bone of wrist and excision of portion of fractured scaphoid — somewhat

sore and easily strained, some limitation of motion; abscess of hip — bedridden.

No Improvement.— Periostitis of femur; chronic synovitis of knee (probably tubercular).

Fistula in Ano. — Of the four good results, three reported themselves well by letter. The fourth has a granulating spot with probably a concealed sinus just inside sphincter. One has not improved — this was the same patient operated on for mice in the knee joint.

Empyema. — One patient complained "that her side troubled her," but she is well and able to do her work.

Cancer of the Breast. — Of the three "good results," two were in operations for recurrent nodules. Both of these show still further recurrence, and in one the growth has involved the brachial plexus causing complete paralysis of the arm. The third "good result" reports herself well by letter. Two cases died during the following winter, whether of the disease or not is not known.

Hemorrhoids. — The two "good results" reported themselves well by letter.

Tubercular Glands of Neck. — The three "good results" complain only that the scars are ugly or tender.

MISCELLANEOUS MALIGNANT DISEASES.

Perfect Results. — One was a sarcoma of the parotid; the other a case of supposed recurrent gland in the neck following operation on the lip five years before (the gland was not malignant). Of the six good results, four are known to have had recurrence. Two of those which died were not operated upon (both cancer of rectum).

Accident Cases. — The results are only of individual interest.

The Miscellaneous Cases are incapable of classification though the individual results are often of interest. Of the two cases "not improved" one, a morbus coxæ senilis, was not operated upon; the other, a girl with an obscure lesion of the elbow, was not helped by an exploratory operation. The bad result was in a case of tuberculosis of the oscalcis, who refused operation.

Fractures. — One perfect result was a fracture of the tibia in a boy of sixteen. The other was a case operated on for a fracture and dislocation of the head of the humerus in a fat woman. The head of the bone was excised and she now has an ideal result for excision of the shoulder.

The following cases died during or after the service:

Cases which died unoperated: Accident cases, 7; burns, 2; erysipelas, 1.

Cases in which death was probably hastened by operation: Acute appendicitis, 2; general peritonitis, 1; carcinoma of the intestinal tract, 3; carcinoma of the jaw, 1; carcinoma of the uterus, 3; duodenal ulcer, 1; fibroid of the uterus, 1; inguinal hernia (pneumonia), 1; cholelithiasis, 3; tabes mesenterica, 1; hypertrophy of the prostate, 1; pelvic abscess, 1.

Cases in which death was not hastened or probably not more than a few days by operation: One each of strangulated umbilical hernia, duodenal ulcer, obstruction from Meckel's diverticulum, cancer of the stomach, mesenteric thrombosis, rupture of the intestines, multiple tubercular sinuses, head injury. Two cases of general peritonitis.

Died after leaving hospital: One each of Hodgkins disease, cancer of the hepatic flexure, cancer of the cervix; two each of cancer of the breast and rectum.

Besides these, three cases died of other causes than those for which they were in the hospital.

A CASE OF PREGNANCY IN A UTERUS BICORNIS UNICOLLIS.

BY CHARLES M. GREEN, M.D., BOSTON.

CAREFULLY observed cases of pregnancy in bicornate uteri are sufficiently rare to make the following case worthy of record:

M. F. entered the Boston Lying-in Hospital Jan. 27, 1896, with the following history: —

1893, miscarriage at two months.

1894, full-term child, easy labor.

1895, June 3, premature labor at seven months; no catamenia since.

1896, Jan. 26, 7 P.M., while sitting in the house of a friend, patient began to flow profusely (fully a quart of blood was said to have been collected), finally fainted, and was seen by the late Dr. George Haven, who advised removal to the Lying-in Hospital.

On entrance patient was in fair condition, pulse 105, color good. The cervix was not wholly taken up, the external os uteri was dilated to an inch in diameter. The presenting head was high, O. D. P. The abdomen was large and broad for that period of pregnancy (seven months). There was a large and well-marked median sulcus, suggesting twin pregnancy. During a uterine contraction this sulcus became more marked and could be distinctly felt: beginning just below the umbilicus it extended upward, becoming broader and deeper, and dividing the fundus uteri into two distinct and nearly equal parts. The part on the right was firm and resistant: in it the outline of the fetus could be distinctly palpated, and the fetal heart could be heard over it. The left cornu was less resistant; no part of the fetus could be felt in it; nor could the fetal heart be heard there, but a loud placental bruit was heard over this area. (Figure 1.) During a contraction both halves of the uterus seemed to harden equally; but the left half stood out with greater prominence.

Four hours after entrance dilatation was complete, the membranes ruptured, and a large amount of liquor amnii escaped. Five minutes later the baby was born, and was followed by some large, dark clots. The baby weighed only 3.75 lbs., and lived but six hours.

After the birth of the baby abdominal palpation showed on the left a mass which had the size and feeling of a normal uterus during the third stage. To the right of this, and closely connected with it, was a smaller mass, presumably that portion of the uterus which had contained the child. (Figure 2.)

At the end of forty minutes pressure was made on the left, or larger part of the uterus and the placenta was easily expressed. After the birth of the placenta, the left cornu of the uterus

became of an equal size with the right: the division between the two cornua was very distinct, and both were well contracted. (Figure 3.)

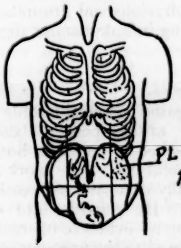

FIG. 1. — Before birth of child.

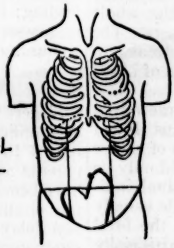

FIG. 2. — After child (third stage).

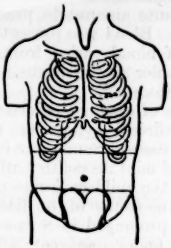

FIG. 3. — After placenta.

There was no post-partum bleeding. The amniotic sac was partially divided into two parts, obviously by the sulcus between the two cornua.

The labor was carefully observed and recorded by Dr. Francis P. Denny, of Brookline, then house physician, and to him I am indebted for the notes of the case. The puerperium was under my own observation; and the bicornate condition was easily appreciable to the touch. On the fourteenth day the uterus was explored with a sound: the sound would pass only a short distance in the median line, but deviated towards one side or the other. The depth of the right cornu was four inches; that of the left, four inches and a half.

Medical Progress.

REPORT ON PEDIATRICS.

BY THOMAS MORGAN ROTCH, M.D., AND JOHN LOVETT MORSE, M.D.

THE PATHOLOGICAL ANATOMY OF SHIGA BACILLUS INFECTION OF THE INTESTINES IN INFANTS.

HOWLAND [1] reports the results of autopsies in the New York Foundling Hospital, the Babies' Hospital and the Nursery and Child's Hospital. The Shiga bacillus was proved to be present in the great majority of cases by examination of the stools, but in 7 cases it was obtained post-mortem by scraping the mucous membrane of the colon, and in 3 cases was obtained both ante-mortem and post-mortem. All corresponded to the type known as the "acid," "Harris" or "Flexner-Manila" bacillus. The first 17 cases were winter cases and the last 15, summer cases. There seemed to be no difference in the histological findings between the two. Four cases are reported in full detail and discussed. The conclusion is that the Shiga bacillus infection has a most diverse pathological anatomy, and a large percentage of the fatal cases show no evidence of profound structural lesion. The question arises as to how much of the process is to be regarded as due to the Shiga bacillus. The evidence, the author thinks, is in favor of the belief that the primary necrotic lesion is the result of the action of the dysentery bacillus, the subsequent ulceration being brought about probably by the interaction of various micro-organisms and the ordinary processes of demarcating inflammation. The lesions in the intestines must be considered as of two kinds: (1) Those due to the dysentery bacillus, and (2) those from toxic products of this and perhaps other organisms. He says that in summing up the evidence we shall have to say that there are comprised under the lesions associated with the Shiga bacillus all grades and types of diarrheal disease as distinguished by clinical symptoms and pathologic findings, and that it can be affirmed that no particular type is distinguished from the others by a special etiology.

[1] Medical News, March 5, 1904. Abstract in The Journal of the American Medical Association, March 19, 1904. Vol. XLII, p. 794.

A CLINICAL STUDY OF SIXTY-TWO CASES OF INTESTINAL INFECTION BY THE BACILLUS DYSENTERIÆ (SHIGA) IN INFANTS.

The authors [2] studied 64 successive cases of diarrhea at the Vanderbilt Clinic during the summer of 1903. No selection of cases was attempted. Sixty-two showed infection with the Shiga bacillus. They were unable to determine whether the patients had previously suffered from diarrhea and were for this reason more susceptible to infection with the bacillus dysenteriæ. No other predisposing cause in the way of disease could be discovered. Fourteen were entirely and two partly breast-fed. The others were fed in a great variety of ways. Thirty-one were well nourished, two fairly nourished, 11 poorly nourished and 15 in miserable condition at the beginning of the attack. The most important factor in determining the character and severity of the disease seemed to be the previous condition of the child, — those who were in good condition being much more likely to have a mild or only moderately severe form of the disease. Sixteen cases were very mild, 31 were moderately severe and 14 severe. Thirty-four of the cases did not show a temperature of over 100.5° F. The temperature of the severe cases was usually considerably elevated, but many of them and some of the most severe ran an almost afebrile course. Vomiting occurred in 19 cases, usually at the beginning of the attack. The number of

[2] La Fétra and Howland Archives of Pediatrics, 1904, Vol. 21, p. 161.

movements in twenty-four hours was from 2 to 5 in 5 cases, 5 to 10 in 35 cases, over 10 in 20 cases. In two the movements did not contain mucus. Mucus was present in all the other cases, varying from a minute amount to practically the whole movement. Blood was present in 17 cases. The quantity of blood varied from a few streaks to enough to color all the mucus. No clots of blood were ever observed.

All types of diarrheal disease as characterized by their clinical symptoms were thus found among the cases. Some were examples of severe and some of mild ileocolitis; others could only be classed as the mildest forms of intestinal indigestion. The course of the disease, while usually short, was prolonged in 8 cases. All the fatal cases were under one year; all were artificially fed and were in very poor condition when first observed; they also had only the poorest care and attention. All the breast-fed cases ran a very mild course, the average being three to four days after coming under observation. Save for the bacteriological findings there was nothing to indicate that their sickness had any relation to true dysentery. Blood was observed in but one case. The acid type ("Harris") of organism was found in 42 cases, the true Shiga in 15, both in 5. The type of infection seemed to make no difference in the severity of the disease.

Serum was injected in 10 cases; 4 were infections with the acid type of organism and were given "Harris" serum; 6 were infections with the true Shiga bacillus and were given "Shiga" serum. This treatment was used only in the severe cases. The number of cases treated was too small to warrant any conclusions. While of apparent benefit in some, in others no effect whatever was noticed.

STARCH DIGESTION IN INFANCY.

Shaw [3] studied 35 infants, giving them barley water in place of their regular food. One hundred such barley meals were removed in from fifteen minutes to two hours after feeding. Free starch was present in 2%, erythrodextrin in 41% and achroodextrin or maltose in 57% of the tests. In the two instances in which free starch was detected the babies were sick. Starch conversion was found in these same infants at other times.

A ½% starch solution was added to the stomach contents removed from 8 infants under two months old, one-half to two hours after a regular or a barley water feeding. The youngest infant was six days old and a breast-milk feeding was removed a half-hour after nursing. Three parts of the stomach contents and one part of the starch solution were mixed and placed in a thermostat for an hour. On the addition of Lugol's solution, the indigo-blue of starch did not appear in a single instance.

Saliva was obtained from 7 babies ranging in age from sixteen days to two months. Partial conversion of starch took place in two minutes in all cases.

He concludes that the saliva of very young infants contains a diastatic enzyme capable of converting small amounts of starch into maltose; that the diastatic action of the saliva may continue in the stomach as long as two hours after feeding; that, on physiological grounds, there is no reason why young infants cannot digest small amounts of starch.

THE HEREDITY OF RACHITIS.

Siegert [4] investigated a considerable number of families, mostly of the poorer classes, with regard to the presence of rachitis both in the parents and in the children. His work seems to have been as carefully done as was possible under the circumstances. He regards late dentition and delay in walking as evidence of rachitis, but rarely gives any data as to the presence or absence of skeletal changes.

He concludes that heredity is one of the most important etiological factors of rachitis. It is transmitted principally by the mother. Hereditary rachitis is milder and occurs later in breast-fed than in artificially-fed infants, occurring in them very seldom before the third month. The severest forms of rachitis may, however, occur in the breast-fed infants of rachitic parents, while the natural nourishment is, in those in which there is no inherited predisposition, the best preventive for the disease. Prolonged nursing and the age of the mother are not in themselves direct causes of rachitis. Infection may be excluded as an etiological factor. Social position and diseases of the digestive and respiratory tracts are, next to heredity, the chief causes of rachitis. The time of dentition and standing is dependent on constitutional hereditary influences.

LOCATION AND PHYSIOLOGICAL DISPLACEMENT OF THE CARDIAC APEX IN CHILDREN FROM FIVE TO FIFTEEN YEARS OF AGE.

Terrien and Lamy [5] first studied the position of the impulse when the child lay on its back, and noted the changes in position when the child lay on the right and left sides.

They found that in the dorsal decubitus at five years the impulse was usually in the fourth space. With the increase in age it descended little by little, following an almost vertical line which passed almost always outside the nipple. At ten years it was at the upper border of the fifth rib and was nearer the mammillary line. At fourteen years it was in the fifth space inside the mammillary line. The impulse at first descended almost vertically, then moved mostly transversely.

In the left lateral decubitus the apex always moves very markedly, even at five years. It moves in an oblique line backward, downward and outward, the amount of movement varying with the age of the child. At five years the deviation is to the left and very little downward, being from 18 mm. to 20 mm. transversely, and only 5 mm. downward. At seven years it moves

[4] Jahrb. f. Kinderheilkunde, 1903, vol. 58, p. 929.
[5] Revue Mensuelle des Maladies de l'Enfance, 1903, vol. 21, p. 548.

on the average 22 mm. transversely and 14 mm. downward. From twelve to fifteen years the deviation is almost the same in both directions, 30 mm. horizontally and from 20 mm. to 25 mm. vertically.

In the right lateral decubitus the displacement of the apex is more complex, being much less marked and also subject to numerous individual variations. From five to seven years it descends almost vertically, following a line which is inclined very slightly inward. The total displacement is about 15 mm. After seven years it descends very little, but moves almost horizontally inward, the displacement being very much less than in the left lateral decubitus.

On account of the relative infrequency of pericardial adhesions in childhood and the difficulty in their diagnosis, these facts should be of use, as a lack of mobility of the apex is one of the most important signs in the diagnosis of this condition.

CONTRIBUTION TO THE STUDY OF ACID INTOXICATION IN THE CHRONIC DISEASES OF NUTRITION IN THE INFANT.

Keller and Bergh, some years ago, developed the theory that athrepsia was due to an acid intoxication resulting from the absorption of abnormal acids formed in the intestine. The organism responded to this intoxication by manufacturing ammonia to neutralize the acids. They found large quantities of ammonia in the urine in these cases. More recently Keller has asked if the acidosis might not have another origin, namely, saponification of fats in the intestine. During saponification fats take up the available alkalis, calcium and magnesia. These not being absorbed can, therefore, no longer neutralize the acids which pass into the blood. Keller's experiments in this direction did not give definite results.

Steinitz [6] repeated his experiments on both well and dyspeptic infants to whom he gave skimmed milk or milk with cream added. If Keller's theory is correct the feces should contain but little alkali and the urine but little ammonia and much alkali when skimmed milk is given, and, on the other hand, the feces should contain a large quantity of alkali and the urine little alkali but much ammonia when rich milk is given. His experiments prove the truth of Keller's theory. He sums up his work as follows: Feeding milk rich in fat causes the appearance of large amounts of ammonia in the urine. This is due to the utilization of the alkalis in the intestine. The alkalis which, when skimmed milk is used, pass into the blood and there neutralize the acids, the intermediary products of metabolism, are fixed in the intestine and eliminated with the feces when milk rich in fat is given. In order to avoid too great a loss of alkalis in these conditions the organism is obliged to manufacture ammonia to neutralize the acids. The infant's organism, however, possesses to only a limited degree the power to manufacture ammonia. A rich milk, therefore, robs the infantile organism of alkalis. This impoverishment occurs in the sick infant as well as in the well infant. Since the alkalis play an important part in the normal development of the organism this impoverishment must be harmful. Milk rich in fat acts in still another way. Like all fats it causes an increase in the phosphoric acid eliminated in the urine, which acid, not finding available alkalis, can only be neutralized by ammonia which the organism is obliged to furnish in large quantities.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

THE nineteenth annual meeting was held at Washington, May 10, 1904.

The meeting was called to order by the President, DR. WM. T. COUNCILMAN, of Boston.

(Concluded from No. 22, p. 597.)

INFECTIOUS NEURITIS: WITH REPORT OF A CASE. DR. J. J. PUTNAM.

DR. PUTNAM reported, in behalf of Dr. Waterman and himself, a series of cases illustrating different sorts of reaction of the nervous system to infectious processes. A possible bond between certain of these cases lay in the fact that they had occurred during the same period, namely, in the winter of 1902–03. The most important case was that of a man of thirty who suffered from an unusual, gradually progressive form of "myelitis" which spread slowly upward through the whole length of the spinal cord, the entire illness covering a period of about two months. All the functions of the cord were involved, and the paralysis was associated with constant fever, leucocytosis, gradually increasing pyelitis, and, eventually, with bloody dejecta. The post-mortem examination showed a disintegration of the nerve elements accompanied with but few signs of active vascular change or of exudation processes, and no evidence of antecedent anemia as due to arterio-sclerosis or thrombosis.

The other cases were of the following sort; meningo-encephalitis, possibly due in part to alcoholic excess, progressive paralysis, eventually involving certain cranial nerves, but ending in complete or incomplete recovery, infectious neuritis followed by encephalitis, cases of the type of poliomyelitis, but coming on slowiy, and, myelitis during typhoid. He called attention to the complex results of infections of the nervous system and the impossibility at present of making sharp divisions.

THE CLINICAL FEATURES, PROGNOSIS AND TREATMENT OF CEREBRO-SPINAL MENINGITIS IN INFANTS AND CHILDREN. DR. HENRY KOPLIK.

The cases studied by Dr. Koplik numbered 89, of which 39 were absolutely confirmed by lumbar puncture; 35 were tuberculous, 1 staphylococcus, 1 streptococcus and 2 pseudo-influenza cases. Sixty per cent of the cases were below two years of age. The mode of onset was, as a rule, sudden, except in the tuberculous cases. Rigidity of the neck was present in all cases at some time. Babinski's reflex was present in 77%, while Kŏnig's reflex was of little value in the cases under two years of age. In the tuberculous cases, Macewen's sign was present in the majority of instances.

Optic neuritis was more common in the tuberculous type than in any other class of cases.

Dr. Koplik considered the disease to be self-limited and scarcely influenced by any mode of treatment. He did not consider lumbar puncture as curative nor had it, in his cases, relieved the symptoms of pressure.

A CASE OF SPASMODIC STRICTURE OF THE ESOPHAGUS WITH SACCULATION, TREATED BY DILATATION, AND LATER, BY GASTROTOMY. DRS. JAMES TYSON, EDWARD MARTIN AND JOSEPH EVANS.

DR. TYSON read this paper, which opened with a review of the literature upon the subject of diverticula and dilatations of the esophagus, their etiology, treatment and diagnosis. Then followed the detailed clinical history of two extremely interesting cases of spasm of the cardiac orifice with resulting dilatation of the esophagus. The first patient was a man aged thirty-three years, who had been suffering from dysphagia from the time he was twelve years old, his first attack coming on suddenly while he was at his supper, and compelling the immediate regurgitation of all that he had eaten. As he described his symptoms, "while in the act of swallowing solid food he was suddenly seized with a sensation of the material sticking in the esophagus at a point posterior to the middle of the sternum." For a moment he felt as if his heart had stopped beating and then, without any nausea, he threw off the food and was relieved. He made several successive attempts to swallow more food but without success. After four or five days he discovered that by drinking very hurriedly a large amount of liquid immediately after the taking of solid food he was able to overcome the stoppage in the esophagus and could feel the material enter the stomach; in addition to the drinking of the liquid it was necessary for him, however, to exert considerable effort. For fifteen years he continued this method of feeding, but at times the dysphagia would increase and he could not force the food into the stomach. At such times, and whenever any remnants were left in the esophagus, the food was immediately regurgitated or would be a few hours later. If any food remained at the time he was asleep it would run out of his mouth and be discovered by him the next morning. If he assumed the horizontal position immediately after eating an irritating cough would start in and he could secure relief only by regurgitating the food. Dr. Tyson attempted dilatation with all sorts of tubes but without much success. Attempts to measure the capacity of the dilated esophagus showed that he could drink thirty-four ounces of fluid without any unpleasant sensation and, apparently without any of it reaching his stomach.

The second case was a woman, aged thirty-three, who had been suffering in much the same way for a period of eight months. A special instrument was devised by Dr. Martin for dilatation in this case, the principle of the instrument being the same as that of the Kollmann urethral dilator. It was felt that its continued use would have given satisfactory results through the production of a partial paralysis of the muscular ring at the cardiac opening, but in order to put the esophagus at rest, and to force the patient's nourishment it became necessary to do a gastrostomy.

IDIOPATHIC DILATATION OF THE ESOPHAGUS: CARDIOSPASM. DR. B. W. SIPPY.

DR. SIPPY reported a case in all essentials like that described above by Dr. Tyson. He exhibited the specimens from this case, the patient having died shortly after a gastro-enterostomy performed for the relief of what was at the time believed to be a pyloric obstruction. At autopsy it was found that there was no anatomical narrowing of the cardia, but an hypertrophy of the circular fibres of the esophagus wall so that it was fully one quarter of an inch in thickness.

DILATATION OF THE ESOPHAGUS AND STOMACH. DR. FRANCIS P. KINNICUTT.

Another case of the same general character was described by DR. KINNICUTT and the pathological specimens shown. The esophagus from this patient had a capacity of 1,800 cm. of fluid and was, so far as could be determined, the most enormously dilated stomach and esophagus recorded.

Discussion. — DR. JANEWAY reported a case like Dr. Tyson's, except that it was complicated by hemoptysis. This patient could take 800 cm. of fluid into the esophagus without difficulty, and a photograph was exhibited showing the condition with this amount of dilatation. Dr. Janeway spoke of two mistakes often made in these cases, *i. e.*, considering them as hysterical, and as tuberculosis.

DR. MELTZER, having been called upon to say something of this condition, described his discovery of and first description of it in 1888. At that time he saw a case that had been suffering from it for nineteen years and presenting the symptoms given above. Previous to that time they had all been described as idiopathic or hysterical dilatations. Dr. Meltzer was the first to determine the true condition and ascribe to it the proper cause and mode of action. His patient was operated upon by a gynecologist five years later for a supposed malignant growth, and when, later, an autopsy was done it was found that the anatomical condition was precisely what he had described from the theoretical standpoint.

SECOND DAY, WEDNESDAY, MAY 11, 1904.

At the opening of the morning session the following-named gentlemen were elected to membership: Drs. P. K. Brown, San Francisco; Joseph Collins, New York; David L. Edsall, Philadelphia; Frederick G. Finley, Montreal; H. C. Gordinier, Troy; Richard M. Pearce, Albany; Mark W. Richardson, Boston; and Richard P. Strong, Manila, P. I.

Honorary Members: Drs. Beverly Robinson, Starling Loving and Henry P. Walcott.

The following officers were elected for the ensuing year: President, Dr. Edward L. Trudeau; vice-president, Dr. Frank Billings; secretary, Dr. Henry Hun; treasurer, Dr. J. P. Crozer Griffith; recorder, Dr. S. Solis Cohen; councillor, Dr. F. Forchheimer; representative in the Executive Committee of the Congress of American Physicians and Surgeons, Dr. William Osler; alternate, Dr. F. H. Williams.

THE RELATION OF CELLS WITH EOSINOPHILE GRANULATION TO BACTERIAL INFECTION. DR. EUGENE L. OPIE.

DR. OPIE presents a most elaborate study of the action of eosinophile cells when micro-organisms are introduced into the body. He reviews the literature of the subject at length, quotes from his own published work, and then relates in detail the behavior of these leucocytes during the course of fatal and of non-fatal bacterial infection. He worked with a variety of organisms and offers the following conclusions:

Certain bacteria (*Bac. tuberculosis, Bac. choleræ suis*) producing somewhat chronic, fatal infection in guinea pigs cause the eosinophiles to disappear from the circulating blood. After death a few can be found in those tissues in which they are usually found in abundance. During more active and acute infections produced by inoculating bacteria into the peritoneal

cavity, eosinophile leucocytes disappear almost completely from the peripheral circulation within a few hours. After the inoculation of an organism producing an infection from which the animal is capable of recovering they disappear from the peripheral circulation, so that their proportion may fall from 5 or 10% to less than 1%. The number then gradually increases until in four or five days it exceeds the normal proportion, and then slowly falls back to normal. When the number of eosinophiles is at the lowest point in the peripheral circulation they are found in great numbers in the vessels of the inflamed mesentery and omentum near the site of inoculation. Unlike the polynuclear leucocytes they rarely if ever act as phagocytes. In the region of the bacterial poison they undergo degenerative changes of which nuclear fragmentation is the most characteristic. Under the influence of severe bacterial infection eosinophile myelocytes, together with other elements, usually regarded as characteristic of the bone marrow, accumulate in the spleen and may be found in the circulating blood. The occurrence of this phenomena within two to four hours demonstrates that the elements are derived from the bone marrow and are not formed in the spleen. Bacteria exert a chemotactic influence upon cells with eosinophile granulation, attracting them from the circulating blood to the site of inoculation and from the bone marrow into the blood, Eosinophile leucocytes, like the finely granular polynuclears, accumulate in the neighborhood of bacteria injected into the body, and through they rarely act as phagocytes, have a part in the series of changes which follow bacterial invasion.

A NEW CASE OF CHLOROMA WITH LEUKEMIA, WITH A STUDY OF THE CASES REPORTED SINCE 1893. DRS. GEORGE DOCK AND A. S. WARTHIN.

Dr. Dock presented these conclusions: (1) Chloroma is a tumor-like hyperplasia of the parent-cells of the leucocytes, primary in the red marrow, the periosteum being involved only secondarily. The possibility of a primary chloroma in any part of the body in which white cells are formed must be considered. (2) As a result of this leucoblastic hyperplasia atypical leucocytes may appear in the circulating blood in varying number. Chloroma is therefore to be classed with the leukemias. (3) The white cells resulting from the atypical proliferation may in different cases attain different stages of differentiation. In some cases they may be of the large lymphocyte type, in others of the type of neutrophile or eosinophile myelocytes. (4) It is evident, therefore, as in the case of other leukemias, that the blood picture in chloroma may be very varied, and if this be used for a basis of classification it is possible to designate different varieties of chloroma. (5) The essential difference between chloroma and other forms of leukemia is the more marked neoplastic character of the former and the formation of the green infiltrations and metastases. (6) Chloroma is probably to be regarded as a more malignant form of leukemia. This malignancy of chloroma depends chiefly upon the replacement of the red marrow and erythroblastic elements by the proliferating white cells and the consequent diminished red cell formation. (7) The cause of the green color remains unknown.

TYPES OF SPLENIC ANEMIA OR SPLENOMEGALY. DR. ALFRED STENGEL.

Dr. Stengel reported a series of cases that had been carefully studied clinically and microscopically. The first case was that of a child three years old, that had at the age of two shown an increase in the size of the abdomen and marked pallor. Physical examination showed an enlarged spleen, and blood examination gave 30% of hemoglobin, 2,900,000 red cells and 7,600 white cells. A general dropsical condition appeared, and at the same time a leucocytosis of about 20,000. Autopsy revealed a general splenic enlargement with infarcts in the spleen and kidneys, a bronchopneumonia, vegetative endocarditis of the mitral valve and miliary tuberculosis of the lungs, liver and spleen. The lymphatic glands showed a marked hyperplasia and necrosis of the end endothelial cells.

The second case was an adult showing splenic anemia with cirrhosis of the liver. There were a generally stunted growth, club fingers and pigment changes in the skin. Autopsy examination disclosed hyperplastic changes in the spleen, cirrhosis of the liver, and fibroid changes in the lungs and other organs. The third case was a young woman twenty-five years of age whose condition was diagnosed as primitive splenomegaly. The spleen was removed by operation and the patient recovered. Microscopic sections of the spleen showed very marked hyperplasia with extensive fibroid growth.

Discussion. — Dr. Osler thought that these cases illustrate the extreme complexity of the subject and said that while the third case belonged to a very definite group it was doubtful if they could often be recognized clinically. He had seen such a case operated upon by Miculiez some years ago and the patient was afterwards exhibited before the German Surgical Congress. Since Dr. Osler's last report on this subject he has seen nine cases of great enlargement of the spleen associated with anemia. One was a case of so-called primitive splenomegaly; 4 were cases of chronic splenic enlargement with pigmentation of the skin; 2 belonged to that group which resembles Hanneaux disease, and 2 were cases of splenic anemia subsequently becoming pernicious anemia.

Dr. Sippy related one case which he had seen since the report he published in 1899. The patient was a woman with a movable spleen that came down below the umbilicus and readily moved about in the abdominal cavity. She presented the picture of a gradually developing anemia. The spleen was removed by operation and she made a complete and satisfactory recovery. Dr. Sippy raised the question whether the splenic anemia in these cases might be due to poisonous substances secreted by the enlarged spleen or whether it be due to malnutrition.

Dr. Cabot replied to this point, that there is no evidence, clinical or experimental, that splenic anemia is ever due to malnutrition.

THE AGGLUTINATION AND FILTRATION OF TRYPANOSOMES. DR. F. G. NOVY.

The main features presented in this work by Dr. Novy and his associates Drs. McNeal and Hare may be briefly summed up as follows: (1) The trypanosome present in the Philippine surra can be cultivated artificially. (2) Attenuated cultures of this organism can be obtained as in the case of *Trypanosome brucei*. (3) This trypanosome is differentiated by its cultural characteristics from *Trypanosome brucei* and *Trypanosome lewisi*. (4) The Philippine surra is therefore a distinct disease, different from nagana, and this observation confirms the work of Laveran and Mesnil on the non-identity of nagana and the surra of Mauretius. (5) The morphological differences between the Mauretian and Philippine trypanosomes suggest the probability that these organisms are distinct species, and hence that the term "surra" covers a group of closely allied diseases.

ZONAL NECROSIS OF THE LIVER. DR. E. L. OPIE.

DR. OPIE reviewed the vascular and other anatomical features peculiar to the liver structure to show the varying facility with which necrosis occurs in different zones of that organ. He referred at length to the experimental work which has heretofore been done on this subject, and then considered in sections the conditions associated with zonal necrosis of the liver in various diseases, dividing the subject into central necrosis, peripheral necrosis and mid-zonal necrosis, and followed that with a special consideration of the relation of mid-zonal necrosis to acute yellow atrophy of the liver. He related the clinical and anatomical histories of cases in each class. The paper is an extremely interesting one, not susceptible of satisfactory abstraction, and can be profitably read in full by those who are interested in the subject.

EXPERIMENTAL ARTHRITIS AND ENDOCARDITIS PRODUCED BY A STREPTOCOCCUS ISOLATED FROM THE BLOOD OF A CASE OF RHEUMATISM, ENDOCARDITIS AND CHOREA. DRS. M. J. LEWIS AND W. P. LONGCOPE.

In a fatal case of rheumatism, endocarditis and chorea a streptococcus was isolated from the blood before death. This organism did not differ materially from the common varieties of Streptococcus pyogenes in cultural properties, but produced very characteristic lesions in rabbits when injected intravenously. Such inoculations were always followed after a few days' incubation period by a multiple arthritis which usually started in the ankles. In one rabbit extensive vegetations were found on the mitral valve while typical infarctions were seen in the spleen and kidneys. This organism was believed to be the same as that described by Wassermann, Meyer, Poynton and Paine and Ainley Walker, and considered by them to be the specific cause of rheumatic fever.

Recent Literature.

A Manual of General or Experimental Pathology for Students and Practitioners. By WALTER SYDNEY LAZARUS-BARLOW, B.A., B.C., M.D., F.R.C.P., Director of the Cancer Research Laboratories of the Middlesex Hospital. Second edition. Philadelphia: P. Blakiston's Son & Co. 1904.

The first edition of this work appeared five years ago and was favorably reviewed in this journal at that time. The present edition has been greatly enriched by the addition of new matter, and the plan of the work has been slightly altered so that it forms a companion volume to the author's "Pathological Anatomy and Histology," recently issued.

In describing the advances made in pathological knowledge the names of the chief investigators are mentioned. This commendable feature adds to the value of the book and quickens the student's interest in the masters of medical science. The fact that the number of authors cited in the text has been increased by nearly two hundred shows that the work of revision has been thorough.

The general scope of the work is not quite the same as that of the well known textbooks of Thoma, Ziegler and Ribbert. It deals with pathological physiology and occupies an intermediate place between these works on general pathology and Krehl's classical "*Pathologische Physiologie.*"

There is a good detailed account of the pathology of the circulation, but unfortunately the results of the important studies made by the young "Leipsic School" are not incorporated.

The author agrees with other recent writers that the old division of anemias into primary and secondary should be abandoned. He does not, however, mention the classification of Ehrlich who divides anemias into the simple and the pernicious, according as to whether blood formation occurs in a normal or abnormal manner. Lazarus-Barlow groups the anemias into two great classes: anemias in which leucocytic changes are absent and those in which leucocytic changes are present. The first group is subdivided into (*a*) anemias in which the principal change is a diminution in the number of red blood corpuscles, and (*b*) anemias in which the principal change is a diminution in the hemoglobin content of the individual red blood corpuscles. This classification seems more artificial and less satisfactory than that of Ehrlich.

In the short discussion of the present views on coagulation of the blood the importance of tissue fluid is recognized and the experiments of Delezenne and other recent workers are described. The chapter on edema is shortened in this edition, but the author's own researches on this subject make his treatment of this topic of particular interest. The various theories of lymph and edema formation are clearly set forth.

Inflammations, the degenerations and new growths are considered in this volume as well as in the textbook of pathological anatomy. This arrangement is confusing and leads to some repetition. We think it is a better plan to consider together in one article the anatomical and physiological aspects of these topics.

In the excellent chapter on infection and immunity there is an admirable presentation of Ehrlich's side-chain theory.

The section on fever is worthy of special commendation. It contains a summary of recent literature which is one of the best in English.

The discussion of fatty metamorphosis needs further revision. The assertion that fatty degeneration of the liver and other parenchymatous organs occurs as the result of phosphorus poisoning can no longer be accepted as true. Rosenfeld has clearly shown that the fatty change is due to fatty infiltration. Furthermore, it has been recently shown that other supposed examples of fatty degeneration are in reality fatty infiltrations.

Pathological physiology is a subject of fundamental importance to the physician. This volume deserves a wide circulation as it covers the field better than any other English work and is interesting throughout. The practitioner who is striving against routinism and the student who wishes to found his knowledge of clinical medicine on the solid rock of natural science will be strengthened and stimulated by this book.

King's Manual of Obstetrics. By A. F. A. King, M.D., Professor of Obstetrics and Diseases of Women, in the Medical Department of the Columbian University, Washington, D. C., and in the Medical Department of the University of Vermont. Ninth edition, revised and enlarged. In one 12mo volume of 628 pages, with 275 illustrations. Philadelphia and New York: Lea Brothers & Co. 1903.

This book shows its continued popularity by the appearance of a new edition, the ninth. While more than the usual manual in its scope, yet the book has not been changed materially from the former edition. It still retains its elementary character, and no attempt has been made to develop it into a systematic treatise.

The book has been enlarged slightly, new illustrations have replaced old ones, and some of the text has been rewritten in order to make it correspond to modern practice. This it does to an unusual degree for a manual, and although necessarily too much abbreviated to use alone as a textbook, the work is one to be commended, and contains much of value.

The Principles of "Open-Air" Treatment of Phthisis and of Sanatorium Construction. By Arthur Ransome, M.D. Smith, Elder & Co.: London. 1903.

The name of the author of this book would in itself ensure respectful attention to the contents of the book. In this case a series of essays has been put together bearing chiefly upon the sanatorium treatment of phthisis, although one chapter is devoted to the "home treatment" of patients. Essay II seems to the reader somewhat desultory and, although containing much that is true, does not on the whole seem quite in place in the midst of matter devoted chiefly to the details of sanatorium treatment. The diagram of a sanatorium is cleverly conceived, and in one particular especially is worthy of consideration, namely, the arrangement of a two-story building by which the balcony of the upper room scarcely overshadows the chamber below, a detail of great importance in any institution of this nature.

The book is worthy of a conspicuous place upon the book-shelves of anyone who is devoting his attention to the study and treatment of tuberculosis according to modern methods.

Enzyklopädisches Handbuch der Schulhygiene. A. Pichler's Wittwe & Sohn: Leipzig and Wien. 1904. 1055 pages.

This valuable handbook embraces the whole range of school hygiene. Every topic connected with this important subject being treated, and nearly all civilized nations levied upon for contributions. The work is compiled by Dr. R. Wehmer of Berlin, assisted by thirty or more collaborators representing nearly as many different countries.

The volume is fully illustrated with more than 300 cuts, plans and heliotype illustrations. Physicians, school superintendents, teachers and others who are desirous of being well-informed upon this subject will find it a valuable work of reference.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 9, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY.

The one hundred and twenty-third annual meeting of the Massachusetts Medical Society came to an end Wednesday of this week with the usual anniversary dinner. The literary portion of the meeting was arranged this year much as in the several preceding years by reducing the number of original papers to relatively few, and concentrating attention on certain special subjects of great general interest. Experience has shown that through this method the section meetings are better attended.

The Shattuck Lecture, which was this year delivered by Dr. George S. Huntington of New York on the subject, "The Relation of Comparative Anatomy to Medical Education and Practice," was particularly well attended. Dr. Huntington presented a cogent argument on the desirability of the study of comparative forms as a means of the better understanding both of pathological and normal conditions in the human subject. The lecture was admirably illustrated by lantern slides. It will later appear in these columns. The annual discourse by Dr. Harold C. Ernst concerned itself with certain educational problems of the present and future and brought up again the question of two degrees for students of medicine, depending upon the character of work done in their undergraduate course.

The retiring president of the society, Dr. George E. Francis, presided at the annual dinner, which as usual was largely attended. The custom of reducing the number of after-dinner speeches is also to be approved since the hall is a peculiarly difficult one in which to be heard.

Dr. Francis first introduced Bishop Vinton of the Episcopal Diocese of Western Massachusetts, who spoke in a happy vein of the physician, old and new, and of the responsibilities and privileges of the medical profession. He thought it possible that the physican considered somewhat too exclusively the physical side of his patient, and that it might be well if more stress were laid upon the psychical element in his ministrations. This is undoubtedly being realized to a very much greater degree than Bishop Vinton recognizes, although possibly not in precisely the way he indicated. Dr. Horace D. Arnold spoke in place of Dr. George W. Gay, who was unavoidably absent, on the general subject of the Boston Medical Library and the proposed enlargement of its scope into a so-called academy of medicine. He urged upon the physicians of the state their hearty co-operation in a plan through which the library may hold medical meetings which shall not supersede those of existing societies, but will tend to combine the activities of Boston and outlying districts. He expressed the hope that such an organization might be representative, not only of Boston and Massachusetts, but also of New England. The Hon. Carroll D. Wright spoke humorously, and yet with much seriousness, upon the subject of trade unionism, designating the medical profession as the oldest union in the country. He insisted upon both the necessity and desirability of combination and organization, if perfection in any calling is to be attained, and felt that the best in the union idea might be, and in fact was, demonstrated in the profession of medicine. He thanked God that " the baby that rocks in the cradle bears the union label of union made." Finally he spoke feelingly of the fact that the popular idea of trade unionism, as everywhere at the present time manifest, was in great measure erroneous; that the troubles and difficulties caused by unionism are exceptional, and that the vast number of differences and disputes amicably settled through their agency is wholly unknown. The exercises were concluded by the introduction of the new president, Dr. Arthur T. Cabot, who spoke briefly of the honor conferred upon him and begged the co-operation of the fellows of the society.

The meeting in general, like the long list of its predecessors, must be regarded as a decided success, not only in presenting certain medical matters of vital interest to practitioners, but also in encouraging that sense of fellowship for which such an association in great measure exists.

THE DEVELOPMENT OF THE PRIVATE HOSPITAL.

THE recent opening of the Corey Hill Hospital in Brookline is no doubt a forerunner of the development in this community of this type of private institution. For many years it has been evident, both in this and other large cities, that the public hospitals, constituted as they are, do not meet the requirements of all the sick. This is naturally due to the fact, in the first place, that our public institutions are designed, and rightly so, for the care of the poor who must be the subjects of charity. Private wards appended to such hospitals have no doubt proved themselves of value, but the demand has long since surpassed the supply, and further accommodations are imperatively required. In the second place, the prejuduce against going to a hospital for the treatment of various types of disease has apparently entirely disappeared, so that now people not only are willing to go, but prefer to do so rather than remain in their home surroundings, whatever their circumstances in life may be. Reasons for this are sufficiently obvious.

The Corey Hill Hospital is a private enterprise undertaken by fifteen physicians, chiefly surgeons of Boston, for the purpose of providing further accommodations for their patients. The hospital is not designed for the treatment of any one class in the community, but is rather intended to provide an abundance of fresh air, which, if hitherto obtainable in private hospitals in this city, has only been so in less degree, and the possibility, if necessity requires, of a long stay at the hospital. In fact, the treatment of certain chronic forms of disease was especially considered in the design of the hospital, although this naturally will not be its exclusive province.

The financial management of the institution has been placed in the hands of trustees, and it is neither expected nor desired that the investment will return a large rate of interest. The nursing is to be done wholly by women who have already had experience in other hospitals, and who will serve at this hospital for a period of from three to six months for the purpose of acquiring detailed knowledge of the treatment of the individual patient as seen rather under the conditions of a private house than of an institution. Accommodations have up to the present time been provided for upwards of thirty patients. The situation of the hospital is most salubrious, on the summit of a considerable eminence in the neighborhood of Boston; the equipment is

altogether attractive, and the operating facilities complete in every detail.

It is, of course, generally known that private hospitals have existed in this as in other cities for many years. They have arisen and flourished in direct response to the demand of the public as well as of physicians who see the desirability of hospital treatment for many of their private cases. These hospitals have fulfilled a valuable function under certain disadvantages, often of construction, and we see in this elaborate addition to the private hospitals of Boston simply a further step in the direction which has already been taken by less pretentious enterprises of a similar sort. In general, the movement is one which deserves encouragement. There can be no question that patients with many forms of disease may be better taken care of, and in the end more economically, at such specially constituted hospitals than at their own homes. Not many years ago the only variety of private hospital was that for the mentally disordered. Now there is hardly a type of disease which has not its special place of treatment. We are glad to see in this latest hospital that one of the distinct objects is the treatment of chronic forms of disease which have rarely hitherto found an adequate resting place.

EXTINCTION OF RABIES IN GREAT BRITAIN.

The practicability of stamping out an infectious disease in an insular community by preventive measures has been demonstrated by the Board of Agriculture of Great Britain, as shown in its recent report upon the diseases of animals.[1] Prior to 1897, power to make regulations imposing the muzzling of dogs was vested in the hands of the local authorities, and it was not until that year that the Board decided to take active measures for the suppression of rabies.

"Six years have now elapsed," says the report, "since a determined effort was made by the Board to extinguish this disease, and strange to say, some of the most ardent opponents to the measures adopted have been the owners of dogs. As the eradication of rabies was distinctly in the interest and for the benefit of all the dog owners in the country, one would have thought that any measure which would have had the effect of saving their animals from such a direful and fatal malady would have received the entire sympathy of that particular section of the community. But even at the risk of offending the minority of dog owners, it was worth while to make a bold attempt to exterminate a disease which, when communicated to the human being, produces what is generally admitted to be one of the most hideous and incurable diseases to which mankind is liable, — and happily the attempt has been attended with remarkable success."

An interesting table is presented, showing the number of deaths from hydrophobia in Great Britain since 1848. Deaths from this cause were registered every year until 1898. In 1874 there were 61; in 1877, 79; and in 1885, 60. But in the past five years there have been only two deaths reported from this cause, one of which was that of a military officer who was bitten by a dog when out of the country.

Among dogs, there were 672 cases of rabies reported in 1895, 438 in 1896, 151 in 1897; but in 1901 there was only one. "This diminution of hydrophobia," says the Board, "runs concurrently with the eradication of rabies in the dog, and has followed upon and is due to the measures adopted by the Board for stamping out rabies in the dog."

[1] Proceedings under the Diseases of Animals Acts, for the year 1903, London, 1904.

NEW BUILDINGS AT THE BOSTON CITY HOSPITAL.

We have already commented briefly on the fact of the opening of the new out-patient building and surgical wards at the Boston City Hospital, but lack of space has hitherto prevented a fuller statement of the significance of this new addition to the hospital. For many years there has been a growing necessity at this institution for a more adequate out-patient department, and the work of the physicians has been done under distinct disadvantages owing to the crowding and general lack of space. The new out-patient building will do much to obviate this condition of affairs.

The building is three stories in height, with two wings at right angles to each other, with the general entrance at the internal angle. The whole lower floor is given up to the male surgical department, the second floor to the surgery of women and children, and the third floor to special departments for the eye, ear and throat. Although the various rooms are not of great size, they certainly should be altogether adequate for meeting the contingency of the constantly growing clientele of this hospital. The general furnishing, wood work and appearance of the

various rooms is in excellent taste from the fact that the equipment fits the use to which it is to be put. Ornateness and elaborateness are neither attractive nor desirable in such a department of a hospital. Both of these defects have been admirably avoided in this building. The new surgical wards at the extreme western end of the hospital grounds occupy a building of three stories with fourteen ward rooms on each floor each accommodating two patients. A room of particular interest to visitors is one on the first floor in which has been collected pictures of surgeons and trustees connected with the institution since its dedication forty years ago. It is proposed finally to so alter the medical out-patient department that it will more fully meet modern requirements. With this further addition to the hospital buildings the out-patient department should be adequate for many years to come, although the phenomenal growth of this institution makes prophecy dangerous.

MEDICAL NOTES.

INTERNATIONAL TUBERCULOSIS CONGRESS. — The International Tuberculosis Congress began its session in Copenhagen May 27, under the presidency of Professor Brouardel of Paris. Delegates from many countries were present, the United States being represented by Dr. E. L. Trudeau of Saranac Lake.

BOVINE PLAGUE IN EGYPT. — In addition to bubonic plague it is reported, according to *American Medicine*, that bovine plague is very widespread in Egypt. Severe precautionary measures are being taken, but owing to the nomadic character of the population the results, it is said, are unsatisfactory as far as the cattle disease is concerned. According to reports Egypt is also menaced this year with an invasion of locusts. In certain districts the government has ordered the destruction of the eggs left by the clouds of these insects that have already made their visitation. Under the direction of experts sent out by the ministry of the interior almost the entire population of some sections of Egypt is engaged in destroying the eggs.

AMERICAN CLIMATOLOGICAL ASSOCIATION. — The American Climatological Association met at Philadelphia on June 2, 3, and 4, and Dr. J. C. Wilson of Philadelphia presided. The program included thirty papers. At the business session the following officers were elected for the ensuing year: President, Dr. W. F. R. Phillips, Washington, D. C.; 1st Vice-President, Dr. S. G. Bonney, Denver; 2d Vice-President, Dr. S. D. Risley, Philadelphia; Secretary and Treasurer, Dr. Guy Hinsdale, Hot Springs, Va. Member of the Council Dr. J. C. Wilson, Philadelphia; representative to the Executive Committee of the Congress of American Physicians and Surgeons, Dr. Frederick I. Knight, Boston. The place of meeting for 1905 was not decided.

WALTER REED MEMORIAL ASSOCIATION. — The Walter Reed Memorial Association has been incorporated under the laws of the District of Columbia to provide some special recognition for the scientific work of the late Maj. Walter Reed, U. S. A. The American Medical Association and the Association for the Advancement of Science have appointed committees to co-operate with this association, and it is desired that subscriptions to the fund in process of collection be handed to any member of these committees, or such contributions may be sent to Mr. Charles J. Bell, President of the American Security and Trust Company, Washington, D. C. It is thought that at least $25,000 should be raised, but the exact character of the memorial will not be determined until later. Chief dependence must be placed upon physicians in arousing interest in the general project by pointing out the far-reaching results of Major Reed's yellow fever investigations.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 8, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 72, scarlatina 14, typhoid fever 7, measles 125, smallpox 0.

THE JOHN W. PRAY PRIZE. — This prize, offered by the trustees of the New Hampshire State Medical Society for the best essay on a medical subject, was awarded at the recent meeting of the society to Dr. Frederick L. Hills, first assistant physician at the New Hampshire State Hospital, the title of the paper being "The Sanatorium for Incipient Pulmonary Tuberculosis; Its Aims, Methods and Results."

ANTHRAX IN LYNN. — The reappearance of anthrax in Lynn has led to a special meeting of the Board of Health for the purpose of considering means for checking the spread of the disease. Certain specially qualified persons are to be called to the aid of the Board of Health in providing for means to this end. It is thought that some special regulations for em-

ployees in morocco factories may be required, and the matter of isolation of patients also demands consideration. It is said that there have been eighteen cases in Lynn during the past three years, with a number of deaths. The latest victim is expected to recover.

NEW YORK.

Reception for Prof. Hoffa. — During the past week Prof. Albert Hoffa of Berlin has been the recipient of much attention, and among the entertainments given for him was a large reception by Dr. Reginald H. Sayer.

Bequests to Hospitals. — Among other charitable bequests made in the will of the late Charles Emmons are $500 each to the House of Rest for Consumptives at Mount Hope, Borough of the Bronx, and the Eastern District Hospital and Dispensary of Brooklyn.

Tuberculosis in Street-Cleaning Department. — By order of Dr. Woodbury, commissioner of street cleaning, a systematic medical examination has been commenced of the 6,000 sweepers in the employ of his department, for the purpose of ascertaining what percentage of the men are affected with tuberculosis. Out of 87 employees from the Second District, embracing the territory between Broadway and the East River, Chambers and Broome Streets, who were examined on June 3, the physicians in charge reported that they had found 11 cases. In 9 the disease was quiescent, while in two it was in an active stage.

The City Death-Rate. — With the advance of milder weather there has been a gradual diminution in the death-rate of the city, although it still remains very considerably higher than at the same time last year. The mortality during the month of May represented an annual death-rate of 21.70, as against 24.82 in April and 18.51 in May, 1903. The corrected death-rate, excluding non-residents and infants under one week old, was 20.79. The most marked decrease in fatality has been in pneumonia, from which the weekly average of deaths was 173.25, as against 244.75 in April. During the last week in May there were 115 deaths from it, while in the last week of April the deaths numbered 258, or more than twice as many. In broncho-pneumonia the decline was not so great, the weekly average of deaths from this disease being 101.25, as against 132.25 in April. Other diseases showing a decreased mortality were the following: The weekly average of deaths from diphtheria and croup declined from 60.25 to 47.25; from scarlet fever, from 29 to 25; from measles, from 41.5 to 38.75; from influenza, from 22 to 7.5; from acute bronchitis, from 44.5 to 39; from pulmonary tuberculosis, from 202.75 to 178.5; from Bright's disease and nephritis, from 135.5 to 126; and from organic heart diseases, from 114 to 102. Among the few diseases which showed an increased mortality were typhoid fever and cancer. The weekly average of deaths from the first increased from 6.25 to 10, and from the the second, from 48.25 to 53.25.

Obituary.

PROFESSOR WILHELM HIS.

Dr. Wilhelm His, professor of anatomy at the University of Leipzig, died May 1, after an illness entailing much suffering. By his death the medical profession loses one of its most brilliant and productive members. He was born at Basle in 1831, and studied medicine successively in Basle, Berne, Berlin, and Würzburg. During his stay in Berlin he came under the instruction of Johannes Müller and Remak from whom he acquired the rudiments of anatomy and embryology which later he developed in such remarkable degree. At Würzburg he came under the observation of Virchow and worked in his laboratory. Later he went to Paris and studied under Claude Bernard and Brown-Séquard.

At the age of twenty-six, through the promotion of Meissner, he became professor of anatomy and physiology at Berne, his birthplace. He remained at the University of Basle until 1872 and then went to the University of Leipzig as professor of anatomy and director of the anatomical laboratory, succeeding Prof. E. H. Weber. During many years of his stay in Leipzig he was very intimate with Professor Braune who became professor of topographical anatomy at the university. As a writer and contributor to scientific literature he was active throughout his professional career, contributing papers to nearly every department of anatomical knowledge and creating for himself the highest possible position as an embryologist; in fact, he may with justice be said to have been the most influential man in the development of modern embryological theory. His researches on the nervous system, and what he regarded as the developmental evidence for the neurone theory are matters of common knowledge. His work on the anatomy of human embryos formed the basis of much of the subsequent study of this subject. The death of Professor His removes another of that most eminent group of German scientists of a former generation, and he may with justice be placed in the same category with Helmholz, Virchow and du Bois Reymond, who have all died within the past decade.

RECORD OF MORTALITY
FOR THE WEEK ENDING SATURDAY, MAY 28, 1904.

Deaths reported, 3,314; under five years of age, 900; principal infectious diseases (smallpox, measles, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 850; acute lung diseases 468, consumption 375, scarlet fever 46, whooping cough 7, cerebro-spinal meningitis 85, smallpox 4, erysipelas 13, puerperal fever 20, measles 44, typhoid fever 60, diarrheal diseases 120, diphtheria and croup 77.

From whooping cough, New York 2, Chicago 2, Baltimore 1, Pittsburg 1. From smallpox, Philadelphia 2, Baltimore 1, Pittsburg 1. From cerebro-spinal meningitis, New York 80, Pittsburg 1, Providence 1, Boston 1, Gardner 2. From erysipelas, New York 9, Chicago 2, Boston 2. From typhoid fever, New York 14, Chicago 4, Philadelphia 22, Baltimore 3, Pittsburg 10, Providence 1, Boston 1, Fall River 1, Lynn 1, Brockton 1, Newton 1, North Adams 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending May 14, the death-rate was 16.1. Deaths reported 4,705; acute diseases of the respiratory organs (London) 116, whooping cough 193, diphtheria 58, measles 181, smallpox 6, scarlet fever 30.

The death-rate ranged from 6.0 in Smethwick, to 24.0 in Warrington; London 16.3, West Ham 14.5, Brighton 14.9, Southampton 14.4, Plymouth 13.7, Bristol 14.0, Birmingham 22.0, Leicester 12.1, Nottingham 14.7, Liverpool 17.2, Bolton 17.8, Manchester 21.3, Salford 17.8, Bradford 17.9, Leeds 16.6, Hull 17.5, Cardiff 17.4, Rhondda 17.1, Wigan 17.4, Merthyr Tydfil 10.8, St. Helens 13.0.

METEOROLOGICAL RECORD.

For the week ending May 28, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING JUNE 4, 1904.

I. W. KITE, surgeon. Detached from the "Maine" and ordered to the naval hospital, Pensacola, Fla., for treatment.

A. M. FAUNTLEROY, assistant surgeon. Detached from the "Scorpion" and ordered home and to await orders.

R. R. RICHARDSON, assistant surgeon. Detached from the naval hospital, Pensacola, Fla., and ordered home and to await orders.

J. L. TAYLOR, acting assistant surgeon. Detached from duty with naval recruiting party No. 6, May 28, and ordered to duty at the naval hospital, Pensacola, Fla.

F. A. RICHARDSON, acting assistant surgeon. Detached from the naval hospital, Newport, R. I., and ordered to the "Scorpion," June 2.

J. F. MURPHY, assistant surgeon. Detached from the "Isla de Cuba" and ordered home and to wait orders.

W. D. OWENS, assistant surgeon. Ordered to the naval hospital, Newport, R. I.

BOOKS AND PAMPHLETS RECEIVED.

The Elements of Kellgren's Manual Treatment. By Edgar F. Cyriax, M.D., Edinburgh. Illustrated. New York: William Wood & Co. 1904.

Railway and Other Accidents with Relation to Injury and Disease of the Nervous System. A Book for Court Use. By Allan McLane Hamilton, M.D., F.R.S.E. Illustrated. New York: William Wood & Co. 1904.

Lectures on Clinical Psychiatry. By Dr. Emil Kraepelin. Authorized translation from the German. Revised and edited by Thomas Johnstone, M.D., Edin., M.R.C.P. (Lond.). New York: William Wood & Co. 1904.

Torticollis and Spinal Curvature due to Eyestrain. By George M. Gould, M.D. Reprint.

The History and Etiology of "Migraine." By George M. Gould, M.D. Reprint.

Medical Discoveries by the Non-Medical. By George M. Gould, M.D. Reprint.

The Nonoperative Relief of Eyestrain for the Possible Cure of Epilepsy as tested in sixty-eight cases at the Craig Colony. By William P. Spratling, M.D. Reprint.

Pervigilium, or Long Periods of Physiologic Wakefulness. By George M. Gould, M.D. Reprint.

Studies from the Rockefeller Institute for Medical Research. Reprints. Vol. I. 1904.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By Prof. Dr. Carl von Noordin. Authorized American Edition translated under the direction of Boardman Reed, M.D. Part V. New York: E. B. Treat & Co. 1904.

The Life-Study of Patients, or the Biographic and Multiple Biographic Method of Discovering Medical Truth. By George M. Gould, M.D. Reprint.

Addresses.

SOME ASPECT OF MEDICAL EDUCATION.[1]

BY JOHN H. MUSSER, M.D., PHILADELPHIA, PA.

It is no trifling occasion that draws together from the uttermost parts of the country one fifth of an organization of a profession that is taxed to its utmost in the prosecution of its duties. It is not with sounding trumpets and tinkling cymbals that from the sorrowing bedside,— whether in the hovel of the poor or the palace of the rich,— from the excitement of the operating room, from the stimulus of the hospital ward, or the quiet, but inspiring haunts of the laboratory, this assembly gathers. That it is possible is a handsome tribute to the noble animus in which are embodied a spirit of inquiry, a thirst for knowledge, a longing for inspiration, a desire to uplift and to be uplifted that pervades the profession. The event is one that should be fraught with the dignity, the inspiration, one might almost say solemnity, befitting a symphonal march. For such animus, fellow members, we have just cause for self-congratulation.

It scarcely need be reiterated here that the spirit which pervades such a meeting is the outcome of that evolution which began with the introduction of precision in medicine. Just as soon as the art of medicine had for its foundation the science of medicine, the possibility of harmonious medical organization arose. When "rule of thumb" or intuition gave way to precision; idealism to realism; when speculation was displaced by fact; when, in short, inductive methods were employed and honest inquiry became the guiding star of action, then harmony could sit in council.

With medical, as with all organizations made up of human elements, it would be only human if not pervaded by the essence of science — truth. Hence with the latter wanting, jealousies and ambitions, self and selfishness, would prevail to the end that the true object of organization — a fraternal spirit and conscientious seeking for truth — would be as a flickering flame. A little observation will show that that society, whether county, state or national, that does not have this true reason for its existence, for its guide of action, will be a failure. The reverse is also true that that organization which may be called unsuccessful and unhappy, of snarling men and backbiting colleagues, can be labeled at once as without its true vocation, to the discredit of its members.

The great heights to which our organization is rising rapidly precludes the activities of such as have self for their basis of action, so that each day we see more and more a noble rivalry of its members to do the utmost and the best for the organization; a healthful vying of one another for its welfare. Self and selfishness are looked at askance; partisanship and faction, save for a common end — the welfare of the association — are memories.

But, fellow members of the Association, at this the fifty-fifth session of our Association we have other causes for congratulation and felicitation. We are on the eve of a union of all the members of the profession in one harmonious organization, each individual of which is willing and proud to consider his fellow a gentleman until he is proved not to be, and not, as of yore, a knave until he is proved to be a saint. We are reaping the rewards of that untiring committee which gave to us this organization with which we now labor. We are prospering beyond measure, and gathering a force scarcely to be estimated, in great part as a result of the untiring efforts of the apostle of organization — our McCormack. To say that thirty-four states have adopted the uniform plan of organization, and "that membership in the reorganized states has increased 400%, and enthusiasm," writes our coadjutor, "tenfold more," is enough. We are standing out in our own manliness with the majesty that belongs thereto because of the sentiments expressed when our broadly inspired committee voiced the unanimity of feeling which belonged to the Association, in our principles of ethics. We are letting our light shine through the instrumentality of that genius of medical editors — our Simmons. From five thousand to twenty thousand in less than a decade is a statement of circulation which appals and at the same time arouses a feeling of pride and stimulates to further effort, increased all the more when we reflect that the scientific value of the articles in *The Journal* are surpassed by none of its contemporaries; its tone is emulated by all.

Such causes for congratulation bring to this association greater responsibilities and weightier problems for solution. It is held to be the bounds of this address to indicate responsibilities, some trite and apparently trifling, others most weighty; to point out duties, many so grave and vast, beyond the powers of your official to justly define.

NECROLOGY.

Before passing to the task, let us pause a moment and with due reverence take cognizance of our colleagues who have, since our last meeting, gone to the great majority. The Silent Reaper has been as rapacious as in the past, and more than fifteen hundred fell in his swath. He has spared neither the humble nor the great. The less conspicuous but just as potent laborers in the vineyard can say with the others: "I have fought a good fight, I have finished my course, I have kept the faith."

Of those who have been honored by this association in the past, we lost two ex-presidents, the hearty, rugged, yet withal gentle and kindly Donald MacLean, surgeon and teacher, and the urbane James Farquhar Hibbard, a revered general practitioner and teacher; two ex-vice-presidents in John Bates Johnson, one of the

[1] President's address at the fifty-fifth annual session of the American Medical Association at Atlantic City, June 7-10, 1904. By courtesy of the Journal of the American Medical Association.

founders of the Association, a great practitioner, an honored teacher, and Isaac Newton Love, genial and magnetic. From the ranks we lost Edmund Andrews, scientist, pioneer in surgery and medical education in the West; George Julius Englemann, obstetrician, scientist, litterateur, teacher, honored at home and abroad by membership in great organizations; James McFadden Gaston, pioneer in the surgical treatment of affections of the gall bladder and gall ducts, an esteemed practitioner; Franklin Staples, Hamilton Atchison West, Orpheus Everts, each obtained prominence and respect by force of character and natural attainments; Emile A. de Schweinitz, scientist and brilliant investigator, laboring not for his own renown but for that of his profession, passing away at the threshold of a most promising career; Frank Savary Pearce, untiring and enthusiastic, who had been expected to counsel with us this week.

HOUSE OF DELEGATES.

The conduct of business under the new constitution bodes success. The two years of trial have indicated that to the House of Delegates the greatest responsibilities fall. When its members consider the great power the American Medical Association will have for weal or woe in the future and that the great body gives that power almost unstintingly to the delegates, they should justly realize the honor and confidence bestowed on them. With such realization will come honest purpose and deliberate action. All the county and state organizations must appreciate the vast duties to be undertaken, and the breadth of view, deliberation and wisdom essential to their correct performance, and consequently select from their number the best of their possessions. Let us as an organization see to it that honor and homage come to those who labor unceasingly in the House of Delegates.

NATIONAL LIFE.

It can be readily seen that an organization of the magnitude and with the object and the spirit of our Association must, in justice to itself and duty to its country, take part in its social and political life. In order that we can be in touch with such life it would be well for the Association to devote some time to the discussion of broad general topics. We have provided for discussions at this meeting, the advisability of which may be termed tentative. We feel they can be productive of great good, and if the experience on this occasion is the least encouraging, we would urge their continuance. We had hoped to have government officials take up matters pertaining to the relation of the medical profession to the executive, legislative and administrative departments of the government. The exigencies of politics forbade our obtaining the services of those worthy to address this body. All men of political affairs are too busy at this junction. At other times we may learn with profit from our rulers and law makers. As arranged for this week, so in various parts of the country in which the meetings are held, broad topics of general interest, perhaps with local flavor, could be discussed. From those in the far West we might learn much of climate or how to conquer the plague or the medical aspect of "the yellow peril." The good judgment of the committee or the president can be relied on to select topics suitable to the occasion.

It is needless to refer to the demands that will be made on us by the nation in the future. You will learn through the representatives of the army, the navy and the marine-hospital service what is expected of us. My distinguished predecessors, Reed, Keen and others, have pointed out our possibilities for good in the legislative halls of county, state and nation. We must have care never to be partisan or factional toward the weighty matters we will have to decide. We must realize that the power we have may be our undoing. We must realize that we are entering on dangerous ground and that it would better become us to be bidden rather than to intrude ourselves into such territory. Indeed, one may tremble not a little at the possibilities of our development in the wrong direction. So long, however, as we hold true to the spirit which comes out of devotion to science we need not fear.

THE SECTIONS.

The work in most of the sections the past few years bears favorable comparison with that of co-ordinated organizations throughout the country. To inflict discussion concerning them on this general meeting is, we realize, somewhat of a hardship. Your indulgence is craved, however, for through your medium alone can the sections be reached, while peradventure the work of these sections is fully as important as that of any branch of our Association work. If you will look into it you will find the rise of the Association came with the development of section work. To enhance the value of such work is, therefore, to uplift the organization. The present methods are worthy of trial for a few years, just as we should not make haste in changing the new constitution. Regarding it, may we suggest thought along these lines?

(1) The continuance of the secretary for a term of years.

(2) The collaboration of sections so that one topic can be exhaustively considered at the meeting of the Association without repetition in other sections. For this purpose the officers of the section should meet for consultation six or eight months before the annual meeting. We feel we did good work by having our distinguished chairman and secretaries come together last October.

(3) The division of the Association into two main sections for work in the mornings, that of (*a*) *medicine*, including pathology, diseases of children, nervous and mental diseases, materia medica, stomatology, cutaneous medicine and sanitary science; (*b*) *surgery*, including obstetrics, gynecology and the more closely related surgical

specialties. The members interested in diseases of the eye or nose or throat could contribute to either section the result of any studies related to the respective section. The afternoons could be occupied by the specialized labor of the twelve sections now in existence.

Perhaps it might be thought better to have one morning, at the direction of the Section on Practice of Medicine, devoted to the discussion of general topics related to medicine, in which the entire Association could take part; another morning, at the direction of its secretary, to surgery; a third to the specialties; a fourth to sanitary science. The object is to secure the views of physician, surgeon and specialist on general topics. To instance as a subject, endarteritis, is to call up at once the possibilities for the internist, the surgeon and the specialist.

(4) The sections should take up and organize special international congresses when the time is ripe for such meetings. Thus an International Congress of Dermatology could be managed by the correlated section of this Association. With the patronage of the American Medical Association any congress that could command such special energies and broad general support could not fail.

(5) The section should name to the president a list of its members from which he could select, when asked, delegates to important national meetings or international congresses.

SANITARY SCIENCE.

The Section on Hygiene and Sanitary Science should receive greater support from the organization. It is the section which must bring us in closer touch with our national life. Through it and those devoted to it we ought to secure greater respect from the body politic, and hence more wholesome power for the welfare of the community. Through it the profession should learn to take greater interest in the work of sanitary officers throughout the country. The valuable address of Billings on "The Relation of Medical Science to Commerce" and that of Thompson on "The Economic Value of Medical Science" indicate the opportunities and responsibilities of the profession. The time has gone by when sanitary positions should be used for temporary sources of income and obtained by political means. Such offices are growing more and more vital to the public welfare. They have not been attractive because the rewards have not been commensurate with the responsibility and the labor demanded. They should, we will admit, if looked at from the proper view-point, grant large compensation, and the occupant should be guaranteed tenure of office, not subject to party exigencies, but dependent on value received. The fault is partly ours that such is not the case. In but few medical schools is there a serious attempt to educate sanitarians, consequently the physicians who engage in sanitary science in an amateurish way do not give a *quid pro quo*. It does not pay a community to hire them. In one of the large cities of this country it has been impossible for the health authorities to get men who are competent to take up health matters, even though the city was prepared to pay fair salaries. Speculation need not run riot in estimating what would occur in a few years if our universities would give sound practical courses of a broad character, including some engineering, some economics and other features which would round out the man. In preliminary and subsequently in the elective studies the student should not be tempted to go into the special lines of practice. He should have opportunity to go in for sanitary science, and perhaps for government service in the army, the navy, or other departments. The communities would soon find the worth of men thus educated, and the demand, we would venture to predict, would outrun the supply. In proof of the former, we may cite the fine tribute given to Wende of Buffalo, by the citizens, *en masse* and of one accord, for the work of self-sacrifice, of unselfishness and of worth as official of the health department. Our association could as a body and in its constituent parts encourage the medical schools to make such training possible; they could educate the community to demand such services and insist that good compensation is to be allotted for it. The Section on Sanitary Science could take up this as one feature of their work.

But for a more grievous reason, the profession's attitude, there is public disrespect. Survival of the old dictum that a patient's woes are confidential, supports too often the attending physician in failing to realize his responsibility to the community while attending to the welfare of his client. For this, as well as too often for personal reasons, he readily connives with the patient to thwart civic authority, thereby endangering a community. Instead of aiding in securing respect for and obedience to the rules of his sanitary colleague he joins in opposing him. Candor must compel us to admit that too often he fears the advent of the health official may mean some disclosure of his own incapacity. It is fair to say the official on his part is often too ready to give advice, to sneer at diagnosis or rail at treatment. To inspire, therefore, wholesome respect toward these coworkers and establish an *esprit de corps* should be one of the educational prerogatives of this section. Were we to be called to account for duties undone, the sin of not fulfilling our obligation to the community in sanitary matters would doubtless be found the most conspicuous, the one most detrimental to its interests.

Again, if not too insistent, could not this section further educational exhibits in sanitary matters not unlike the superb exhibit last winter in Baltimore, conceived and conducted in the main by our present official of the Sanitary Section? The Association could not do better than issue a grant for the furtherance of this object.

THE SCIENTIFIC EXHIBIT.

It is gratifying to see the interest and success attendant on this new feature of section work. It is another tribute to the belief in the permanent

tenure of office of an official when we have the good fortune to get a good one. Attention is particularly called to this exhibit to ask the Association and the other sections to look to the conduct of somewhat similar exhibits. The Section on Ophthalmology showed the possibilities at the time of the Helmholtz anniversaries. When a section takes up a subject let us not have the clinical, pathologic and therapeutic aspects alone discussed, but bibliographic and historic features brought out. Let such features be as national as possible. What a fine exhibition it would be to have in connection with, say typhoid fever, a loan collection of the pictures of authors and investigators, of the various editions of their works and of the material things with which they worked, illustrating the evolution of their knowledge of the subject. Who would not be thrilled by a picture of the wards of the old Pennsylvania Hospital where Gerhard worked, of the instruments or materials he worked with, how he lived and what he did, of the first editions of his works, indeed of the manuscript of them? We must confess to a quiver of delight, mingled with reverence, when permitted to handle the manuscript on which Stillé inscribed his communication to the Paris Society. This is not the time or place to indulge in a homily on the value of such exhibits, agreeable though it might be. Through them, as of biography and sculpture and painting, we keep in touch with our history. Foster efforts in these directions, gentlemen of the Association, grant liberally to sections their small demands on you, to the end that you will be stimulating the best instincts in our profession.

THE ASSOCIATION OF LIBRARIANS.

We are not far amiss when we call attention to an organization which in a quiet, unobtrusive way is bringing together the members of the profession on a common ground, where tares do not spring up and thistles do not blossom, but, instead, in an atmosphere clear, refreshing, invigorating. Jealousies do not thrive in libraries; books soften ambitions. No stronger, more liberal friendships can develop than those that come to book lovers. We owe a debt of gratitude to the Library Association and to its distinguished president, under whose fostering care the influence and power of the Association is unfolding as the hardy rose, exhaling like it a fragrance which cheers and stimulates. Of the many abundant works we owe him, none, we venture, will be more satisfying to him and more lasting for good than the work of the Association of Librarians. This Association should hold not its hand nor stint its heart in upholding its educational efforts.

THE RUSH MONUMENT.

Before this session adjourns, by proper ceremony, graced by the presence of the President of the United States, with an oration befitting the occasion by our distinguished colleague, Dr. Wilson, the monument erected by the Association to the memory of Benjamin Rush will be dedicated. The Association is to be congratulated on the completion of this tribute in perpetual bronze to one of the most distinguished of our countrymen. Not alone should we rejoice on the fruition of this agreeable task, but also because it augurs for the erection in the future of tributes to the memory of others full worthy of our reverence. The invigorating, stimulating influence that comes from having about us our heroes of the past in stone or bronze behooves this Association and its constituent bodies to strain every effort to encourage in this manner hero worship. It is due ourselves to perpetuate the inspirations, the thoughts, the feelings, in the counterfeit presentment of our fellows. We are not of those who decry the world because it has not recognized our Jenner, our Pasteur, our innumerable heroes either by reward in their life time or by permanent tribute. We do not begrudge the mead of praise and the plenteous bounty which flows to our warriors and statesmen. It is true their glory has been attained often by carnage, lives sacrificed to avenge some insult. It was not life that was at stake. It was principle or thought or feeling or, our misanthrope suggests, greed. What countless lives are sacrificed for aspirations; what thousands of innocents for national gain! So, to the actors who stand for such, unstinted regard is given. The public neither appreciates the loss nor the saving of life. Hence, so long as it does not come close to them, civic murders from bad hygienic conditions do not move them. Even when home is devastated they submit to that which they consider mystifying or providential, and merely go their way. They are callous beyond measure to the presence of epidemics. They do not consider for one moment the power they have to assuage the virulence or even wipe out the existence of pestilence. Every effort for amelioration, as we see in tuberculosis, comes from our profession. With such lack of appreciation of their own welfare we need not expect much appreciation from them of our efforts.

In all honesty we must admit, among ourselves, we may not deserve public appreciation. If we realize the truth we may make amends. Could the public be expected to revere and respect when, as usual in the past, perhaps too common now, the profession was divided against itself, not from principle but generally because of pocket, of sordid ambition, of devouring jealousy? Look ye to your county societies! Do the brethren dwell together in harmony? Go to the warfaring court rooms! Do we emerge from them respected and respectful of one another? Until such sores are healed, as they happily will be, when science — and hence liberality of mind and largeness of heart — is furthered by associations like ours, it must remain to us a cherished heritage and privilege to worship our heroes alone. When we learn to respect ourselves, then will we be respected.

MEDICAL EDUCATION.

"An object of this Association shall be the elevation of the standard of Medical Education."

This Association has been, should be, and we trust will be, the storm center of legislation for reform in medical education. Since the memorable editorials of Wood in the old Philadelphia *Times*, and the masterly papers and addresses of Pepper and the practical action of the University of Pennsylvania there has been virile progress. In most respects it seems definitely settled as to the course of education a candidate for the degree of medicine should take. Questions of pedagogy are still debatable, but we take it that that student who wishes the quickest returns, the most lasting remuneration, perennial stimulation of the intellect and continuous enjoyment in the pursuit of his labors, should take a college education of three or four years, a four years' course in medicine and, if possible, a hospital interneship.

Reference need only be made to the reports to this Association, to the famous report of the majority committee of the Association of American Medical Colleges, to the numbers of *The Journal* comprehensively devoted to education, and to many recent admirable addresses in support of the statements.

There is talk about maximum and minimum requirements, about laboratory and hospital courses, the merits of didactic and clinical teaching — a mass of material brought forth from the view-point of the educator, or looking to the welfare of the medical profession. We do not minimize the value of such lines of discussion. It has brought us to the position we have attained. But what of the medical student? Should we not look at education from his point of view? Is he quite able to decide whether he should take up the profession of medicine? We hold that a great duty is due the aspirant for medical honors from teacher and practitioner. It is a kindness due him to point out the best methods of securing such education as will yield him results commensurate with the time and expense required. It would be a greater kindness to be enabled to show him that by reason of intellectual temperament or of physical or moral qualities he is not likely to reap the rewards he is anticipating.

The large majority of medical students do not have a good reason for studying medicine. They are ignorant of the mental and physical demands made on them. They are attracted by an uncertain glamor and a specious glory, and heedlessly they go in. The failure of a large percentage of graduates in medicine to acquire more than a bare existence, and too often not even that, proves that they were not educated properly, not fitted temperamentally or physically, to pursue its duties. Should they not have opportunity for learning of the responsibilities and difficulties, rather than to have the brighter phases glorified? Would it not be well to have, in our college curriculum, a course of lectures for the student who contemplates entering a profession, pointing out the rocks and shoals in his prospective career? An eminent practitioner, not connected with medical schools, would light up and darken the pathway in due proportions. Then, too, should not, as in the army and navy, some physical tests be required? The trophy is to the robust, and sad will be the career of the man who is physically handicapped.

If there is any doubt about the value of a college degree to a man entering the medical profession it could be set at naught since the report of the Mosely Education Commission. Quotations like the following, while not pertaining to medicine alone, the result of extensive inquiry and mature deliberation, supported by the statistics they give, uphold the contention of a large employer, that "for 99 per cent of the non-university men, it is hopeless to expect to get to the top." One opinion they express is that "there is still room for the boy of marked ability 'to come through,' but that his difficulties are greatly increasing, and that, useful as he is, his usefulness would have been greatly enhanced had he had the benefit of a college training." Still another commissioner reports that while only "1 per cent of the entire population of America has received a higher education in her colleges and universities, this 1 per cent holds more than 40 per cent of all positions of confidence, of trust and of profit." It is well known that the "geist" of the individual brings success, for which, they say, "it is recognized that the educated man takes in a wide horizon and puts more 'soul' into his work."

The essential of success in any department is diagnosis, which requires powers of intellectual penetration and discrimination. President Thwing has again forcefully urged that "the reasoning of the mathematics — and mathematics is only reasoning — tends to promote *clearness* and *accuracy in perception, inevitableness in inference*, a sense of logical *orderliness*. The study of the languages represents the element of *interpretation*. The study of history means the interpretation of life." Are these not the main studies of a college education? While they may promote scholarship, they surely cultivate thought. It need scarcely be pointed out to this audience that to be a thinker is the salvation of the physician.

To the plea that the acquirement of a college degree takes up too much time and requires too much money, the material answer can be given from other sources to the effect that "the men whom you are surprised to find holding such important positions in factories, though not much over thirty years, are the very men who did not leave the technical college till they were twenty-three or twenty-four; the graduate may have been twenty-five before he donned a jumper, but in five years he learned more with the college training he had as a foundation than the regular journeyman of fifteen years of actual work in the shop." The experience of teachers who have watched the alumni agrees in that the

college graduates get quick returns and soon acquire a position of independence.

The poor boy, therefore, need not be deterred, for if he has the spirit and energy to work his way through four years, two years or three years more will be but very little in the final summing up. If the student only knew that the purchase of the best education, whether reckoned in time or money, was the most economical investment, in that as to the former, a thorough education at first is time-saving in later years, and as to the latter, the money outlay is returned more quickly, in more immediate work and larger pay.

There should be one educational requirement — the equivalent of that for which a first-class college degree stands, whether received at a high school or university.

After entering the medical school with, it is presumed, the proper educational attainments, his career the first year should be closely watched. That school has too many students if it does not have enough instructors in the first year to be able to judge with a reasonable degree of accuracy of the character and moral stability of the men. This is not to be taken in a prudish sense or with too critical a scrutiny of habits which are the overflow of the animal spirits or the expiring exuberance of the boy approaching manhood. This can be said, that a student who does not play fair in his exercises, who cheats in one demonstration or evades another, who does not show manliness, frankness and truthfulness in his first-year duties, will not be a good diagnostician. He will cheat himself; he will cheat his patient. The teachers of the first year, or at least the second, should know this and block the student there and then. It would be a kindness. Let us then agitate whether we should not have a certificate of manliness, a certificate of health, as well as a certificate of mental proficiency, before we admit students to our medical schools or permit them to go beyond the first year. Let us not be decoys, alluring them on to later destruction, but rather be guardians, wrapping the strong arm of experience about them to lead them to the fitting pathway.

Having permitted the student to pass further in his pursuits, we still owe him much. We must see to it that such course is given him the first two years of his student career that he will acquire such fondness for the science of medicine, such reverence for the exploration of its truths, that until his dying day devotion to it will be his stimulus and solace. As a corollary, we must insist that medical schools secure the best men in the market for these places and pay them salaries commensurate with their ability — good, living salaries.

It is in the first and second years of his career that the foundations are laid whereby the student becomes the medical thinker. To quote again: "The power of thinking should not be of a base and barren character. The thinking should represent and be concerned with a fine and rich content of knowledge. It should have the exactness of intellectual discrimination; it should have the fullness of noble scholarship; it should embody a culture which is at once emotional and esthetic and ethical, as well as intellectual."

That a desire to relieve suffering, to extend sympathy, to save life, is the impulse of the physician, we all admit, but where is the man among us who will not also admit that a scientific habit more quickly brings it about and more surely sustains and fortifies the humane instinct through the trials and tribulations of exacting practice? That prosecution of professional duties soon becomes commercial that does not have for its basis a true spirit of scientific inquiry. How miserable must that life be which conducts an exacting, drudging, daily routine with only material reward in view. Few are the practitioners who have this sordid view; we can be as sure medicine would soon be forsaken if this view-point alone were considered. Hence, in the laboratory of the first two years must be aroused and fostered the stimulus for life work.

The final years should be clinical years, and the last should be in a hospital. The medical school that allows its students to think such opportunity is not due them is most unfair to them. As our schools are now constituted, most of them cannot give such requirements. The students should know, however, such requirement is necessary. What has been said regarding the preliminary college education applies equally forcefully to the hospital training. He is thrice armed who enters the arena thus equipped. Medical schools that cannot give such education are cruelly unkind and unjust to the students by having them think it is not essential. Medical colleges that pass off a hospital training for one that is not truly such fake their students. The student who pays well for his training has the right to demand such as to fit him for immediate action.

It is not the fault of the medical school alone that he cannot get it. The public that cries out when there is mistake in diagnosis, fault in treatment, and that shakes its head at the deficient education of our students, must share the blame with the medical school. The public admits that its individual members may at any moment be almost at the mercy of a half-educated physician. It is not necessary to recount, for it is well known, how on land or sea, by day or night, some event may arise in an individual life, the care of which may mean life or death. Even with this knowledge they withhold means to relieve themselves. They admit the necessity of a hospital training. But they, and particularly the public in control of hospitals not used for teaching, say each medical college should have its teaching hospital. They do not appreciate that to give an education which involves a hospital course would require an expenditure to $500 a year for four years by each student. It has been estimated that the cost of maintaining a plant and paying salaries sufficiently large to accommodate 600 students would require the above outlay by each student. Unfortunately,

it is impossible to expect students to pay such figures, as it would render entrance into the profession almost prohibitive. It is manifestly impossible, as medical schools are constituted now, to educate all the students of the land properly. Hospital training cannot be given except by a few favored institutions, because the doors of hospitals are closed either by the governing body of the hospital or by the teachers in the medical schools.

We believe, personally, if a decree should be issued that no medical school, including its hospital, should exist except on the fees derived from students, but little hardship would follow. The lessened supply of students would increase the demands on the practitioner, so that larger returns would follow. The poor student would sacrifice and strive to get a degree, knowing then he had a good asset. A diminution in number and an increase in quality is demanded alike by the public and the profession. Such diminution in number would mean that the student would get back his investment quicker and in larger amount than at present; hence good men would be attracted. If we could abolish sentiment for sense and educate accordingly, there might be betterment all around. At it is now, medical students receive part of their education through the bounty of the state or the charity of the public, as such education can only be given in endowed institutions. The public is taxed so that the prospective physician can make a living. Is it right that it should be? Perhaps a mechanic should demand such right to make his son a good workman. We must all admit it is the duty of the state to educate the youth, so that good citizenship is maintained; we can question whether the state should educate the members to obtain a livelihood.

With the same indifference that the public views an epidemic's march they allow hospitals that are engaged in teaching to suffer for the want of funds. Moreover, they close their doors to the advent of teaching in the hospitals under their control. We must admit, those who do not appreciate the true function of a hospital have some ground for their contention. Ruled by sentiment chiefly, unfortunately an impracticable master, they sympathize with the patient who still harbors the belief of old that the medical student is one of a class that prowl about not unlike harpies. The public does not realize the difference in the student of to-day and the student of tradition. We cannot hold to account the governing body of the hospital who has the point of view that it is harmful to a sick person to have him under the surveillance of an alleged student rabble. We must admit, some patients become alarmed, particularly in institutions where they know they will have the sympathy of the government body. An analysis of motive will show that the usual patient who will not allow a judicious amount of clinical demonstration when the sense of delicacy is not offended, is truly selfish, in that there is prevented that increase of knowledge and development of skill whereby suffering of others may be alleviated. A little encouragement from the officials would allay alarm on the part of the patient. The desire to help others is infectious, and when one yields in a word, others vie in the work.

The truth of the matter is that in hospitals in which teaching is carried on, rarely, if ever, do the patients complain. Indeed, it is the experience of those teaching institutions that judiciously conducted instruction is appreciated by the patient. In one hospital we might name, most of the inmates are pay patients, giving $7 a week willingly, because they know they are buying the services of the best practitioners in the land — the teachers of medicine — which service they could not get at tenfold the figure. The fact that teaching hospitals are overcrowded not by the poor alone, but by people independent of charity, shows that clinical instruction is not a bugbear. If the governing boards would know that while a few patients might be alarmed, on the whole most of them would be gratified by the attention paid them, and their sense of rectitude and manliness appealed to by the satisfaction that they are doing some good in enlightening students, so that others could be relieved; that their administration would be stimulated to do work beyond criticism; that the nurses would be aroused to better activity while under the observation of those not connected with the hospital; that the internes would do their very best to have most complete studies of the case, and, finally, that the chief in attendance, compelled to do his best at the risk of his reputation, they would gladly open their doors, even at the discomfort of the few, but to the advantage of the many. In short, the hospital should have teaching not to oblige the medical school, but for its own survival and regeneration. The benefits the student derives by the object lesson of an orderly hospital cannot be estimated. Will not every member of a hospital board admit that his own character, his own sympathies, have been benefited by his connection with the hospital, even though, perhaps, he has not the advantage of an impressionable age? Can he not see, therefore, how the youthful student can be influenced in thought and character and feeling? He cannot lightly toss aside this responsibility, nor even hide it by putting the onus of medical education on the teaching hospital. Every dollar endowing a non-teaching hospital robs the teaching hospital which is engaged in this larger duty.

It is true, a class which is compelled to have hospital attention may not sympathize with this feeling. How can we obtain the confidence of this class? Let us organize such association of prominent people in our teaching centers who will agree to have any operation, any feature of disease, witnessed by medical students at the judgment of their attending physician. It would be well if the individuals of such an organization would agree, first, to undergo hospital treatment; second, to be the object of observation by students; third, to have an autopsy performed

in case of untimely end. We feel sure that it would be wholesome, individually and publicly, if each would agree to ward treatment. Such association would rob hospitals of their terror and teaching of its dread. No one can deny that on the whole the public would be benefited from whatsoever point of view we look at it. Indeed, the public ought to learn that disease is an enemy to themselves and their country. Just as we make sacrifices in time of national warfare, so we should be willing to make sacrifices in the daily battle for life. Just as aristocrat and plebeian, landlord and tenant, fight side by side in the former, so they should array in solid phalanx in the latter.

But there are hospitals willing to admit students, and yet the privilege is not availed of. This arises because the teaching force of the medical college is not willing to sink its personality and allow the student to go wheresoever he will for his instruction. Courage and some sacrifice are required, perhaps. But, when one thinks of the mighty opportunity and the frightful waste, it is saddening. Every hospital should be a school. The fourth year should be so arranged that the student could avail himself of the advantages of hospitals in the immediate vicinity. Let each teaching body have the students understand what he must see and do, and trust you, the true student will see it at the best place and with the best men. He must be accountable, of course, with a rigidity that means the exact acquirement of knowledge. To this end the first two years could be well spent in the properly equipped laboratory university, whether in town or country, the third in the authorized hospital of the school, the fourth in extramural hospital work.

Is it not anomalous that the hospital boards give to the nurses who are to act as aids to the physician the highest opportunities, and yet deny it to those who are to give orders to the nurses? This, of course, arises because training schools are the product of modern thought and have not been trammeled by tradition.

But all this talk of the primary education avails but little if we do not see to it ourselves that education is continuous; that from the day of our graduation, forwards, we do naught but toil, toil, toil. It should go without saying, as a mere business proposition, that unless we unceasingly labor but little of the fruits do we pluck. It is demonstrated in a practical manner, for when we look about us and find the methods of those of our brethren whose labors are not in vain each one bears the scent of midnight oil.

The development of post-graduate schools, the growth of libraries, the groans of the printing press, the enthusiasm of medical societies, all testify to the spirit of persistent self-education that is abroad. It is not for me to urge further the importance of each of us taking from time to time months for study and reflection. Every active doctor should have his sabbatical year. We dare say, extended observations would uphold that in income a gain is one hundredfold for each dollar invested in educational outings, and for every hour thus employed, ten are added to life. To finance a medical man from first to last successfully, we dare say, spend all net earnings of the first five years on self-education; after ten years, 10% of the annual net earnings for an assistant, continuing the 25% investment for five years. Health, happiness, increased usefulness to the community, a success, which never comes from eccentricity, equal to doubling capital every five years, would follow.

In the course of our work it is necessary for us to halt from time to time and review. Not alone must our mental storehouse be swept out, refurnished, but we must constantly "jack up," if the term is permissible, our mental and moral machinery. Few of us are they who will not find, as our days grow fuller, an unconscious tendency to slight our work, to become slip-shod, to hurry over matters. It is partly an evidence of overwork. The post-graduate school is the salvation. No obstacle can withstand the continuity of drill, which the earnest of us keep in action. If, to continue the imposition, asked what element of character is perhaps lacking to the greatest detriment to the profession and public, we possibly, one and all, would say, courage. This is seen in the hesitancy which members of the profession show in giving an opinion, in advising an operation and in asking for an autopsy. How much confidence is destroyed by the want of free, frank avowal of the physician that he does not know on the one hand, or of clear, precise statement of his judgment concerning a case on the other! The greatest success in life is confidence. How many lives are lost by the worker in internal medicine not advising early and unequivocally an operation for fear he might be wrong in his diagnosis! And how many more are lost because the surgeon lacks courage to do, either because he fears the patient may die and his record be marred, or because he may operate when it is not necessary! We must admit we have had some operations done when they were not required, but let it be said to the credit of modern surgery, we have never seen an operation of such character performed by the right man that did any harm to the patient. On the other hand, the resort to operative procedures early, and in cases that even yet are not considered of surgical relief, has saved lives and lessened suffering to a degree that far overbalances the now and then futile measure. It may be assumed, without contradiction, that every case of bad appendicitis that happens to get well without surgical relief has in its wake three to five that die for the want of an operation. In other words, the pernicious influence of a surgical case that recovers without operation is evident in creating the hope that other cases demanding operation might get well without it.

And the man who does not want an autopsy — not only the centers of courage need stimulation, but too often the entire medical storehouse needs refitting. Something, best known to the phy-

sician himself, we trust, is lacking in the one who treats an obscure case for a day, six days, six weeks, and then does not want an autopsy. If true to himself, true to the demands of his profession, courage will not fail him. In our mental and physical round-up, we must see to it that courage is given a new backbone from time to time.

But, fellow members of the Association, not alone as members of this organization may we indulge in self-congratulation, but as members of a profession whose limitation knows no bounds we may join in felicitation. Neither language nor creed nor country fetters our profession's munificent sway. The thoughts of Ehrlich in Frankfurt, of our own Welch or Councilman, of Kitasato in Japan, are correlated. The knife of Mayo in America, of Robson in London, of Kocher in Berne, contributes to the relief of suffering in far Cathay. The founts of Lister's genius and Pasteur's divine inspiration bring countless blessings to England, to India, to France, and to Africa. What a stimulus it is to realize that, howsoever small the contribution of the humblest of us may be, its impulse will be felt in climes near and far and ages present and remote! What awe cannot but overtake us when we consider each heart throb we study entwines us to Harvey of two centuries ago; with every percussion tone reverberates the sound of Laennec's voice of a century; with each vaccine inoculation, the simple observation and reasoning of Jenner to stimulate our question and deductions!

We rejoice together and cherish our history, by the warp and woof of which we are woven to the past. What heritage for us and our children! Dead must be the soul that wearies of communion with the spirits of the past; deep must be its slumber on which falls the thought of centuries; lethargic its activities that are aroused not by the deeds of heroic men! "Honor and fortune exist to him who always recognizes the neighborhood of the great, always feels himself in the presence of high causes." We worship together our science, devotion to which brings forth character, smothers egotism, levels pretension, drives out solitude, develops such loftiness of thought which can see that "against all appearances the nature of things works for truth and right forever." Of our art, let us see to it that when the final summons comes it can be said of us, "Greater love hath no man than this, that a man lay down his life for his friends."

THE ASSOCIATION OF SURGICAL LESIONS IN THE UPPER ABDOMEN.[1]

WILLIAM J. MAYO, A.M., M.D., ROCHESTER, MINN.,
Surgeon to St. Mary's Hospital.

THE history of medical advance from the empirical treatment of symptoms to scientific expectancy has been based on the study of death and modern research work. The spirit has been fine, although somewhat pessimistic. The great advances have been along the line of preventive medicine and in the elucidation of problems connected with the eitology of disease.

Surgical progress has been, to a certain extent, through similar channels; the spirit, however, has been one of magnificent optimism. The great advances in surgery have come from the clinical side, modern technic having enabled examination of primary conditions during life.

As a groundwork for the study of medicine the pathologic laboratory and autopsy room offer unrivaled advantage, but they teach end results only. Who of us has not admired the precision with which a trained observer makes a diagnosis? A few days later one visits the autopsy room and here observes that this almost clairvoyant analysis was correct. At the same time, we must also acknowledge that the patient has not profited; it means a hundred pages of pathology and two meager lines of treatment. How many times do we notice in the autopsy revelations that the original lesion has been but slight, and at one stage easily curable, the pathology present largely the result of secondary complications and terminal infections?

The post mortem has been an institution for years, yet what did we know about appendicitis until surgery led the way, or about gallstone disease, supposed to be an "innocent postmortem finding," until operation opened up the field? Did knowledge of extrauterine gestation come from the autopsy? By no means. It was through the surgeon's knife, and why? Because secondary conditions so often mask the original lesion at the postmortem. On the contrary, our understanding of acute conditions causing sudden death has been brought about by dead-house investigations; for instance, fatal hemorrhage and perforation placed acute gastric ulcer on a sound foundation. Not so chronic gastric and duodenal ulcers, with late death from complications, cholangeitis from gallstone disease, and chronic pancreatitis from the same cause. These conditions could not be correctly studied, excepting after death from accidental cause, and real progress lay dormant until surgery invaded the field.

From research work we have profited much; we are gaining rapidly by this means day by day, but we cannot compare the animal to the man, nor can we always artificially create similar conditions. Like the postmortem, it has its limitations, yet these two fundamental methods have enabled us to advance. Without them we would still be in the Middle Ages. Now the time has arrived, in the light of these investigations, to view conditions from a new standpoint at a time when the lesion is in its infancy, long before the postmortem, while the patient may be benefited and the research work applied to the elucidation of living problems.

The medical man must haunt the operating theater as he has haunted the autopsy room and the laboratory. The times have changed; we

[1] Oration on surgery at the fifty-fifth annual session of the American Medical Association, at Atlantic City, June 7 to 10, 1904. By the courtesy of the Journal of the American Medical Association.

must have more treatment and less pathology. It is here that surgery wins its triumphs. We must not forget, however, that to physicians of pathologic training we owe the knowledge which enables us to approach the subject. Courvoisier was the real father of gallstone surgery. It was Balzer, Fitz, Opie and others who cleared up the pathology of pancreatitis, and surgery followed their lead. It is in the union of the internist and surgeon that progress is most rapidly made, and in the readjustment of science the former will be the architect and the latter the master builder.

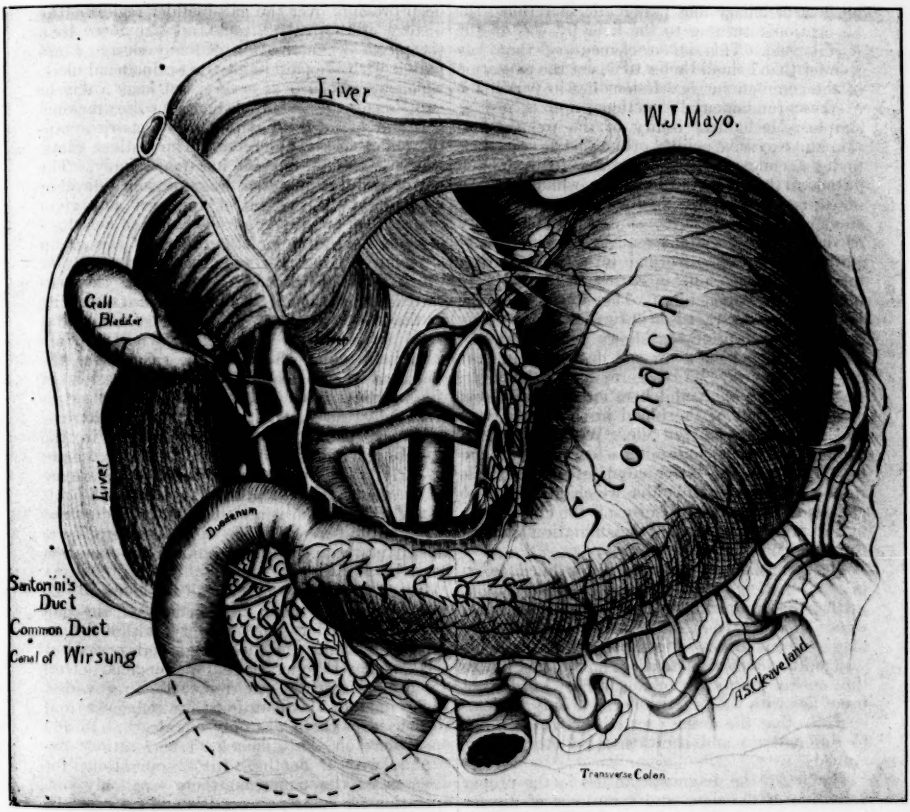
Once more the physician and surgeon will come together, and the mistakes of endeavor in new fields will receive timely correction at the hands of the pathologist and experimental worker.

The surgical borderland of to-day lies in the upper region of the abdomen, a locality until recently considered almost purely medical. What are the reasons for this invasion, and have the results justified the attempt?

Surgery must be judged on three grounds: First, the mortality of the operation itself and the question whether this is greater than under the expectant plan; second, the permanence of cure contrasted with medical treatment; third, the question of disability, either introduced by the operation itself or the natural length of time which the healing process involves. On each one of these considerations we must answer Yes, and we can go still farther and say that earlier operation would reduce the mortality and increase the permanence of cure and lessen the disability.

Certain parts of the body are so closely related in their anatomy, function and pathology as to be almost necessarily considered as part of the same system. The generative organs of women form so distinct a field of work as to have built up a specialty. Can we separate diseases of the kidney from the ureter, bladder and urethra? By no means. Each may stand in an etiologic relationship to the others which cannot be ignored.

In the upper abdomen we have attempted to study the stomach independent of the associated organs, the liver and bile passages, the duodenum and pancreas. The result has been a confusion in diagnosis and treatment. The palm of a hand may cover a serious lesion of any one of these organs, and that, too, at the point of greatest liabilty; not only so, but any one of this group may start a pathologic process which may extend to any one of the others, and with fully as great frequency as occurs under similar conditions in either the generative or urinary systems.



Note the disturbance of the stomach which occurs with gallstone disease; the adhesions to the duodenum and the pancreatitis, an association direct as it is vital. Again, let me call attention to chronic ulcer of the stomach with adhesions to the pancreas, secondary ulcer of the duodenum adherent to the bile passages or gall bladder. These are not fanciful pictures, but drawn from everyday work. I have no hesitation in saying that with an operative experience of over 1,400 cases of this description, mistakes in exact diagnosis are still common, and in many instances unavoidable. The history may be the only valuable diagnostic resource when the patient comes to us, and we all know how unreliable that may be. Given a history of painful attacks which have been very severe, but which have completely ceased, with tenderness on deep palpation in the epigastrium, and we may have disease of any one of these four organs, and not infrequently an association either direct or indirect of the pathologic process. If we clearly understand the possibilities of error, we are better prepared to meet complications or execute a change of front and operate on one organ when another procedure was planned. In the majority of cases a pathologic diagnosis is possible, and one can say with certainty, "This is gallstone disease," or "This is ulcer of the stomach"; but in a considerable minority a surgical diagnosis is the best that can be made. That is, we can say: "In this locality is a diseased process which requires operative treatment, the exact nature of which must be determined by incision." The patient does not come to us for the purpose of having a certain operation performed, but seeks relief from suffering and disability.

Let me call your attention for a few minutes to the anatomic diagram, showing the nearly vertical position of the stomach with the pylorus in the middle line of the body, and but little elevated above the lowest point of the gastric cavity. It is turned upward and to the right just enough to prevent the weight of the gastric contents bearing directly on the sphincter apparatus. The only portion of the duodenum in which we are interested is the four inches lying between the pylorus and the papilla of the common duct of the liver and pancreas. This may be called the vestibule of the small intestines. Its position subjects it internally to the perils of ulcer from the acid gastric juices which its thin tunics but inadequately resist. Externally its function is often interfered with by adhesions to the gall bladder and bile tract, secondary to gallstone disease. This unoffending bit of intestine is so often offended against as to cause it to become the most frequently diseased portion of bowel of the same length. The remaining eight inches of the duodenum is protected by the alkaline secretions of the pancreas and liver. Its fixed position and peculiar horseshoe shape, with its delivery point nearly as high as its origin, enable it to mechanically slow the ingested material during the mixing process, for which its large caliber affords accommodation.

The anatomy of the bile tract is equally interesting, and especially the relations of the common liver duct to the pancreatic duct and the duodenum. There is continuity of mucous surface, each protecting itself from the secretions of the others by the mechanical washing effects of its own secretion, the joint discharge and a feeble sphincter apparatus preventing entrance of the duodenal contents.

The gall bladder, as it furnished the initial lesion in more than one half of the diseases of this group, is of great interest. Like the appendix, an obsolete organ of storage function and limited outlet, it gives rise to a variety of troubles, which we are only of late beginning to appreciate. It is an old aphorism that "nature finds mischief for idle hands to do." The gall bladder has a capacity of about an ounce, and, as we find almost universally in organs of storage function, the neck is raised slightly about the lowest point to

The pancreas, composed of two originally separated parts, has in nearly half of the specimens which have been examined two patent ducts, that of Wirsung, which is the important one, uniting with the common liver duct. The minor duct of Santorini, however, has a possibility of useful function in certain diseased processes, as pointed out by Opie. The pancreas was originally an intraperitoneal organ, becoming retroperitoneal by a later evolution (Huntington), and in this anatomic peculiarity, Brewer

prevent the weight of contents resting directly against the outlet. The little pouch thus formed may be called the pelvis of the gall bladder (Brewer). It is here that the obstructing stone is so frequently lodged in cystic impactions. Murphy observes that the fundus of all organs has but few lymphatics, while the region of the neck has an abundant supply; hence, even with septic contents, there is but a mild reaction when the pelvis is obstructed, as compared with the startling temperature curves of duct stones.

believes, lies one of the reasons for the diffusion of fat necrosis resulting from acute pancreatitis. Mikulicz has called attention to the fact that adhesions to the pancreas in gastric cancer gave a mortality of 73% in his resection cases. Robson also notes the pancreatic mischief occasioned by perforating gastric ulcer on the posterior wall.

The blood supply of this group of organs is almost entirely from a single source in the celiac axis. It has been experimentally developed that the severance of all connections of the pancreas

excepting its blood supply does not check secretion if food is placed in the gastrointestinal tract. In the nerve supply from the pneumogastrics and sympathetic ganglion, we find the same direct relationship involved. If we study the function we see the same association. The stomach can be compared to a mill, the fundus the hopper, in which the food is macerated in a weak solution of pepsin and hydrochloric acid, and the muscular pyloric portion the grindstones in which the masses are broken up into a homogeneous whole. The entrance of food into the duodenum causes the outflow of biliary and pancreatic secretions, the absorption returning to the liver by way of the portal vein. This is so elementary that you wonder that I should refer to it, yet the causation of the common surgical lesions lies in perversion of these fundamental functions, and is just as simple. Mechanical injury of the pyloric portion and excessive acidity of the gastric secretions under anemic conditions give rise to ulcer, and lie behind the precancerous lesions, which, Ochsner notes, is found in the history of cancer of the stomach in the majority of cases. The acidity of the gastric secretions renders the contents of the stomach, when turned into the intestine, relatively sterile, but increases the liability of ulcer of the duodenum. The sterility of the upper intestinal tract is still further increased by intestinal absorption, as shown by Adami, the bacteria being picked up and destroyed in part by the glands. Many germs are, however, carried to the liver, and here either annihilated or screened out of the blood in the portal vein and discharged with the bile. We must look on the bile as always containing a few bacteria, and it is probably this attenuated infection of bile retained in the gall bladder which gives rise to gallstone disease, which in turn is the chief factor in the production of duct inflammation of both the liver and pancreas.

These considerations, so briefly outlined, taken in conjunction with the embryologic origin, justify the grouping of *the surgical lesions of the upper digestive tract*, and at once enable the diagnostician to associate the symptoms and the surgeon to direct his attention, not to one, but to the entire group of organs. The burden of proof lies with the practitioner, not only to demonstrate that the disease rests in one organ, but to differentiate and show that no other is involved.

The art of the diagnostician lies in the proper valuation of the signs and symptoms of disease in organs of associated function and pathology. The instinct which seems to lead some men to a correct conclusion, and by a mental process they could not themselves analyze, usually depends on few things, the immaterial or inconclusive evidence being unconsciously discarded. For instance, note the value of the colic in the diagnosis of gallstones. The typical attack comes on and stops abruptly, is relieved by vomiting or a feeling of movement of gas, is irregular in time, in regard to food, and not accompanied by temperature or pulse elevation, and leaves the patient able to attend her duties almost immediately after cessation of pain. While the pain lasts, it is excruciating, felt in its greatest intensity in the epigastrium, radiating upward behind the sternum and into the back. The distress penetrates to the right side, but occasionally to the left, and lasts from a few minutes to six or eight hours. When the patient comes to the physician it may have been years since the typical attacks; he may have forgotten them, the present trouble complained of being pain, digestive disturbance and tenderness on deep pressure over the gall-bladder region. The history of the early attack is worth more than the physical examination in many cases. Compare it with the pain in gastric or duodenal ulcer, which may be just as severe, but lasts a day or two longer, especially when due to regional peritonitis, and is accompanied by gastric symptoms and local tenderness. The patient diets, which means he reduces his food supply. The symptoms last more or less for some days or weeks, and the interval of apparent cure gives some weeks or months of comparative health.

Acute perforations of the organs of this group are relatively common, and give rise to symptoms which would be at once recognized if they occurred in the region of the appendix, but occurring in the upper abdomen too often go to a fatal issue unoperated. The initial symptoms are remarkably alike, whether of the gall bladder, the duodenum, stomach or acute perforation of the pancreas with fat necrosis. The onset is essentially the same in each. Sudden extreme epigastric pain, with collapse, ushers in the attack, and muscular rigidity, as a rule, comes on early. The diagnosis of perforation, if we are on our guard, is easy, although it may be difficult to say which organ is affected; but this does not make any difference. The vital consideration is that it has happened, and immediate operation must be performed.

In 811 operations on the gall bladder and bile tract we had 4 acute perforations of the gall bladder, with but one recovery, although the average mortality in the benign series was but 4.47%. In 45 operations for duodenal ulcer, 4 acute perforations occurred, with 2 recoveries, while in the 41 operations for subacute and chronic ulcer there was only one death. In 469 operations on the stomach, 5 perforations occurred, with 2 deaths. In 32 operations for diseases of the pancreas, there was only one operation for acute pancreatitis and fat necrosis, with recovery. This gives 14 cases of acute perforation, with a mortality of 50%, and why? Because the operation was usually too late. The death-rate in over 1,150 operations for subacute and chronic benign conditions of this group of organs averaged a little less than 5%, counting as a death from operation any patient dying in the hospital without regard to cause or time elapsed between the operation and the fatal issue. If we add to this mortality of 50% in operations for acute perforation, the cases seen in a moribund condition beyond even attempt

at relief, and the still larger number in which death occurs without an ante-mortem diagnosis, we get some idea of the appalling nature of the disaster. To be successful, operation must be immediate; the condition is as imperative as hemorrhage from an artery of the third class. Few recover operated on later than ten hours after perforation. The conditions simulating perforation in the upper abdomen, such as thrombosis of the mesenteric or splenic vessels, diaphragmatic and duodenal hernia with strangulation, and so forth, are rare, and likewise call for early operation.

As a rule, the history and location of the early acute pain will furnish evidence as to the origin of the trouble. Preceding perforation of the gall bladder there are often symptoms of several days' duration with a history of gallstones. The acute pain occurs in the gall-bladder region. Early drainage with removal of the gall bladder should give a mortality of not to exceed 10%.

Duodenal perforation usually occurs in cases of chronic ulcer with years of symptoms preceding; but the immediate onset is exceedingly acute, and not ushered in by a few days or hours of prodromata, as is often the case with the gall bladder. The location of the early pain is just to the right of the median line. The liquids gravitate at once to the appendiceal region and simulate perforated appendix. The rapid diffusion of escaping contents is fatal to delay. Operation for acute perforation of the duodenum is rarely successful after eight hours. Suture of the perforation with suprapubic pelvic drainage and after-treatment in the sitting posture (exaggerated Fowler's) in early cases should give 80% or more of recoveries.

Gastric perforations occur on the anterior wall, according to Brunner, 7 times to 1 posterior, and near the cardiac end 5 times to 3 times in the pyloric portion, and near the lesser curvature 122 times to 16 times near the greater curvature. The initial pain is usually to the left of the median line, and early diffusion of fluids is to be expected. Only 10% occur without previous symptoms of chronic ulcer. The results of operation being in direct ratio to the amount of gastric contents, and the length of time which has elapsed, the treatment is similar to the duodenal ulcer.

The term perforation of the pancreas from inflammation with resulting fat necrosis is a purely pictorial expression, and not a pathologic entity in the sense the word is used in the preceding remarks, yet it conveys the idea and calls attention to the value of peritoneal drainage in its treatment, as shown by Woolsey. The symptoms are sudden pain in the epigastrium, collapse and early extreme distention of the abdomen. On opening the peritoneal cavity, free fluid often of a hemorrhagic character is evacuated. The little fatty masses in every direction and the enlarged pancreas call attention to the source of the trouble. This particular phase of acute pancreatitis cannot be separated from the hemorrhagic type in which treatment is as yet in an unsettled state. Those interested in this question will find a mine of information in the Hunterian lectures for 1904 by Mayo Robson.

The group of acute perforations gives an unsatisfactory mortality, with a prolonged period of disability from drainage, and without a certainty of permanent cure of previous underlying conditions. This will not long continue. Like acute gangrenous appendicitis, the condition will be recognized early with corresponding improvement in results.

The diagnosis of the chronic infective lesions of the organs of this group is in a far more satisfactory condition. The general mortality of gallstone operations is not above 5%, taking the cases as they come, but even this is too high. Grouping the cases in which the entire process is limited to the gall bladder, the mortality is from 1 to 2%, and depends to a large extent on the general condition of the patient. Secondary complications, chiefly those which involve the hepatic and common ducts with resultant cholangeitis, pancreatitis and so forth, are responsible for the death-rate. As practically all of the patients have symptoms on which a diagnosis could be based previous to the complications, it will not be long before early operation in patients otherwise in good health will be the rule as it is now in chronic and relapsing appendicitis. Not only is the mortality thereby reduced, but the disability is likewise lessened. The average stay in the hospital for uncomplicated gallstone patients is slightly less than seventeen days; the convalescence of the complicated duct cases is prolonged one or two weeks.

Chronic infections of the pancreas are usually secondary to gallstone disease, and, as a rule, do not occur excepting where the common duct has been directly irritated by the presence of calculi, although the consequences may continue for some time after the passage of the offending body. The results of drainage of the gall bladder and bile ducts are extremely satisfactory. In our series of 32 cases there were but 2 deaths; these patients had coincident suppurative cholangeitis.

Chronic infective lesions of the stomach with ulcer as a type are becoming better understood every day, as surgical operation discloses the actual conditions present. The primary mortality of operations for their relief are in a fairly satisfactory condition, but as to ultimate results we cannot say definitely. For the obstructive complications the result of ulcer, there can be no question as to the relief afforded and at a nominal risk. The dilated stomach with retention or stagnation of food suggests at once drainage operations with gastrojejunostomy as the type. We have patients of this description alive and well more than twelve years after operation.

Chronic ulcer without mechanical obstruction gives a less promising outlook. The very fact that there is normal gastric motility indicates that gastroenterostomy or other drainage operation is less necessary. Our results in operations for this description of lesion have not been wholly satisfactory, and furnish a considerable percent-

age of secondary operations and failures to relieve.

Cannon's experiments have shown the same results. A gastroenterostomy on a normal stomach of an animal does not drain the gastric cavity, even if placed at the lowest point. The gravity advantage of the gastroenterostomy is overcome by intra-abdominal tension, and the food, by muscular action, is carried out the pylorus rather than the artificial opening. The magnificent showing of gastroenterostomy in obstruction has led to the indiscriminate performance of the operation in those cases of ulcer in which gastric drainage is normal. This particular phase of the subject must be further investigated.

Chronic ulcer of the duodenum is relatively more common in the upper two inches than in any corresponding portion of the stomach. It is especially liable to perforate, although its sheltered situation usually leads to adhesive protection. Many pyloric ulcers will be found to have their origin on the duodenal side. Gastroenterostomy is the operation of choice, as it diverts the irritating gastric juices and food products from the sensitive surface, thus promoting rapid healing. We have performed gastrojejunostomy 286 times for all purposes, with a mortality of 5½% in the benign series. The recent improvements in the technic of gastroenterostomy has greatly reduced the mortality and largely eliminated the causes of failure to mechanically relieve the conditions. Moynihan well says that "the surgeon may not unreasonably expect that from being a last resource gastroenterostomy may be considered as a method of treatment worthy of consideration in a much earlier stage of chronic ulcer of the stomach." Excision of gastric and duodenal ulcers would seem to be a wise procedure, but is open to certain strong objections. In 20% of cases more than one ulcer is present, and one or more may be undetected or lie in an inaccessible situation. It leaves the ulcer tendency unrelieved, and more ulcers may form. Rodman has suggested the removal of the pyloric or ulcer-bearing portion of the stomach with complete closure of both duodenal and stomach ends and independent gastrojejunostomy. We have followed this plan in 5 cases of inveterate ulcer relapsing after gastroenterostomy, with good results. The gastroduodenostomy of Finney is a most excellent operation, and we would predict a wider field of usefulness than it has enjoyed. We have performed this operation 46 times, with one death and no relapse. The theoretical objection is that in open ulcer the food must pass the ulcerated area before reaching the widened pylorus, and obstruction has no part in the production of ulcer, as is shown by the development of duodenal ulcers. Pyloroplasty must be discarded. While we had no deaths in 20 operations, we had 7 relapses.

In briefly calling attention to the malignant diseases of this group of organs, the writer would emphasize the possibilities of cure by means of operation. In the gall bladder we found 4% of cases at the operating table had malignant disease, and all of these cases had gallstones present or evidence that they had been present at one time.

Since it has become the practice to remove all thick-walled gall bladders as useless and a possible source of future trouble, many cases of malignant disease in an early stage have been in this way, as one might say, accidentally cured. We have met with several such instances.

Cancer of the stomach is the most common type of malignant disease in the human body, constituting one fourth to one third of the total number. The radical treatment of gastric carcinoma is now on assured ground, with a mortality of 10%, or less in favorable cases, to 20% in late but still operable disease. The only necessary thing for success is an early diagnosis, and this must be on clinical grounds, supplemented by early exploratory incision. In 46 gastric resections for pyloric cancer we had 7 deaths.

The profession may well look on the surgical achievements in this new field of work with pardonable pride. That there are many shortcomings must be admitted, but in the history of surgery there has never been a territory opened up with equal rapidity, nor one in which the physician and surgeon have worked together in such harmony for the common good. The statistics on which this paper is based represent the operative experience of Dr. Charles H. Mayo and myself.

THE CASPER–HIRSCHMANN DEMONSTRATION AND PHOTOGRAPHIC CYSTOSCOPE.[1]

BY G. S. WHITESIDE, M.D., BOSTON.

I WANT to demonstrate to you this evening, a new cystoscope that combines several features of much interest, and I shall preface my remarks with a few words on cystoscopy in general and in the female in particular. On account of the anatomical arrangement of the female urethra and bladder, digital and instrumental exploration have been practiced since prehistoric times. Visual examination of the bladder is a diagnostic method of more recent date, but, nevertheless, was practiced so long ago that no one living now can claim to have been the first to attempt it. The first instruments, of course, were crude; later, various improvements were introduced along different lines, resulting at the present time in two classes of instruments for the examination of the bladder in the female. The simplest and most generally employed of these two classes is that which has been perfected and brought to notice in modern times, and in this country especially, by Kelly of Baltimore.

This, as you all who are doubtless familiar with

The most excellent wider field of We have perfo one death a objection is th the ulcerated pylorus, and production of ment of duode... ulcers. Pyloroplasty must be discarded. While we had no deaths in 20 operations, we had 7 relapses.

In briefly calling attention to the malignant diseases of this group of organs, the writer would emphasize the possibilities of cure by means of operation. In the gall bladder we found 4% of cases at the operating table had ... that which has been perfected and brought to notice in modern times, and in this country especially, by Kelly of Baltimore.

This, as you all who are doubtless familiar with

[1] Presented at the meeting of the Suffolk District Medical Society; Section for Obstetrics and Diseases of Women, March 23, 1904.

it, through having used it as well as heard of it, are aware, consists essentially of an open endoscopic tube, the cavity of the bladder being illuminated by a light reflected from the outside. In this class of cases the bladder is dilated with air induced to distend it by the assumption of a favorable posture on the part of the patient, namely, the knee-chest position. The disadvantages of this method of examination are several; the most important of them being that the knee-chest position is an extremely tiresome and objectionable one for the unetherized patient to assume, and a very inconvenient one in which to place a completely etherized patient. The next most important objection is that the light, being reflected from the outside, often does not give as clear and satisfactory an illumination of the bladder cavity as one might wish. The advantages of this instrument are also several. The size of the endoscopic tube which it is possible to use is satisfactorily large. The fact that it is an open tube allows the possibility of various instruments, such as probes, curettes, forceps, scissors or catheter, being introduced through it for purposes of diagnosis or treatment. The cost of the apparatus is very small, and its simplicity prevents it from ever getting out of order. The technique of this method of examination is comparatively easy and requires but little practice to be remembered.

The other class of cystoscopes, of which I especially wish to speak to-night, has one great general advantage in that they may be used with precisely the same technique in either the male or the female. This class of instruments was originally made practically useful by Nitze, twenty-five years ago. They carry the light at the inner end of the instrument itself. The view is obtained through the modified telescope in the shaft of the instrument, and the medium used for distending the bladder is clear boric acid solution. Many modifications, all dependent on the same essential principle, have been devised by surgeons in almost every civilized country.

The one of which I especially wish to speak, the Casper-Hirschmann, is an instrument combining three valuable features. It may be used as a simple inspection cystoscope, or it may be used as a means of demonstrating and teaching cystoscopy and vesical pathology, in the living, to students, or it may be used for taking permanent photographic records of interesting features in normal or diseased bladders. First, with regard to its use as a demonstration cystoscope, I wish to say that the greatest difficulty experienced by those who wished to teach cystoscopy has hitherto been owing to the fact that after some object of interest had been seen and focused by the instructor, the student almost invariably moved the instrument sufficiently so that he did not see what it was intended that he should see when his turn came to look through the instrument. With this cystoscope it is possible for the student and the instructor to look through it simultaneously and observe every feature of the interior of the bladder while the instructor explains the significance of each object demonstrated. With regard to its use as a photographic instrument it is also extremely satisfactory, because the difficulty which existed in previous photograph cystoscopes has been eliminated. This difficulty was that after the surgeon had focused the object he wished to photograph, he was obliged to unscrew the eyepiece of the cystoscope and screw on the camera, thereby taking his picture entirely uncontrolled by sight. In this instrument, it is possible to observe the object not only before but during the time it is being photographed, because the surgeon may look through one eyepiece of the instrument while the camera is placed at the other.

I have used this instrument for diagnosis, demonstration and for photography in several female and in a larger number of male cases. I will pass around a few photographs which I have taken with it recently. I think all of you will agree, on giving the matter thought, that the technique is simple and the view of the object far more satisfactory than is usually the case with the open endoscopic tube.

I have here some bladders which have been taken at autopsy and hardened in formalin. It is possible in these specimen dummies to demonstrate the cystoscope almost as well as in the living.

With regard to cystoscopy in the female I wish to say that it is a field as yet comparatively little explored. There are many pathological conditions associated with the uterus and its appendages which press upon, distort or even invade the cavity of the bladder, producing characteristic appearances in the interior of that viscus, and if the gynecologist will perfect himself in the use of the cystoscope, he will be rewarded by observing appearances in the bladder which will lead him to a more accurate diagnosis in inflammatory or malignant disease, or even in cases of simple malposition of the uterus.

EXPLANATION OF PLATE.

FIGS. 1 and 2 show normal ureter openings. Notice the shadow cast by the ureteral papilla on the bladder wall and the door, pit-like orifice of the ureter opening in the apex of the papilla.

FIGS. 3 and 5 are from a case in which an incomplete litholapaxy had been done. Fig. 3 shows a long slit-like opening of a ureter. At the base of the papilla is a fissure of fold in the mucous membrane. Notice the solid, leathery appearance of the mucosa due to chronic cystitis. Fig. 5 shows three broken fragments of stone lying on the bladder floor.

FIGS. 4 and 6 are views taken in a case where chronic obstruction to the outflow of urine has caused hypertrophy of certain bundles of muscle fibers in the bladder wall — a so-called, trabeculated bladder. The arrangement of the muscle bundles is well shown in Fig. 6 and also in Fig. 4 above the catheter which has been inserted in the ureter. The shadow of this catheter shows below it on the bladder wall.

HUMAN SLAVERY AS A PREVENTION OF PULMONARY CONSUMPTION.*

BY THOMAS J. MAYS, A.M., M.D., PHILADELPHIA, PA.

IN the arduous research for new measures to stamp out pulmonary consumption it is astonishing to find that one of the most interesting episodes in the history of our country, which

* Read before the Philadelphia meeting of the American Climatological Association, June 4, 1904.

clearly points out the true and only rational path for the extermination of this disease, is entirely overlooked, *viz.:* that pulmonary consumption was comparatively unknown among the plantation slaves of the South before the war, while in the large cities of the South during that period it was no more prevalent among them than it was among the whites. This rarity was so obvious, and is verified by so many lay and medical authorities, that it does not call for any extended statistical support. Thus, according to the health statistics of Charleston, S. C., of which I was not able to obtain an uninterrupted report up to the present time, the negro death-rate by consumption in that city in 1860 was the same as among the whites, *viz.:* 1.75 per thousand living. In 1867, whites, 2.00, negroes, 3.40; in 1876, whites, 2.00, negroes, 6.95; in 1881, whites, 2.60, negroes, 7.03; in 1890, whites, 3.55, negroes, 6.86; in 1900, whites, 1.23, negroes, 6.15; in 1901, whites, 1.89, negroes, 5.04; in 1902, whites, 1.43, negroes, 5.74. This shows that the disease was 228% more prevalent among the negroes in 1902 than it was in 1860, and that its death-rate was 300% greater among the negroes than among the whites in 1902. A similar vulnerability of the negro race to consumption is shown in other sections of the South. Thus in New Orleans its annual average death from 1897 to 1891 — a period of five years — is 123% greater among the negroes than among the whites; in Atlanta, Ga., from 1899 to 1901 — a period of three years — it is 141% greater; and in Augusta, Ga., from 1898 to 1902 — a period of four years — it is 424% greater among the negroes than among the whites.

Now on what score can we account for the enormous increase of consumption among the former slaves of the South since 1860? Why should the death-rate from consumption be from two hundred to four hundred per cent larger among the negroes than among the whites of the South at the present time, and this in spite of the fact that they were on an even basis, in this respect, in 1860? What destructive change has occurred in the environment of the southern negroes since 1860 that has left the white race practically untouched? Why should the negroes in the course of thirty-five years be transformed from the least to the most consumptive race in this country? This came to them neither through a change of climate nor through the influence of migration, but in the land of their unwilling adoption in which they had continually lived for more than two hundred years, and without a single visible sign of warning. It is this: Since they obtained their freedom their entire social, economic and political being has been revolutionized. In place of being dependent on their owners for their food, clothing, shelter, medical care and nursing as they did in the days of slavery, they are thrown on their own resources and are forced into a struggle for existence that is as unequal as it is tragical. They are thus brought into the most intense competition for existence with a people whose civilization is thousands of years ahead of their own development. Their condition may be fitly compared to that of an animal which is confronted by a new geological epoch to which it must adjust itself or perish. It is not surprising, therefore, that in this task of re-adjustment many of them fall a prey to diseases of the brain and nervous system, the very organs which bear the brunt of the battle in adapting this race to its changed environment; and for this and no other reason do they become consumptive.

That the brain and nervous system endure the strain of this great contest is amply attested by the fact that before the Civil War insanity, like consumption, was comparatively rare among the negro slaves, yet, according to Dr. T. O. Powell,[1] this disease has increased 705% among these people from 1870 to 1890 in the state of Georgia. This high authority also states: "I am forced to believe that insanity and tuberculosis are first cousins, or at least closely allied. The sudden outburst of insanity with the colored race of the South came associated with tuberculosis, hand in hand, keeping pace one with the other."

The same is true of North Carolina, for Dr. J. F. Miller, Superintendent of the Eastern Insane Hospital of that state, declares[2] that from 1885 to 1896 insanity increased 256% among the colored people in that state, and that in 1884 consumption caused 14%, and in 1895 27%, of the total number of deaths in his hospital, and this in spite of a reduction of the general mortality rate.

Dr. James D. Moncure, Superintendent of the Eastern Hospital for the Insane, in Virginia,[3] states that before emancipation there were about 60 insane negroes in that hospital, that now (1896) there are over 1,000 — an increase of over 1,600% — and that they readily contract consumption.

It is obvious, therefore, that the tremendous increase of consumption and insanity among the southern negroes is, in the first place, due to the heavy economic and industrial burdens which were suddenly placed on their shoulders, and which they had neither the wisdom nor the organized constitutional or mental strength to discharge; and in the second place to improvidence of living, to poor and improperly prepared food, to ignorance of the laws of physiology, to bad hygienic surroundings, to overcrowding, laziness and the lack of persistent employment, to improper care and nursing when ill, to dissipation of all sorts, to lack of self restraint, to alcoholism, and other vices. On this point the testimony of Dr. Miller, who has been quoted, is very emphatic and applicable. He says: "The negro in slavery had no thought for the morrow, . . . but he spent his quiet, humble life in his little cabin, with his master to care for every want of self and family. He lived under

[1] Dr. T. O. Powell, Superintendent of the Georgia Asylum for the Insane. Report on the increase of insanity and its supposed causes.

[3] Private communication.

the best hygienic restraint. His habits of life were regular, food and clothing substantial and sufficient, and the edict of his master kept him in-doors at night and restrained him from promiscuous indulgence and the baneful influence of the liquor saloon. In sickness he was promptly and properly cared for by physician and nurse. Freedom came to him, and a change came over his entire life. Under his former manner of living he enjoyed wonderful immunity from brain and lung trouble; and I confidently assert that the germs of these troubles came to the same man and race in consequence of his changed environment and the manner of life which followed."

That the same influence which gave immunity to the southern slaves from consumption will produce the same effects elsewhere is shown on a somewhat less extensive scale by the event of the importation of Chinese labor into Cuba.[4] Thus, from 1860 to 1870 Spain brought 250,000 coolies under contract to the island of Cuba. Their ages ranged from eighteen to thirty years, and they consisted of the scum and off-scourings, principally of the cities of Canton and Macao, and in spite of the most careful selection they brought with them consumption and other diseases and vices for which China is noted. The vast majority of them were placed on plantations, and being under contract, and under the supervision of overseers, who ministered to all their physical necessities, their conditions were identical to those which surrounded the negro slaves in the South before the war. The result was that within the first few years consumption was eliminated, either through death or cure, and never reappeared in them or their offspring.

From all that has been said, the prevention of pulmonary consumption resolves itself into such efforts of education as will impress the masses with the importance of leading a life similar to that (excepting slavery), which made the slave population of the South practically immune from this disease before the Civil War. What was done once may be done again, for the laws of health which held true then are equally applicable now. Such efforts of prevention mean the inculcation of sound principles of hygiene; the eating of wholesome and properly prepared food; the wearing of suitable and seasonable clothing; the avoidance of damp, unsanitary and overcrowded dwellings; the abstinence from nerve-strain and over-work; the shunning of strong drink and other vices; the teaching of the value of useful labor; the encouragement of agricultural and mechanical pursuits; the training in physical development; the supervision of proper convalescence from what to them seems a trivial cold or cough, or from acute illness or injury; the procurement of effective medical attendance and nursing in sickness or accident, etc.

Now a large hospital and dispensary practice among consumptives extending over a period of eighteen years has convinced me that the practical solution of the prevention of this disease is one of reaching the masses. People who are predisposed to, or are suffering from, this disease do not come to such institutions until the malady has gained a strong foothold, and the stage of prevention has been passed; not because they would not eagerly do so, for they possess as strong a share of the instinct of self-preservation as the common run of mankind, but they fail to realize the true significance of their condition until it is too late. Hence the only effective measure is to bring yourself in contact with the people by inaugurating a campaign of education. To bring this about is for a charitable organization to divide a city, or some of its wards, into convenient sized sections, allot each section to a competent physician, whose duty it will be to make a general canvass of his section once a month, or as often as is necessary, among all willing residents who show or possess a family taint, or who for any reasons are believed to be in danger of consumption, to take condensed histories of all such individuals and families, to impart advice in regard to food, clothing, shelter, habits, etc., etc., to give medical counsel and treatment whenever needed, and to send all cases which need active supervision to an institution which is well supplied with all the paraphernalia necessary for the treatment of every defect in such individuals.

Clinical Department.

A CASE OF CARBOLIC ACID POISONING.

BY WILLIAM W. HARVEY, M.D., BOSTON.

THE following case so well illustrates the action of carbolic acid in toxic doses, and the value of prompt and persistent treatment in such cases, that it seems especially worthy of report.

The patient, a child of two years of age, swallowed a certain quantity of strong carbolic acid which had been left carelessly in a cup on the floor by the mother who was engaged in the process of exterminating bedbugs.

According to family reports, the child barely had time to take a few steps, when it fell, limp and unconscious. I arrived ten minutes later. At this time the pulse could not be obtained at the wrist. The entire body was cold and mottled. Respirations were infrequent, irregular and stertorous.

While considering the child moribund and the case hopeless, I gave in rapid succession a large number of subcutaneous injections of brandy and $\frac{1}{60}$ grain of strychnia. In a few minutes the pulse was perceptible at the wrist and respirations improved.

By combining a glass syringe and a large, soft rubber catheter, I improvised an excellent stomach pump and washed out the stomach, after which the whites of two eggs and a half ounce of brandy were introduced through the tube. I do not think the stomach contained much of the carbolic acid, the symptoms having been produced, rather, by the immediate absorption of a small quantity of the substance.

Pulse and respirations continued fair for about a

half hour, when respirations again failed. In spite of the Sylvester method of artificial respiration being employed faithfully, cyanosis increased; pupils dilated, lips became black, muscles rigid. Patient refused to inspire. At this crisis the lungs were filled several times by mouth to mouth insufflation before the least tendency to automatic function became apparent. By these methods, extending over perhaps ten minutes, respiration was again restored.

Close watching and occasional stimulation were required during the next three or four hours, when patient was left in practically a normal condition, conscious and desirous of sitting up. The few slight burns were superficial and insignificant.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION. SECTION ON PRACTICE OF MEDICINE.

DR. ALEXANDER LAMBERT of New York City, Chairman.

FIRST DAY. JUNE 7.

Chairman's address:

THE ADAPTATION OF PURE SCIENCE TO MEDICINE.

DR. ALEXANDER LAMBERT, of New York, read this paper. He said the most complete adaptation of scientific work to clinical medicine was the work of Behring and others in the antitoxic sera for diphtheria and tetanus, conceived and worked out completely in the laboratory before it was applied to medicine. The preventive inoculation against typhoid fever, plague and cholera was the practical application of our ideas of immunity, and the success so far obtained seemed to be that about 50% of those inoculated were protected against these diseases, and of those who acquired these diseases after being inoculated the mortality was about 50% less than in the uninoculated. The practical value of the study in the variations of blood pressure was just beginning to be recognized. The knowledge obtained by the use of blood pressure instruments would increase our therapeutic capabilities, for they gave valuable indications of the variations in the vaso-motor control, and they seemed to promise a distinct gain in a more intelligent treatment of cardiac and renal diseases, and would give valuable indications in infectious diseases of when to give and when to withhold stimulants. The closest co-operation between clinicians and laboratory workers, unfortunately not always present, was a thing to be desired. One often saw the worker in the laboratory failing to appreciate the clinical situation and the difficulties of the clinician. On the other hand, clinicians were often prone to throw the responsibility of a difficult diagnosis on the worker in the laboratory, and when he failed, to criticize the result and in turn throw discredit on all laboratory results.

PERNICIOUS ANEMIA AND ITS RELATION TO GASTRIC DIGESTION BASED ON TWENTY-FIVE CASES.

DR. CHARLES G. STOCKTON, of Buffalo, read this paper and gave the following summary: Of the 24 cases here reported, the youngest was thirty-two, the oldest seventy; average forty-five plus years; there were 20 males and 4 females; 13 had outdoor occupation and 11 indoor; the longest duration of illness was in one five years, the shortest six months and fatal; 12 were known to be dead, 5 living, the others unknown. All had dyspnea on exercise; all suffered from faintness and weakness; 16 had the gaseous pulse; 16 had a heart slightly enlarged; 16 had systolic apical bruit; 6 had *bruit de diable;* 8 had other bruit; 22 had a distinct lemon-colored tint of the skin; 15 had a tongue strikingly denuded of epithelium; 10 had good appetites, 7 capricious, and 7 anorexia; 18 complained of symptoms of stomach trouble; 10 had constipation, 8 diarrhea, and 6 irregularity of the bowels; in 11 the liver was enlarged; 1 had four periods of improvement, 3 two periods, 8 one period and 8 no period of improvement. After his attention was called to the subject by Billing's paper, he found signs of spinal cord involvement in 6 out of 9 cases. Nine cases showed slight dilatation of the stomach; in 13 the gastric digestion was absent, in 8 it was very low, and in 3 it was fairly good. Five showed evidences of gastric catarrh. Six showed no acidity of the gastric contents, one (the highest) showed a total acidity of 46, one 26, and the average about 10. Four showed the presence of combined chlorides. One showed free hydrochloric acid .05%, one .06% and one .022%, in all the others it was absent. Six showed lactic acid present; 4 showed other organic acids. The acid salts were very low, 18 being the highest, 5 having none whatever; 7 showed the biuret reaction; 6 showed rennet present. The digestion of starch was poor in all save two cases.

DR. R. C. CABOT, of Boston, said that of 150 cases of pernicious anemia, five sixths showed the absence of hydrochloric acid, and yet digestion went on perfectly well. Hydrochloric acid appeared to be a luxury, not a necessity.

DR. MAX EINHORN, of New York, said he had met with many cases of pernicious anemia in which the gastric digestion was not impaired, and that cases of achylia gastrica might develop into acute pernicious anemia.

DR. ALLEN JONES, of Buffalo, wished to emphasize the fact that achylia gastrica was more often encountered without pernicious anemia than with it.

DR. WILLIAM OSLER, of Baltimore, said that we were still much at a loss in our attempts at finding an exact pathology of pernicious anemia.

DR. J. N. HALL, of Denver, Colo., has seen striking improvement when hydrochloric acid was given in large doses.

DR. GEORGE DOCK, of Ann Arbor, Mich., had met with success in the treatment of pernicious anemia with large doses of dilute hydrochloric acid, fresh air and diet.

DR. CHARLES G. STOCKTON, of Buffalo, thought that we should draw a distinct line between achylia gastrica with atrophy of the mucosa and cases of pernicious anemia.

THE DIAGNOSIS AND TREATMENT OF PERFORATION IN TYPHOID FEVER; WITH A REPORT OF NINETEEN CASES, OF WHICH SIXTEEN WERE OPERATED UPON, WITH FIVE RECOVERIES.

DR. MORRIS MANGES, of New York, read this paper. He said that in drawing practical conclusions from this analysis of the varied clinical features of perforation as it occurred in the series presented, it would at once be seen that there was no symptom or group of symptoms which were pathognomonic. In suspected perforation the condition of the abdomen as regards tenderness, rigidity, distention, respiratory excursions, and liver dullness should be routinely observed. The leucocyte count was of little value. He said that most physicians expected too many and too pronounced symptoms for an early diagnosis of perforation. Granting the possibility of spontaneous cure, the best results ever claimed for nature's method had been 5%; contrast this with the latest statistics published by Hare and Ashhurst of 362 cases which they had collected with a recovery of 26% with operation.

The only exception to the rule of early operation was that moribund patients could not be operated upon.

A CASE OF TYPHOID FEVER WITH AN UNUSUAL COMPLICATION.

Dr. William Edgar Darnall, of Atlantic City, reported this case. The case was a very mild one and was known as "walking typhoid" up to the time the patient came to Atlantic City. The case seemed peculiar in that there was a uterine flow which assumed the proportion of a hemorrhage, and only packing the vagina with gauze succeeded in checking it. He said that hemorrhage as a complication of typhoid fever presented some interesting phases. No mention was made of uterine hemorrhage as a complication of typhoid fever by most authorities. Osler, however, mentioned "a rare and fatal form of typhoid fever characterized by cutaneous and mucous hemorrhages." In the case reported the hemorrhage did not usher in the attack, but occurred in what must have been the third week of the trouble. The normal monthly period did not figure in any way in the case because the menstrual epoch occurred two weeks previous.

Dr. William Osler, of Baltimore, said that the essential and most important thing was intelligent watchfulness on the part of the physician. In hospital rules can explicitly be laid down, and specific directions be given the house physician who should be on the alert for certain changes in the typhoid cases pointing to the possibility of intestinal perforation.

Dr. J. C. Wilson, of Philadelphia, said that in the German and Pennsylvania hospitals at every visit of the house physician, as a matter of routine, rigidity of the abdominal muscles was looked for. If they suspected rigidity of the right side or the right lower quadrant of the abdomen the attending physician was immediately called. If pain, especially when associated with rigidity, the patient was immediately removed to the operating room. His experience had led him to believe that perforation of the bowels was preceded by, in a considerable number of cases, hemorrhage, but seldom did they occur coincidentally.

THE MORTALITY AND MANAGEMENT OF PNEUMONIA.

Dr. Edward F. Wells, of Chicago, said that pneumonia was responsible for an annual morbidity of about 0.7%; a mortality rate of about 0.13% and it caused about 8.1% of all deaths. In New York there was an annual mortality of about 1.3 for 1,000 of the population in the decade 1804–1813, and rose to about 2.5% per 1,000 during the terminal decade of the century. He said that: (1) pneumonia was a very prevalent disease and its prevalence was increasing; (2) this increasing prevalence was probably due to the wider diffusion of the more vigorous strains of the pneumococcus, made possible by the increasing commingling of people; (3) the pneumococcus was to be found in the upper respiratory passages of a very large proportion of healthy persons, and it was the migration of these ever present germs into the pulmonary alveoli which caused pneumonia; (4) pneumonia was a very fatal disease and its mortality was increasing; (5) the increasing mortality was probably due to the greater average virulency of the pneumococcus. The following prophylactic measures were offered for consideration: (1)pneumonic sputum should be destroyed before it has become dry. (2) The nostrils, mouth and throat should be kept as clean as possible. Taking a drink of water after eating is a habit which should be formed and cultivated. (3) The room occupied by a pneumonic patient should be afterwards disinfected. Remaining unnecessarily in a room occupied by a pneumonic patient should be avoided. (4) Respiratory catarrhs should be avoided, and if contracted should be relieved. (5) Physical and mental exhaustion, privation, undue exposure to cold and inclement weather should be avoided. In the ordinary cases he supplemented the efforts of nature by giving during the first few hours only three to five drops of tincture of *Veratrum viride* every two or three hours until nausea had been produced or the initiatory violence of the attack had passed. To combat temperature he used the ice cap and the external application of fifteen to twenty drops of guiacol. Pulmonary edema was treated by energetic stimulation of the nervous system by strychnia, of the capillaries by adrenalin, and of the heart by small doses of morphia. Oxygen inhalations met his approval.

THE STUDY OF A SERIES OF CASES OF PNEUMONIA, WITH SPECIAL REFERENCE TO DIAGNOSIS AND COMPLICATIONS.

Dr. Joseph Sailer, of Philadelphia, read this paper. He based his study on 65 cases in the Philadelphia Hospital during the past winter. Nearly 40% were over sixty years of age and the mortality was correspondingly high. Thirty-five cases dying and 30 surviving. The distribution as determined by physical signs and confirmed where possible by autopsy was: left lower lobe alone 16, left upper lobe alone 2; right lower lobe 12, right upper lobe 13. In 5 cases a diagnosis was made of involvement of the right upper and middle lobes. The entire left lung was involved in 4 cases and the entire right lung in 3 cases. It had been asserted that leucocytosis rendered prognosis more favorable. In the cases that recovered there were less than 10,000 leucocytes in 3 cases and between 10,000 and 20,000 in 10 cases; between 20,000 and 30,000 in 5 cases; between 30,000 and 40,000 in 5 cases; between 40,000 and 50,000 in 1 case, and between 50,000 and 60,000 in 2 cases. Of the cases that died the leucocytes were: between 10,000 and 20,000 in 11 cases; between 20,000 and 30,000 in 4 cases; between 30,000 and 40,000 in 1 case and between 40,000 and 50,000 in 1 case. It does not appear that any definite conclusions could be drawn from the leucocyte count. The quantity of chlorides in the urine was not an indication of the subsequent course of the disease, but the comparison of the excretion of chlorides in pneumonia and in other febrile diseases had shown that in the latter states the reduction was comparatively insignificant and in pneumonia always considerable, so we could place the highest value upon it in the diagnosis of pneumonia. Of late years we had practically forgotten the importance placed upon Skoda's sign, the indeterminate or indefinite respiratory murmur characteristic of consolidation of the lung. Two forms of bronchial breathing could be distinguished to which the names of loud and faint could be given. The difference was one of degree. The faint bronchial breathing, although occurring more often in the early stages of the disease, was not by any means limited to the stage of congestion. Wooden tympany was only observed in 2 cases, herpes was observed 4 times, icterus 3 times. Feeble heart action and albuminuria were comparatively common. Profound cyanosis was present in 2 cases, and in 1 was temporarily relieved by venesection. If severe abdominal pain was present it was associated with tenderness in the hypochondrium on the same side as the pneumonia. This happened in 4 cases. The complications were numerous. Chronic nephritis usually of advanced type was found in 17 of 25 autopsies.

Pleurisy, either chronic or acute, was present in all cases. In 2 there was empyema, in 1 gangrene of the lung and in 2 acute fibrinous pericarditis, in 1 acute obliterative pericarditis and in 1 acute ulcerative endocarditis, and in 1 pneumococcus meningitis. In 4 cases tubercular lesions were present. The treatment consisted of expectant stimulation with occasional resort to hypodermoclysis. Ten cases were treated with anti-pneumococcic serum. These cases were selected, part being favorable subjects and part unfavorable. There were 3 deaths and 7 recoveries. Of the fatal cases one was distinctly unfavorable, and one practically moribund when the serum was used. Of the cases that recovered three were regarded as severe. On the whole, the results of the serum were regarded as distinctly encouraging.

DR. DELANCY ROCHESTER, of Buffalo, said that the disease should be treated and not the symptoms, and believed that if we get rid of the toxemia a great many of the symptoms would be got rid of. He approved early bleeding in asthenic cases, but he disapproved of the administration of opium in the beginning. He believed we could get rid of the poison by the proper use of laxatives, particularly calomel, and the proper use of cold. Getting rid of the poison of pneumonia by sweating was of great benefit. He approved of venesection in certain cases.

DR. BABCOCK, of Chicago, referred to the work of an Italian experimenter who attempted to demonstrate that pulmonary edema was not due to heart failure, but to the action of the pneumococcus infection upon the pulmonary alveoli. If blood pressure was low at the start he believed that *Veratrum viride* was contraindicated, and he protested against the use of cardiac depressants when the blood pressure was already low. Digitalis he believed to be of the greatest possible utility in the form of fresh infusion injected hypodermatically.

DR. S. SOLIS-COHEN, of Philadelphia, was firmly convinced that there were two times in the history of the cases of pneumonia when venesection might be employed, *viz.*, in the beginning of attacks; here he believed it reduced the toxemia; and secondly toward the end of the attack when the right heart was overloaded. The keynote of the successful treatment in this disease was individualization. He believed that patients with temperatures of 103, 104 or 105 gave a better prognosis than those with temperature of 100 to 101; the vital reaction seemed to be better in the latter.

APPENDICITIS FROM THE STANDPOINT OF A PHYSICIAN.

DR. S. G. BONNEY, of Denver, said that the responsibility of the physician in appendicitis was far greater than that of the surgeon, because early diagnosis was a factor of supreme importance and afforded solution of the problem as to time of operation. A report of selected illustrative cases from the author's personal experience was appended.

SUICIDE, WITH SOME ILLUSTRATIVE CASES.

DR. JOHN L. DAVIS, of Cincinnati, read this paper. He said that in twelve years there had been over 77,000 suicides recorded in the United States, the number increasing annually from about 3,500 in 1891 to 8,600 in 1903. The greatest number of suicides are credited to middle life. Our American strenuous life he believed to be having a disastrous result on the physical conditions of our people; they were becoming physically unbalanced, and this feverish intensity and eagerness to excel began almost at the cradle and ended only at the grave.

SECOND DAY, JUNE 8.

PATHOLOGY OF ARTERIOSCLEROSIS.

DR. WILLIAM H. WELCH, of Baltimore, opened the symposium on arteriosclerosis. He wished to emphasize the combining of the clinical, the pathological and the anatomical phases of the subject, and he thought that our knowledge would be much advanced by a combination of the work. The disease, arteriosclerosis, was recognized from the time that autopsies began to be made, and was recorded as early as the sixteenth century. A historical review of the subject here followed. He then considered the nature of the trouble as described by Keller and his students. In the cicatricial form of arteriosclerosis there seemed to be a peculiar localization, and it affected chiefly the thoracic arch, especially its ascending portion. It had but little tendency to extend into the large branches of the aorta or to extend down into the abdominal aorta. It was characterized markedly by changes in the adventitia and media, and also by furrows or scar-like depressions seen more particularly in the inner coat of the aorta. Associated with this were elevated plaques, many of which were not to be distinguished from true arteriosclerosis. Sometimes fibrous scar-like patches could be seen. Another type related to syphilis or syphilitic aortitis, so-called by Keller and students. There were at present three anatomical distinct affections that might occur separately, but which were more often combined with each other. Dr. Welch said there were the following forms to be considered: (1) That form with inflammatory thickening of the inner coat of the vessel resembling scar tissue. (2) That form called by some "true arteriosclerosis" and which naturally applied to a thickening of the intima and a splitting of the internal elastic membrane, or the elastic muscular coat, associated with marked degenerative changes, necrotic, fatty and hyaline degenerations. (3) That form of syphilis of the aorta already referred to. He asked if this hypertrophy was not a compensatory act, and a thing to be desired in the muscular coat of the arteries, as in the heart muscle. Experimentation did not shed much light upon the questions raised. The most important underlying cause was the functional strain upon the arteries. There was no question but that extensive arteriosclerosis was a disease without clinical symptoms or any effect upon organs. It was a matter of great importance to determine what were the conditions associated with arteriosclerosis which were responsible for the rise of arterial pressure and for the cardiac hypertrophy. This he considered to be the most important aspect of the subject. The rise of blood pressure was due to causes which led to arteriosclerosis, but not caused directly by it.

ARTERIOSCLEROSIS FROM ACUTE INFECTIOUS DISEASES.

DR. WILLIAM S. THAYER, of Baltimore, said that he was led to the consideration of this part of the symposium by observations on typhoid fever patients. Out of 62 autopsies in cases of typhoid fever, in 19 there were definite sclerotic changes made out, in 4 there were yellow opacities in the intima noted, and in 13 sclerotic changes which were early and fresh. The figures, together with a higher blood pressure than was noted in the control tables, lead him to feel that typhoid fever played some causal part in the thickening of the radial arteries. If that was true, typhoid fever, to a greater or less degree, caused this condition. Light might be thrown upon this by an analysis of the histories of a large number of cases in Dr. Osler's wards. A careful inquiry was made into the question of alcoholism, work, etc. The histories

gone over consecutively numbered 3,894, and they were examined (1) as regards the general presence of palpable radials; (2) in regard to the presence of palpable radials in cases with histories of diphtheria, scarlet fever, malaria, pneumonia, typhoid fever, acute rheumatism, syphilis, gonorrhea, alcoholism, and heavy work. The results obtained were shown by tables. Subdividing these cases into groups in which only one etiological factor was made out, the results were also shown by charts. Where no causal factor existed a general percentage of 18.9 was shown, and cases of diphtheria a slightly lower percentage, then pneumonia with 19.6, malaria 22.6, syphilis 23, scarlet fever with 24, diphtheria with 28.7, rheumatism 41, alcoholism 53.3 and heavy work 62.2. So far he was not justified in drawing any conclusions that acute infectious diseases played a part in the development of arteriosclerosis. The part played by physical labor in the production of arteriosclerosis seemed to be far greater than that played by alcoholism.

ARTERIOSCLEROSIS OF SYPHILITIC ORIGIN.

Dr. C. Travis Drennen, of Hot Springs, said that though there was a connection between arteriosclerosis and syphilis, the connection was obscure. The routine method adopted by the profession at large in the treatment of syphilis he believed was responsible for the production of arteriosclerosis, and the tendency of the disease itself was to produce sclerosis in various organs. He entered a plea for a more rational treatment of syphilis that would lessen the danger of mercury and the iodides and at the same time possibly eliminate the treatment of syphilis as a causative factor in the production of arteriosclerosis.

ARTERIOSCLEROSIS OF NEPHRITIC ORIGIN.

Dr. George Dock, of Ann Arbor, Mich., presented this paper. He said that doubtless in many cases arteriosclerosis was caused by nephritis, and it was of great clinical importance that the kidney lesion might be severe yet latent, often developing symptoms severe enough to cause death. He called attention to the value of clinical study and the recognition of the importance of hyperdistention in causing vascular disease; as the presence of this condition in acute nephritis might lead to disease of the intima, followed by compensatory, and later by degenerative, changes. He cited the case of a boy of fifteen suffering from acute nephritis which terminated in death, during one of several attacks of uremia. The object of his paper was to assert the possibility of renal diseases of all kinds assisting in the production of arterial disease, and to plead for a more extensive clinical investigation in order to show the extent and, if possible, the explanation.

ARTERIOSCLEROSIS DUE TO LEAD.

Dr. Frank Billings, of Chicago, said that the mode of entrance of lead into the body was very easy, and he instanced a case of poisoning from washing the clothes of a man whose occupation was a painter. Regarding the effect of lead upon the blood and other tissues, he said it probably was direct. As the blood circulated, the poison might act directly upon the cells of the vessel wall and produce a proliferative endarteritis. This was associated with degenerative processes of the media and thickening of it, and especially a degeneration of the muscular coat with proliferation and thickening. The effect upon the elastic coat he did not know. There was also an interstitial thickening of the outer covering which was widespread. There was also caused a chronic degeneration of the kidney substance and resulting cirrhosis of the kidney with well-known fibroid changes and hypertrophy of the muscular coat of the arteries. The effect was upon the cells, tubules and glomeruli and blood vessels. In a large number of cases brought to autopsy with nephritis a very large proportion of them was associated with lead. Lead predisposed to gout, and it was well known that arteriosclerosis was common in gout. A diagnosis could not be made, except in cases where the nature of the cause was found.

THE SIGNIFICANCE OF ALCOHOL IN RELATION TO ARTERIOSCLEROSIS.

Dr. Richard C. Cabot, of Boston, in his review of literature on this subject, has found that most standard textbooks assert unconditionally the importance of the excessive use of alcoholic liquors as a causative factor in the production of this disease. His clinical research showed that of 283 cases investigated at the Massachusetts General Hospital, only 18 or 6% showed arterial sclerosis so far as examination of the heart and peripheral vessels gave evidence. This was to the exclusion of those over fifty years of age and those who had syphilis. Excluding those of forty years, the percentage would fall to 1.4%. Similar investigations at the Massachusetts Hospital for Inebriates and at the Long Island Hospital showed that alcoholism had a very slight influence in the causation of the condition. Post-mortem evidence gathered at the Massachusetts General Hospital gave similar results, *i. e.*, that the alcoholic origin of arteriosclerosis was a myth.

ARTERIOSCLEROSIS AND ANGINA PECTORIS.

Dr. William Osler, of Baltimore, said that there were many things doubtful about angina pectoris, and that it was associated with arteriosclerosis was shown by Edward Jenner in post-mortems he made. It had been demonstrated in a large number of post-mortems since then, and there was no question about its association in a very considerable number of cases. With regard to the attacks of pain there were a great many interesting points in this connection. Arteriosclerosis of the blood vessels of the head produced attacks of severe pain associated with migraine. Severe recurring headaches might be seen in connection with embolism and thrombosis. In sclerosis of the abdominal vessels severe pain was rarely met with, yet there were cases of angina pectoris in which the pain was almost entirely abdominal, and might even be mistaken for hyperacidity; such cases might be termed "angina abdominis." Interesting conditions were shown in the lower extremities; cases of numbness and tingling of the extremities were met with in old people, in diabetes and Bright's disease, and this was due to senile arteriosclerosis. Pain caused by plugging of the femoral artery was marked, and there was also pain in thrombosis of the veins in typhoid fever. In old persons attacked with very great pain, with cramps in the muscles, it seemed to deserve the name "angina cruris." Dr. Osler said that there seemed to be four groups of cases as follows: (1) Those in which the angina attacks were definite, distinct and severe in young persons, a neurotic process recurring over long periods of years, terminating fatally, and in which the arteries show no sclerosis whatever. (2) Those cases in which the angina pectoris was associated with syphilitic arteriosclerosis. These were amenable to treatment, occurred in young men, with signs of cardiac lesions, frequently aortic insufficiency, but with evidences of syphilis, definite and distinct. He wished to emphasize the importance of syphilis in producing a distinct type of aortitis. (3) A large group of cases occurring in the pre-senile,

between the ages of forty and sixty. (4) A group of cases occurring between the ages of sixty and eighty and a very important group.

TREATMENT OF ARTERIOSCLEROSIS.

DR. JAMES N. ANDERS, of Philadelphia, said that he had subdivided the cases into etiological categories as follows: (1) Those due to toxic agencies in the blood, *e. g.*, in chronic alcoholism, lead poisoning, diabetes mellitus, syphilis, gout, rheumatism, and other infectious diseases; (2) arteriosclerosis caused by the constant ingestion of an excess of either the carbohydrates or nitrogenous food; (3) cases dependent upon constant hypertension, due to muscular over-exercise, as in certain laborious occupations and violent competitive sports.

Prophylaxis. — He emphasized the importance in early life with reference to competitive efforts in athletics. The maintenance of a complete nutritive equilibrium was a potent means of preventing pathological processes which led to arterial changes. In gouty subjects nothing was so vitally important as a suitable diet and régime. There was, however, no special diet suitable for all cases of gout, no dietetic rules universally applicable. A suitable and considerable restriction in the amount of food was the prime requisite. Such subjects should adopt an open air life coupled with regular systematic muscular exercise. By remembering the principal causes of arteriosclerosis it was clear that by a proper regulation of the séances, massage became a most useful means of prophylaxis, and exercise of beneficial influence upon the glandular secretions and the nervous system as well as upon the vascular system. Warm baths were serviceable in lowering the tension of both the arteries and veins.

It might be seriously doubted whether the disease was ever arrested by medicine; however, we might retard its progress to some extent and restore the normal rapidity of the blood current and lower the blood pressure by dilating the arterioles. The remedies employed for this purpose were nitroglycerin, the nitrites and potassium iodide. Except in cases due to syphilis the results obtained by the use of iodides were in no wise comparable in brilliancy to those obtained by following the careful application of hygienic measures and the use of nitrites. The iodides were called for and had been shown to be of decided value in cases showing a luetic taint. Sphygmographic tracings indicated the results of nitrites and nitroglycerin. The result of these studies made clear the difference in conditions described under the title of arteriosclerosis. The blood pressure was not materially increased in many cases dependent upon senile degeneration, chronic diabetes and certain toxemias. The nitrites were strongly indicated and most effective in that category of cases in which there was an early and marked increase in arterial pressure, and the heart was hypertrophied.

DR. ALFRED STENGEL, of Philadelphia, said that if we wished to accomplish anything in the treatment of arteriosclerosis, especially its consequences, it should be done in the early stages of the disease and, therefore, greater efforts should be made in the direction of diagnosis and its etiology. He felt convinced that alcohol was a very important cause. He was much surprised at a recent meeting of the British Medical Association, in hearing the statement made that the convalescence of typhoid fever should take from one year to eighteen months, and the more he saw of the end results of typhoid fever the more he believed in the truth of this statement. After having had the disease, it was necessary to direct avoidance of strains of any kind until long after.

MULTIPLICITY OF CAUSES.

DR. FRED'K C. SHATTUCK, of Boston, referred to the multiplicity of causes of arteriosclerosis. It seemed to him that the carrying of responsibilities, such as by the captains of industry — men who carry great strain, etc., the men from whom we could not get statistics — that this weight carrying he could not but believe was one of the causes of arteriosclerosis through defective metabolism. There is a high arterial tension in these people, and if you add to that alcoholism, what is the result? The biggest alcohol drinkers in the country who still maintain good health were not the men who lead strenuous lives. In Canada the life was a hard one; the Scotch and the Scandinavians were enormous consumers of alcohol; the Scotch lead intelligent lives, yet not the high tension life as in this country. It was a notorious fact that a man cannot use alcohol here as in Europe. All this seemed to show that there was an extreme complexity of problems with which we were dealing.

DR. WM. KRAUS, of Memphis, Tenn., said that the anatomical classification of the disease was fraught with difficulty. The etiological feature of this disease seemed to be associated with the circulation of toxins in the system and with degeneration in solid organs. Primary degeneration was not so much the result of increased pressure or pathological change as the circulating toxins in the outer coats. With regard to malarial fever, it must be very severe and characterized by long duration before it produced arteriosclerosis. In all cases he found changes in the kidney, and in the severe malarial fever there was usually associated albuminuria. He referred to the instance of a man who twenty-four or twenty-five years ago had suppression of the urine, and to-day this man could not drink alcohol without raising the blood pressure so much as to cause throbbing of the temples.

DR. CHAS. G. STOCKTON, of Buffalo, spoke of the appearance of pain in the abdomen depending upon arteriosclerosis and which was often not even suspected. Instead of using the ordinary warm baths he thought better results were obtained from short hot or vapor baths which had as good effect in opening the capillary vessels. When the nitrites or nitroglycerin was given and it was desired to have a constant and uniform effect, it should be given more frequently. Without the use of the iodides he did not think we would have favorable results in the treatment.

DR. S. J. MELTZER, of New York, assumed that he was not wrong in stating that local causes could cause local arteriosclerosis. In referring to Dr. Cabot's remarks, he said the peripheral arteries only were examined, but the splanchnic area was not examined, and he did not think that Dr. Cabot should draw the conclusions he did without examination of this area. Alcohol in health is sometimes a curse, but alcohol in disease was often a blessing.

DR. BABCOCK, of Chicago, did not think that we should attribute special etiological influence to any one factor in the production of arteriosclerosis. He thought we should consider the form in which alcohol was consumed. The Germans were in the habit of consuming many quarts, 25 to 30 liters of beer a day, and he believed that in dealing with these individuals we must consider not merely the fact that alcohol had been taken, but other factors such as the excessive amounts of fluids consumed and the nutritive material, such as contained in beer.

(To be continued.)

THE BOSTON
Medical and Surgical Journal.
THURSDAY, JUNE 16, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

DR. OSLER ON IMMORTALITY.

We have come to look upon Dr. Osler as the representative of medicine in many and diverse fields; it therefore occasioned no great surprise that he was chosen as this year's Ingersoll Lecturer at Harvard University, the terms of the foundation requiring a discussion of the general subject of immortality. Difficult as such a task must be under any circumstances, it was rendered the more exacting from the fact that the matter had already been treated from many points of view and with much skill and close reasoning by his predecessors in the lectureship, — Rev. George A. Gordon, Prof. William James, Pres. Benjamin Ide Wheeler, Prof. Josiah Royce and Mr. John Fiske. These gentlemen had discussed the subject from the religious, psychological, historical, metaphysical and evolutionary points of view, and it remained for Dr. Osler to interpret the present-day attitude towards the problem, as observed by a representative of applied science. Such an opportunity has seldom been offered to a physician primarily engaged, according to the popular conception, in matters pertaining to the flesh, but that he should have a point of view bred of experience and contact with the gravest problems of life is certainly not extraordinary. It was, therefore, not a source of surprise that Dr. Osler acquitted himself of his task in a most entertaining, suggestive and weighty fashion.

The immediate subject of the lecture was "Science and Immortality," and at no time did he transgress the limitations which he had set himself in the title. Religious conceptions, as such, did not enter into the discussion, nor did the temptation of metaphysical speculation distract him from his object, of stating, with the accuracy of a man of science, the facts of observation which bore upon the question of life after death. Admitting as he did that the methods of science, as hitherto developed, had small significance when applied to supra-sensual phenomena of whatever sort, he still found opportunity to make a critical analysis of prevailing tendencies, and finally, no doubt to the gratification of the audience, to formulate in a measure his own confession of faith.

At the outset of his discourse, after modestly disclaiming his fitness for the task he had undertaken, he drew attention to the fact that science has changed the aspect of the world, through its control of physical energies, through the biological revolution it has wrought, and, finally, by making a good start in the warfare against disease. These were the three great achievements of the nineteenth century. Admitting this, the following query is presented: Has man's conquest of nature made man more or less hopeful of a future life? This the lecturer attempted to answer in a purely objective fashion, and certainly with a large measure of success. The great majority of men, Dr. Osler finds, are uninfluenced by a belief in immortality, though uncritically accepting the popular attitude in the matter. Even in many religions, as well as in our own daily lives, the belief in immortality as a controlling influence is vague. It is ominous that the press is absolutely silent on the subject, and the doctrine of a future life has been uninfluential in the great movements of the world. Usually a man dies as he has lived, and the thought of a future life plays no part in his last hours. On this point Dr. Osler said: "I have careful records of about five hundred death beds, studied particularly with reference to the modes of death and the sensations of the dying. What concerns us here relates only to the latter. Ninety suffered bodily pain or distress of one sort or another, eleven showed mental apprehension, two positive terror, one expressed spiritual exaltation, one, bitter remorse. The great majority gave no sign one way or the other; "like their birth, their death was a sleep and a forgetting."

A second group of more thoughtful men puts the problem aside, as in doubt or unsolvable, and leaves the question open. Such was Darwin's frame of mind, and, in fact, such is the usual attitude of investigators in the physical and natural sciences. Evolution and the modern psychology find the "soul" superfluous. The insistence on the mind as a function of the brain

has naturally led to the doubt of the possibility of the existence of consciousness apart from a material basis. Hitherto, the search for the spirits has been futile, but the methods of the Society for Psychical Research should be endorsed, since, after all, there is no inherent reason why there may not be a supra-sensual world of spirits just as there is a vast range of activities going on wholly beneath the level of our conscious life. The general tendency of science has, however, distinctly been to lay stress upon the immortality of the flesh, through the continuity of the germ-plasm, and to minimize to the last degree the importance of man, as an individual.

Up to this point, those of his listeners who came in the expectation that Dr. Osler had some message of hope must have been grievously disappointed. A more gloomy picture of the destinies of human life drawn in more forceful and picturesque language could hardly be imagined. No doubt, many in the audience experienced a certain sense of relief, when he alluded to the third group of believers, a small group, but one which cannot be ignored, which sways the minds of men through an appeal to the heart rather than to the head. To-day as always the heart controls, and reason is not king, however eager the effort may be to raise it to that position. Women, who largely constitute this group, are pre-eminent, because they are the incarnation of the emotional — an element which must be considered in the daily conduct of our lives. The ardent belief in a future life rests now, as it has in the past, in the safe-keeping of this relatively small but always influential band of the faithful. Science is organized knowledge, and of the unseen it has absolutely no knowledge.

Finally, Dr. Osler, in giving a word of advice to young men, assented as his own confession of faith to the dictum of Cicero, "who had rather be mistaken with Plato than be right with those who deny altogether the life after death."

Such an address does not lend itself to extended comment within the limited space of these columns, but we are convinced the ultimate verdict will be that the lecture embodies a point of view of deep significance. Certain unimaginative critics have complained that it proved nothing and that it lacked originality. Both are no doubt true, and we heartily return thanks to Dr. Osler that the temptation to forestall such a critisiem did not present itself as a possibility. The address was merely a restatement in peculiarly lucid language of the standpoint of a liberally-minded man toward a problem of great import to the human race at large. Its aim was modest and its result correspondingly satisfactory. The suggestion to the men of science as a class is stated in no uncertain language, and herein to our mind lies the kernel of the entire discourse. The peculiarly aggravating tendency to deny what cannot be proved by the methods of so-called exact science is certainly a stumbling-block in the way of progress. The belief in immortality stands as one among many such skepticisms. Of this, Dr. Osler says: "The scientific student should be ready to acknowledge the value of a belief in the hereafter as an asset in human life."

THE INTERNATIONAL CONGRESS OF ARTS AND SCIENCES.

THE International Congress of Arts and Sciences to be held at St. Louis in connection with the International Exposition has issued its programme and list of speakers. The time assigned to the congress is from Sept. 19 to 25. The announcement of the purpose and plan of the congress states that:

The idea of holding such a congress grew out of the thought that the subdivision and multiplication of specialties in science has reached a stage at which investigators and scholars may derive both inspiration and profit from a general survey of the various fields of learning, planned with a view of bringing the scattered sciences into closer mutual relations. The central purpose is the unification of knowledge, an effort toward which seems appropriate on an occasion when the nations bring together an exhibit of their arts and industries. An assemblage is therefore to be convened at which leading representatives of theoretical and applied science shall set forth those general principles and fundamental conceptions which connect groups of sciences, review the historical development of special sciences, show their mutual relations and discuss their present problems.

The speakers to treat the various themes are selected in advance from the European and American continents. The discussions will be arranged on the following general plan:

After the opening of the congress on Monday afternoon, Sept. 19, will follow, on Tuesday forenoon, addresses on main divisions of science and its applications, the general theme being the unification of each of the fields treated. These will be followed by two addresses on each of the twenty-four great departments of knowledge. The theme of one address in each case will be the "Fundamental Conceptions and Methods," while the other will set forth the progress during the last century. The preceding addresses will be delivered by Americans, making the work of

the first two days the contribution of American scholars.

On the third day, with the opening of the sections, the international work will begin. About one hundred and twenty-eight sectional meetings will be held on the four remaining days of the Congress, at each of which two papers will be read, the theme of one being suggested by the relations of the special branch treated to other branches; the other by its present problems. Three hours will be devoted to each sectional meeting, thus enabling each hearer to attend eight such meetings, if he so desires. The program is so arranged that related subjects will be treated, as far as possible, at different times. The length of the principal addresses being limited to forty-five minutes each, there will remain at least one hour for five or six brief communications to each section. The addresses in each department will be collected and published in a special volume.

The officers of the congress are: President, Simon Newcomb of Washington; Vice-Presidents, Hugo Muensterberg, Professor of Psychology in Harvard University, and Albion W. Small, Professor of Sociology in Chicago University.

The subjects to be considered are classified under divisions from A to G inclusive; these divisions are subdivided into 24 departments, and each of these departments is again subdivided into sections, of which it is planned to have about 128.

Department 17 devoted to medicine is the first subdivision under division E, that of Utilitarian Sciences. This department of medicine is divided into 12 sections: (*a*) Public Health. (*b*) Preventive Medicine, (*c*) Pathology, (*d*) Therapeutics and Pharmacology, (*e*) Internal Medicine, (*f*) Neurology, (*g*) Psychiatry, (*h*) Surgery, (*i*) Gynecology, (*j*) Ophthalmology, (*k*) Otology and Laryngology, (*l*) Pediatrics.

The officers of the department of medicine are as follows: Chairman, Dr. William Osler; speakers, Drs. William T. Councilman and Frank Billings; section (*a*) Chairman, Surg.-Gen. Walter Wyman, U. S. Marine Hospital, speakers, Prof. William T. Sedgwick and Dr. Ernst J. Lederle; (*b*) Chairman, Dr. Joseph M. Mathews, speakers, Profs. Ronald Ross, F.R.S., Liverpool, and Angelo Celli, Rome; (*c*) Chairman, Prof. Simon Flexner, speakers, Prof. Felix Marchand, Leipzig, and Johannes Orth, Berlin; (*d*) Chairman, Dr. Hobart A. Hare, speakers, Sir Lauder Brunton, F.R.S., London, and Prof. Mathias E. O. Liebreich, Berlin; (*e*) Chairman, Prof. Frederick C. Shattuck, speakers, Prof. Clifford Allbutt, F.R.S., Cambridge, and William S. Thayer; (*i*) Chairman, Prof. Lewellys F. Barker, speakers, Profs. Shibasaburo Kitasato, Tokio, and James J. Putnam; (*g*) Chairman, Dr. Edward Cowles, speakers, Prof. Th. Ziehen, Berlin, and Dr. Charles L. Dana; (*h*) Chairman, Prof. Carl Beck, speaker, Prof. Nicholas Senn; (*i*) Chairman, Prof. Howard A. Kelly, speakers, Dr. L. Gustave Richelot, Paris, and Prof. John C. Webster; (*j*) Chairman, Dr. George C. Harlan, speaker, Dr. Edward Jackson; (*k*) Chairman, Prof. William C. Glasgow, speakers, Sir Felix Semon, C.V.O., London, and Dr. J. Solis-Cohen; (*l*) Chairman, Prof. Thomas M. Rotch, speakers, Profs. Theodore Escherich, Vienna, and Abraham Jacobi.

The hope is expressed that the names of the speakers and chairmen to be found in this announcement will form a nucleus for bringing together thousands of other interested scholars who sympathize with the efforts to bring unity into the world of knowledge.

THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

The first volume of the "Studies from the Rockefeller Institute for Medical Research" has recently appeared in the form of reprints bound in a common volume. It will be remembered that the Rockefeller Institute for Medical Research was founded in 1901 for the purpose of stimulating original research. During the earlier period of its existence, while the organization was being perfected, it was determined to employ such funds as were available in aiding research already begun and encouraging new investigations. The actual result of the plan is shown by these papers now gathered together into a pamphlet of considerable size. In all, twenty-seven researches are published on a variety of subjects of scientific interest. Among others the names of Herter, A. C. Abbott, Preston Kyes, Meltzer and Theobald Smith appear as contributors. We have no desire to question the wisdom of publication in this form. It would, however, appear on the surface desirable to produce such communications in uniform type and paper, which naturally is not possible under the present mode of publication. The papers themselves are certainly worthy of a somewhat more dignified form than they have been given in this volume.

MEDICAL NOTES.

Meeting of the American Medical Association. — The meeting of the American Medical Association, recently held at Atlantic City, has been one of the most successful in its history. The new plan of organization has had the expected effect of bringing order out of what

threatened at times to be chaos, and thereby has led to better accomplishment than ever before. Registration was unusually large and attendance at meetings excellent. For obvious reasons Atlantic City has again proved itself a highly suitable place of meeting.

HYDROPHOBIA IN CHICAGO. — A recent bulletin of the Chicago health department states that a considerable number of cases of hydrophobia have recently occurred in the city. It is urged that attention should be given to the matter and that all dogs should be muzzled, for the safety of the public as well as of the dogs themselves.

LEPROSY. — In the report on leprosy in New South Wales for the year 1902, just published, it is stated that distribution of leprosy under nationalities is as follows: Natives of New South Wales, 21, of whom 15 have died and 2 were released; of Queensland, 1, deceased; of England, 4, of whom 3 have died; of Ireland, 2, deceased; of New Zealand, 1, deceased; of Fiji, 1, deceased; of Germany, 2, of whom 1 has died; of Belgium, 1, deceased; of the United States of America, 1; and all of these were whites, of European descent. There were also 37 natives of China, of whom 13 have died, and 21 have been returned to their own country; of India, 2, deceased; of the West Indies, 1, discharged in 1885; of Java, 1; of Tanna (New Hebrides), 1, deceased; of New Caledonia, 1, deceased; of Aoba (New Hebrides), 1, returned to his island; and all of these were colored people.

FOURTH PAN-AMERICAN MEDICAL CONGRESS.— The next meeting of the Pan-American Congress will be held in Panama the latter part of December.

The Pan-American Congress meets every three years. It was started by Dr. William Pepper of Philadelphia, Dr. C. A. L. Reed of Cincinnati, Dr. Albert Van der Veer of Albany, and Dr. H. L. E. Johnson of Washington. The first meeting was held in Washington in September, 1893, the second in Mexico in 1896. The third was to have been held in Venezuela in 1899, but was given up on account of the war in that country. The place of meeting was changed to Cuba, but had to be postponed until 1901 on account of the fever there.

These meetings have always been well attended and it is thought that Panama will be an interesting place for the convention.

Further particulars will be given from time to time, together with notifications of the different officers appointed to represent this and other countries.

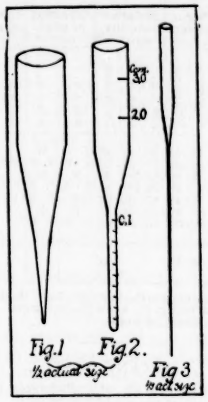
BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 15, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 52, scarlatina 9, typhoid fever 4, measles 72, smallpox 0.

Correspondence.

DIE BEDEUTUNG DER LUMBALPUNKTION FUR DIE PSYCHIATRIE, VON PROF. NISSL (HEIDELBERG).

PROVIDENCE, R. I., JUNE 5, 1904.



MR. EDITOR: Under the above title there appears in the April number of the *Centralblatt fur Nervenheilkunde und Psychiatrie* an unusually timely and important article which deserves a full review.

The *technique* of the puncture as performed by Nissl varies in no radical way from that already described in many recent publications and commonly used wherever this procedure is adopted. The *examination of the fluid* includes cytological, bacterial, physical and chemical analysis, and the pressure under which the flow appears is also of significance. Nissl has not as yet carried on bacteriological investigation. Independently of the cellular constituents the *physical appearance* of the fluid is of interest. In one case of tubercular meningitis, although the red cells were not abnormally increased in number, the fluid had a decidedly yellowish tinge. In one case of purulent meningitis abundant fibrin appeared. As to the *pressure*, the author does not doubt that there is a significance, but he is not sure of our ability correctly to interpret it. Slight changes in manipulation alter the character of the flow, and he has not in his own cases used instruments of precision for determining the exact pressure.

The *chemical experiments* dealt entirely with the albumin group, sugar and other substances being disregarded. *Guillain's and Parant's* test with concentrated magnesium sulphate solution was used in the first fifty-eight punctures. In these, without exception, the fluid remained, after the addition of the sulphate, as clear as water. But when the mixture was boiled the filtrate from the fluid of seventeen cases of paresis, included in the above number, assumed, without exception, a more or less positive opalescence, or even turbidity. With the exception of the cases of meningitis and two cases of syphilis the reaction in the remaining cases was negative. Attention is called, however, to the fact that the reaction after boiling the filtrate with magnesium sulphate is often a light one, and it is difficult to say whether the fluid is clear or somewhat opalescent. After conferring with Professor Cohnheim, concentrated ammonium sulphate was substituted for the magnesium sulphate in all following punctures. The fluid was mixed with ammonium sulphate solution in equal parts. Globulin was separated while the solution was cold, and the filtrate acidulated with acetic acid was boiled. This method proved to be much more convenient. With this test coagulable albumin is found in normal cerebrospinal fluid. But in one hundred and fifty-eight tests only four times was there an unquestionable opalescence after the ammonium sulphate was added in the cold, and these four cases all belonged to general paresis. But in other cases of paresis the solution remained clear before boiling. In most cases of paresis the clouding is so considerable after boiling that there is no doubt as to the pathological increase of the albumin group.

To estimate the total quantity of albumin the following simple method was followed: A glass vessel of something over 3 cm. capacity was used which narrows down gradually to a tube closed at the end and divided into 0.01 ccm. There are ten divisions on the scale. The divisions are sufficiently separate so that fractions can be easily estimated. Fig. 2 represents such a vessel. Two cubic centimeters of centrifuged fluid is placed in this vessel

with the pipette; then 1 ccm. of Esbach's reagent is added and the air is driven out of the tube by means of a fine glass thread. The fluid is then centrifuged for an hour.

The amount of albumin is then easily read off. The method is not claimed to be exact, but, according to Cohnheim, is sufficiently so for practical purposes. The method was used in 90 punctures. An amount of albumin of less than two divisions was considered as within the normal limits. In normal cases it was generally found to be below the second division, but in no normal case below the first. The results were as follows:

The clinically clear cases of general paresis, 4.2, 4.2, 3.8, 4.2, 4.5, 3.5, 8.0, 3.9, 4.0, 4.0, 3.6, 5.0, 3.5, 4.0, 3.8, 3.8, 6.0, 3.2, 4.0; arterial-sclerotic dementia, 4.0; senile dementia, 1.5, 1.2, 1.2; epilepsy, 1.5, 1.0; manic-depressive insanity, 1.5, 1.5, 2.2, 1.2; traumatic hysteria, 1.5; melancholia, 1.8; aphasia (apoplexy), 3.0; choreic insanity, 1.5; imbecility, 3.1, 2.0, 1.0; dementia precox group, 1.4, 1.9, 3.2, 2.0, 1.6, 1.5, 1.3, 1.5, 1.5, 1.2, 1.2, 1.6, 1.9, 1.2, 1.8, 2.2, 1.5, 2.5, 1.2, 1.8, 3.5, 1.6, 1.5, 1.8, 2.0, 2.8, 3.0, 2.0, 2.5, 2.2, 1.8, 3.0, 2.0, 2.0; cases clinically not clear, 2.6, 2.8, 5.2, 2.2 and 1.9, 3.0 and 3.0, 7.0 and 9.0, 2.1. Groups of so-called functional psychoses with negative cytological findings, 1.5, 1.6, 2.8, 1.6. With positive cytological findings, 1.8, 1.3. Normal individuals, 1.8.

While the amount of albumin is undoubtedly of diagnostic value, it is to be noted that the cytological analysis and that of the albumin did not always run parallel. Frequently, strong increase of albumin occurred with negative cytological findings, while a normal percentage of albumin was only once found with positive cytological findings with numerous cellular elements. From a diagnostic standpoint the *cytological examination* is considered by Nissl to be the most important. In this matter it is of greatest importance that a definite technique should be followed so that the results of various investigators may be correlated.

The technique followed by other authorities is described, and certain apparently just criticism is made to which the author adds that, while it is easy to criticise it is difficult to formulate a better technique. Ravaut distinguishes: (1) The large reaction when 20–150 and more cellular elements lie in a single oil immersion visual field. (2) Medium reaction with 7–20 lymphocytes. (3) Appreciable reaction ("*Réaction discrète*") with 4–6 leucocytes, and (4) negative reaction when only 2 or 3, or 0 lymphocytes, are seen in each field. Nissl is dissatisfied with this division, inasmuch as the sources of error in technique may invalidate the "*Réaction discrète*." Practical distinctions are: One positive finding with very numerous cellular elements (as in most cases of paresis), another such with a few, but certainly increased, number of cells, a negative finding with perhaps more than the normal number of elements and, finally, the completely negative finding.

The glasses for the reception of the fluid are made by the author himself. (See Fig. 1.) Each glass is used but once, likewise the pipette is made by him and used but once. The water power centrifuge is used for three quarters of an hour. The centrifuged fluid is then carefully poured into a clean reagent glass and is used for chemical analysis. The glass from which the fluid is poured should not again be placed in the upright position. The welded end of the capillary tube is now broken off squarely and smoothly. When all of the fluid is drained from the glass the capillary tube is thrust down to the very bottom of the tubular portion of the glass without touching the wall. It sucks up for itself the minute particles at the bottom, and the contents of the pipette are then again carefully blown back into the glass so as to bring about as good as possible a mixture of the elements. This is to be so manipulated that the instant the blowing out ceases the sediment will be of itself again sucked up. If all has been correctly performed the sucked-up column of fluid should measure but 2½–3 cm. Now the contents of the pipette are gradually expelled upon three object slides in such a way that on each one is a regular, sharply outlined drop of about 2 mm. in diameter. Squirting of the fluid from the pipette should be carefully avoided. The drop is dried in the air. The slide submerged in alcohol and ether in equal parts for one half hour. Specimen can be stained as desired. If Unna's polychromatic methyl blue is used, a drop of the color is allowed to stand for ten minutes over the specimen which is then rinsed with water, subjected to alcohol, carbol-xylol, xylol, balsam, and finally covered with a cover slide. The specimen is first examined with a low power lens (Zeiss A) and the field controlled with oil immersion.

Nissl made 218 punctures on 166 individuals. The reader must be referred to the original article for a detailed description of the findings, which are there fully discussed and clearly tabulated. At the top of the tabulated results, however, appear the figures for paresis, and these may be given. Out of sixty punctures on twenty-eight clinically pure cases of paresis very numerous mononuclear cells were found fifty-six times, a few mononuclear cells found in two cases, numerous polynuclear leucocytes in one case, and an absolutely negative result in one case. In this negative case twenty days after the puncture a second puncture gave a definite positive result though with fewer lymphocytes than in most cases of paresis.

The number of recognizable cellular elements varies from time to time even in the fluid from paretics, and therefore in any case in which paresis is thought of and the first puncture is negative, it should be repeated a second and third time after long intervals. For the differential diagnosis between paresis and other diseases, (*e. g.*, in the doubt which frequently arises between paresis and certain forms of chronic alcoholism), the reader must be referred to the text where this question is fully discussed.

Histories of twenty-three cases are given in the text in which the punctures presented unusual interest because of peculiar clinical symptoms, or combinations of symptoms, or of difficulties in the way of a sure clinical diagnosis.

The author considers at some length the conclusions which we are warranted in drawing from the results of our punctures in our present state of knowledge of the pathological conditions underlying the various diseases in which the operation finds application. He summarizes with fair minded caution the whole present status of puncture and its relations to psychiatry and makes many valuable suggestions as to procedures by which we may enlarge the diagnostic value of lumbar puncture especially by histopathological analysis of meninges, choroid plexus, etc., in connection with experiments on living animals and subsequent histological examination. He brings up also several questions as to the medico-legal relations of lumbar puncture and the ethical rules involved.

The importance to the whole world of such an article by such an author as Nissl warrants this lengthy though not exhaustive review, and if space were afforded the reviewer would gladly have translated literally the whole of this unusually interesting and complete contribution.

WM. MCDONALD, JR.

RECORD OF MORTALITY
FOR THE WEEK ENDING SATURDAY, JUNE 4, 1904.

Deaths reported, 3,052; under five years of age, 803; principal infectious diseases (smallpox, measles, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 838; acute lung diseases 380, consumption 413, scarlet fever 39, whooping cough 9, cerebrospinal meningitis 73, smallpox 6, erysipelas 10, puerperal fever 9, measles 31, typhoid fever 56, diarrheal diseases 116, diphtheria and croup 75.

From whooping cough, New York 7, Philadelphia 1, Pittsburg 1. From smallpox, Philadelphia 5, Baltimore 1. From cerebrospinal meningitis, New York 63, Baltimore 1, Pittsburg 3, Boston 2, Cambridge, Brockton, Haverhill and Chelsea 1 each. From typhoid fever, New York 6, Chicago 8, Philadelphia 19, Baltimore 6, Pittsburg 14, Lowell 1, New Bedford 2.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending May 21, the death-rate was 15.5. Deaths reported 4,532; acute diseases of the respiratory organs (London) 105, whooping cough 182, diphtheria 45, measles 182, smallpox 4, scarlet fever 30.

The death-rate ranged from 6.9 in Northampton to 21.7 in Norwich, also in Birmingham; London 15.1, West Ham 13.2, Brighton 17.8, Southampton 14.4, Plymouth 10.1, Bristol 13.1, Leicester 11.9, Nottingham 14.5, Birkenhead 16.3, Liverpool 18.4, Bolton 17.5, Manchester 19.6, Salford 16.2, Bradford 17.2, Leeds 20.0, Hull 15.2, Sheffield 15.4, Cardiff 14.2, Rhondda 12.4, Wigan 12.5, Merthyr Tydfil 14.3, Smethwick 11.2, Warrington 17.8.

METEOROLOGICAL RECORD.

For the week ending June 4, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

RECENT DEATHS.

F. SAVARY PEARCE, M.D., of Philadelphia, died in Steubenville, Ohio, May 27, at the age of thirty-seven. He was graduated from the University of Pennsylvania in 1891, and had in late years become identified with neurology in Philadelphia. At the time of his death he was professor in this subject at the Medico-Chirurgical College. He was an ardent student of his chosen subject and had published many papers. This year he was to have been chairman of the section of nervous and mental diseases of the American Medical Association. He was a member of many medical societies and was in general regarded as one of the promising men in the department of neurology.

GEORGE WASHINGTON BROOKS, M.D., of New York died from cerebral apoplexy on June 4, at the age of eighty-seven years. He was graduated from the medical department of the University of the City of New York in 1850, and at one time had among his patients some of the most noted residents of New York. He retired from practice some years ago, and had several attacks of apoplexy before the one which proved fatal. Dr. Brooks' brothers, James and Erastus Brooks, were for many years the editors of the old New York *Express*, and prominent in literary and political circles. He is survived by a widow and one son, Dr. George Frederick Brooks of New York.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING JUNE 11, 1904.

GUTHRIE, J. A., past assistant surgeon. Detached from the "Franklin" and granted leave for three months.

HART, G. G., acting assistant surgeon. Detached from duty with recruiting party No. 5, and ordered home and to wait orders, from June 4.

SELLERS, F. E., acting assistant surgeon. Ordered to the "Franklin."

FAUNTLEROY, A. M., assistant surgeon. Ordered to the "Lancaster," June 22.

ANGWIN, W. A., assistant surgeon. Appointed assistant surgeon with rank of lieutenant, junior grade, from June 2, 1904.

ROSS, J. W., medical director. Detached from the Naval Museum of Hygiene and Medical School, Wash., D.C., and ordered to duty with the Isthmian Canal Commission.

MUNSON, F. M., assistant surgeon. Detached from the naval station, Polloc, P. I., and ordered to the naval station, Olongopo, P. I.

KITE, I. W., surgeon. Orders detaching from the "Maine" revoked; ordered to continue duty on the "Maine."

SMITH, C. G., assistant surgeon. Ordered to the naval hospital, Mare Island, Cal., June 28.

ABEKIN, F. G., assistant surgeon. Detached from the naval station, San Francisco, Cal., and ordered to the "Adams."

NELSON, H. T., jr., acting assistant surgeon. Detached from the naval hospital, Sitka, Alaska, and ordered home and to wait orders.

MILLER, J. T., acting assistant surgeon. Detached from the naval hospital, Mare Island, Cal., and ordered to the naval hospital, Sitka, Alaska.

Addresses.

SOME FERMENTATIONS IN MEDICAL EDUCATION.*

BY HAROLD C. ERNST, A.M., M.D.,

Professor of Bacteriology in the Harvard Medical School.

In looking up the history of the office I am honored in attempting to fill to-day, certain points of interest have been brought to my attention.

In 1804, Dr. Isaac Rand delivered the first annual address — on Phthisis Pulmonalis, and the use of the warm bath — and with six exceptions (1814, 1815, 1819, 1825, 1831, 1832) the practice has been continued annually, until to-day it enters upon the second century of its existence.

The subjects considered in this long line of addresses cover, as might be supposed, a wide range, and it is interesting to note a gradual change that has occurred. About 20% (19 out of 95) have been upon what may be called "specific" lines of thought — such as the first one (mentioned above) or those of Abraham Haskell (1812) on Cynanche Trachealis, Walter Channing (1833) on Irritable Uterus, or Horatio Adams (1858), Investigations upon the Subject of Vaccination. Such specific subjects were, however, very largely treated more than fifty years ago (17 out of 19), and in the last half century the speakers upon this occasion have usually considered matters of general interest to the profession in a long series of entertaining essays.

Evidently, the matter of education has been much in the minds of medical men, for nearly half of the addresses during this latter period have had this for the major or a prominent minor theme. Indeed, it was first treated specifically in 1822 by Dr. John G. Coffin, on Medical Education and on the Medical Profession, but the somewhat marked increase of attention given to it of late years shows how actively the specific fermentations of advanced thought have been producing changes and by-products with which we shall have to deal. The men who have brought these matters before the society command attention by the honorable position they have held in the ranks of the profession, and the list includes many of the names most familiar to us of to-day as being among the leaders of medical thought in the past.

It has been, therefore, with many misgivings that I have endeavored to prepare myself to say something that has not been said and better said before. Without thought that this is possible, it may be well to consider some of the changes — fermentations — going on in medicine, now, as in all previous stages of its history; to see what elements of good have come, and perhaps to forecast some of what may be hoped for when the end results are reached.

One of the most impressive incidents in a recent trip abroad occurred in Paris upon the occasion of a visit to the Institute Pasteur. The spirit of the place is present everywhere — the spirit of earnest search for some addition to human knowledge, for some alleviation of human suffering inculcated in all his pupils by the master mind of the founder. This is not the place for a eulogy of Pasteur, but no man has a nobler monument than this busy hive of industry surrounding his quiet resting-place. Here are workshops where efforts are made to solve some of the problems of disease, by men whose lives are given to the work, and whose hopes do not go beyond that of some success to crown their efforts. These workshops are perfect of their kind, and the tools they hold are handled by a force of men unsurpassed in training, ability and enthusiasm. Besides these investigators, endeavoring to open out new lines of knowledge that shall benefit humanity, others are constantly employed in making use of those already known and in applying the results of past labors to present suffering. One may see there, any day and all day, men of world-wide reputation, each imbued with that spirit of which there is an all too small allowance in existence — the true spirit of scientific research, the desire for the enlightenment of the human race. There can be no other motive that compels this constant devotion to their life work. The pecuniary reward is such that a statement of it is always met with wonder and incredulity. And yet these men are content with what their life offers them — work on day after day and will continue until the time that work is no longer possible. To one knowing these facts and how slight the reward may be, the sight of this busy place is a stimulation not easily forgotten or set aside.

I do not mean that here only is such self-sacrificing devotion to be found; far from it. The impressiveness of the place is due to the thought of how much good to humanity has come and may be expected to come from the workers that have been or are now there. Similar instances of individual devotion to duty in this direction may be found the world over, but, as I believe, no instance of so much accomplished and so much attempted in the same place. The spirit of commercialism is absolutely absent; the fraternity of research for advancing human welfare is the goal to which their efforts tend; money rewards that sometimes come — as the Nobel prize to one of them — are devoted to the common aim, as by Pasteur himself, and no thought of personal aggrandizement comes to any who gain admittance to this brotherhood.

Such a condition of things leads a thoughtful mind to the consideration of how it could have come about — what underlying force could have produced such a band of devotees to a cult that has no attraction for the practical man, and indeed is beyond his comprehension. Still further thought comes, How can such a spirit be bred and cherished among us here; what is our duty and responsibility in the matter? The

* The Annual Address before the Massachusetts Medical Society, June 8, 1904.

impelling force in this instance is undoubtedly that of Pasteur himself — a man distinguished always for his simplicity of life, devotion to duty, and elevation of ideals. As may be read in the story of his life, his career was precisely that of the fermentations he studied; marked by ceaseless activity, the constant production of fresh adjustment of ideas, much uncertainty and doubt, some useless by-products, and an end result of good of lasting and widespread influence over all with whom it came in contact. Courteous in controversy, patient and persistent under failure, generous in praise to others, modest when success was reached, the influence of such a man could not help but be profound upon those it reached at all. It was profound, and to-day it governs the work carried on in his institute and by his pupils.

The racial influence is of course behind it all. The French spirit of scientific investigation in general, in its highest form, is of the same character; this is but an instance made conspicuous by a man of great ability.

That spirit, then, is the basis of the work here spoken of — simplicity, altruism, devotion to the truth. What can we do to develop and cherish it with us?

There is rising, not far from the place we now occupy, a group of buildings that, when completed, will form a noble addition to the beauties of the city. They are the result of many forces, notably of the far-sightedness and enthusiasm of two men, this aided and supported by many others, whose generous contributions have made the result possible. The conception of such a plant was so daring that the first attempts to convince others were discouraged and even now are not infrequently heard with skepticism. The time for such a move had come, however, and the men were at hand to carry it out. Now that their labors are approaching completion it is full time to consider what shall be done in those buildings when completed, and how the great trust shall be administered.

In his last address to the students of the Harvard Medical School, Oliver Wendell Holmes said this: " Leyden, Edinburgh, Paris, were each in turn the Mecca of medical students, just as to-day Vienna and Berlin are the centers where our young men crowd for instruction. These, also, must sooner or later yield their precedence and pass the torch they hold to other hands. Where shall it next flame at the head of the long procession? Shall it find its old place on the shores of the Gulf of Salerno, or shall it mingle its rays with the northern aurora up among the fjords of Norway — or shall it be borne across the Atlantic and reach the banks of the Charles, where Agassiz and Wyman have taught, where Hagan still teaches, glowing like his own *lampyris splendidula* with enthusiasm, where the first of American botanists and the ablest of American surgeons are still counted in the roll of honor of our great university? " [1]

[1] O. W. Holmes, Some of my Early Teachers. Medical Essays. Ed. 1888. p. 438. Houghton, Mifflin & Co.

So far as buildings and facilities are concerned the query and suggestion made twenty odd years ago may be answered in the affirmative, the doubt that remains is the capacity of the successors of the great names mentioned to fully utilize and develop the trust placed in their hands.

The changes that have occurred in the Harvard Medical School within the last generation have been very great; I pointed this out as follows in another place: In the early seventies the Faculty of the school took the step of grading the course of study and requiring students to pass from one subject to another in logical sequence and after examination; a step that was taken with many forebodings, and that resulted in a tremendous pecuniary loss to the school (by cutting off the number of students), but that was so necessary that the struggle to carry it through cannot be realized to-day. In the early eighties the school moved into its present building, and it was then thought that many years would pass before its needs could even occupy the space then had. On the contrary — even with the help of the Sears addition — the most effective work for the students has been hampered for some time past, and some of the departments are and have been crowded to the extent of often being obliged to refuse special students. In 1896 the Faculty decided to raise the standard of admission to the school by the requirement of a degree in arts, letters or science — with some special exceptions — and this regulation went into effect in 1901. It had been looked forward to with much trepidation by many of the teaching force, and with lively fears that the school would lose so many scholars that it would be pecuniarily crippled (as has since occurred). It cannot be doubted, however, that if this unfortunate result should temporarily continue, the friends of the school will support it through any such trying period, as generously as has always been the case. That this is practically certain, is shown by the encouragement to the efforts making to bring about the greatest advance that the school has ever thought of — a scheme for securing its future for generations to come, together with the establishment of what will be, if it can be carried through, the most perfect university of medical science that the world has yet seen. A place where students of medicine in all its branches may come to find an equipment perfectly adapted to their needs, and teachers prepared to foster and encourage research in all its directions for the demonstration of new truths, as well as to give instruction in all branches of present medical knowledge.[2] How this may best be done in any case is matter for much careful thought, and the solution of the problem is to be sought in two different directions.

If a student is to take the best advantage of what is offered to him, he must have an opportunity for the proper care of his body, and the

[2] Adapted from Progress of Medicine, 1850–1900. H. C. Ernst, May 8, 1900.

better the facilities for study that can be given the more likely is the best that is in him to be developed.

Now the right of community life, claimed by all companies of scholars, has been denied to students of medicine in recent generations and in this country. It is but recently that we have begun to look upon the medical school as anything but a trade enterprise — on the part of the teachers as a means for filling their pockets; on the part of the students as a place where they may be taught how to earn a living. The conception of a medical school as in any sense a part of a university, or a place where university study should be carried on and encouraged, is a product of those recent fermentations of which I have already spoken, and has but recently begun to develop in such form as makes it possible to realize it. Directly connected with this thought, and growing from it, is the need for offering such opportunities for a scholar's life as will make the hall-bedroom in a cheap lodging-house a thing of the past, and add to the dignity of student life in medicine what it now lacks — the charm of collective living with a common purpose. The first need, therefore, for the student life of the future university medical department is dormitories, in which the students, attracted by the courses offered or the reputation of the teachers to be heard, may learn to know each other and have easy opportunity for fostering the high ideals and learning early the noble purposes of their life's work.

Nothing can possibly take the place of this community of living in effective development of these ends, and the mantle of the alma mater should be spread over all her sons in embryo — even if not in esse. The refusal of the right to vote for overseers except to graduates of the academic departments is an instance in point.

Even if a student be comfortably housed, he must be fed as well, and as great an obligation rests upon the governing body in this as in the preceding direction. There is no more impressive feeling that a visitor experiences in Oxford or Cambridge than during a visit to the dining-halls of the colleges, each with its customs, its traditions, its portraits and its furniture, bearing a message of loving service to all who care to hear. Why, then, should the students of any university department be left to the mercies of the common eating-house, with never a reminder that life has a more cheering face than faded walls and spattered linen at each renewal of its strength?

How much this question of feeding means, apart from its esthetic side, is indicated in these words of the head of Harvard University — speaking recently at Springfield: "There was another question presented to the corporation that affects another very useful thing in Harvard College, that affects the dining-hall — the dining-hall association. I suppose you realize the fact that it would have been impossible to build up the present university at Cambridge if the corporation had not paid careful attention thirty years ago to the mode of feeding the students at Cambridge in a wholesome and cheap way. I believe that to be the absolute and literal fact."[3]

Here, then, is the practical side of this need emphasized and clearly stated as the result of thirty years' experience. The words mean the simple fact that good fuel must be provided to secure the best results from man's vital engines as for any other mechanism. But in addition to this there should be the influence exerted by comfortable surroundings, made as beautiful and dignified as may be by architectural effect and mural decoration.[4]

A university medical school is as compact a unit as a college of Oxford or Cambridge; its students may be welded into as close a body, very largely by such an influence as this. If thus brought together in study and in play, the influence of the strong will be more strongly felt and the weaknesses that might grow will at least be much less active in that growth.

Further, distinct provision for the mental nourishment of the medical student of to-day should be made. Time has been, when a scalpel or two, a bone and book or two, were all sufficient for his needs. This is no longer true, and the best of textbooks, all of them, the best of journals, all of them, should be in easy reach at convenient hours and in a comfortable home. The Harvard Union, the latest monument of a great citizen's generous love and interest in the young, an enduring influence for good in the community in which it stands, might well be the model which, with proper adaptation to the special needs, would serve the purpose well. Provision for these needs is a duty that cannot be ignored, even if present conditions prevent its immediate fulfillment.

Further than this, too, there should be some care for the student when sick, and help of this sort is to be much more easily given if the student body be closely brought together, than if, as is too often now the case, it be widely scattered and neglected. Recent experience has demonstrated the need of such care as is here meant — that there should be some man or body of men, whose aid might be sought in any difficulty concerning health, and by whom applications would be received with sympathy and attended to with promptness. After such an agency has been once established, its success would depend upon the degree of efficiency with which its duties might be fulfilled. It cannot be doubted that if well done it would prove an ever increasing source of aid and comfort to students standing in need of its services.

This then is the amount and kind of attention that should be paid to the care of the students of the medical department of a university. They should be made to feel that they are a part of a company of scholars — not individuals merely seeking for a means of livelihood. In the particular case used for an example, necessity has compelled the teaching force in medicine to be

[3] Pres. Charles W. Eliot. Speech to Connecticut Valley Harvard Club, March 16, 1904. The Harvard Bulletin, March 30, 1904.

[4] See also Report of Committee of the Board of Overseers of Harvard College to visit the Medical School, 1904, emphasizing the importance of this matter.

widely separated from the rest of the university. This, from many points of view, is most unfortunate, especially because it requires the establishment of complete institutions of the kind spoken of — dormitories, dining-hall, reading and assembly-rooms — separate and distinct from those already in existence for the service of the larger body of students. The complete isolation of this part of the university body makes it all the more imperative that its installation should be complete.

A far more complex problem — even for paper consideration — than that just discussed, in the development of university education in medicine, is as to what shall be taught and how? Minute details it is not intended to enter upon here, but there are general considerations that are of vital importance.

As wise and perfect a course as can be devised should be placed in operation leading to the best training for the practice of medicine. Inasmuch as present usage in this country requires that the practitioner of medicine should hold a doctor's degree it would be impossible to confer a lower with satisfaction to the main body of students, even though it be true that such doctor's degree does not confer the right to practice. It may be hoped that eventually the value of the discarded Bachelor of Medicine may revive, and that a more perfect scheme of university education in medical science may be worked out than is now possible. It should be practicable to lay out a course qualifying the student for the practice of medicine, that would not require, as is now the case in many institutions, the preliminary education represented by the bachelor's degree in arts. As conditions are, this is impossible, and the best schools of to-day are graduate schools in the sense of requiring a preliminary degree — with some exceptions — in arts, letters, philosophy, or science, of those who desire to enter upon the study of medicine.

The degree of Doctor of Medicine should, however, be looked upon, when conferred by this better class of institution — certainly when they are parts or departments of universities — as indicating that the holder has been trained upon broader lines than those qualifying simply for the practice of medicine. One method by which this end has been sought, is by the offering of electives — at present only in the later years of the course — by a selection from which a student may prepare himself for a career in the more purely biological branches. This is not a perfect solution of the problem, for just as long as all practitioners of medicine in this country feel the need for holding the degree of Doctor of Medicine, just so long will it be impossible to give that degree the same standing as a representative of general culture as is now held by the degrees of Doctor of Philosophy or Doctor of Science, which it should do from the university point of view.

The advance of knowledge in branches of biological science connected with a medical school, and the development of laboratories and research work connected with them, brings out a new point of view. It makes it possible to look at them as channels through which a way may be constructed leading to other university degrees. The paths leading to these degrees to run side by side with that to the doctorate of medicine on the one hand, and with those laid out by other departments of the university on the other.

So that the future complete medical department of a university must look forward to a variety of functions and must provide for a variety of degrees, suited to the various sorts of students that will, or should be, attracted by its teaching. It *must* be something more than a simple medical school, offering instruction only to those intending to practice medicine. It must do this, of course, and in the best possible way, making arrangements for instruction in the laboratory branches sufficient for the needs of the well-educated practitioner and supplementing this laboratory instruction with such a profusion of clinical work that the student pursuing the course will be well fitted, upon its completion, for the responsibilities that may soon be placed upon him.

Inasmuch as the best university schools now require the lower degree for admission, it has been argued that their function should cease here, so far as degree giving is concerned, since in one sense they are, as has been said, graduate schools already, and that they should confine their energies solely to courses leading to the degree of Doctor of Medicine and to research. It is, however, but a narrow conception of the importance of many of the fundamental branches of medical science, or of those closely allied to them, that would limit their functions in this way. It is not so very long ago that anatomy, physiology and pathology were all taught by the same person; as well return to this practice, as to claim that the departments now controlling these subjects do not expand further than what is needed by the medical practitioner.

Since their subdivision, other subjects have assumed essential importance; histology, embryology, physiological chemistry, bacteriology, comparative pathology, are some of those that have thus grown to importance and to special names. Others are evidently rapidly coming forward, and students may be found in the laboratories devoted to any one of these subjects, who have no intention of becoming practitioners of medicine, and to whom the clinical work prescribed is unnecessary and possibly distasteful. At the same time their desire may be to study these subjects in direct connection with the human race — it is surely of importance that they should do so; and where could such instruction be as well obtained, or where could it be more easily provided, than if built up side by side with the instruction leading directly to medical practice?

The conception is therefore of something to be planted beside and to grow up with the medical

school as commonly understood. And since the complexities of the education of the medical practitioner are so great, the new sort of education should be administered by a separate executive body with a separate head, to which might be given the name of the Graduate School in Medicine; not *of* medicine, for the plan here suggested involves laying out courses leading to other degrees than the Doctorate, open to non-graduates as well as to graduates in medicine. This new administrative board should, of course, be allied with other existing boards in the Faculty of medicine, and thus the university department of medicine would assume the full functions and dignity that belong to it. Included in such a university department then, if the idea were carried out to its full development, there should be courses leading to degrees other than and in addition to that of Doctor of Medicine, and of varying value.

Provision should undoubtedly be made in this country, as is so generally done elsewhere, for persons desiring to enter upon public health work. There are many positions to be filled in the direction thus indicated — positions that do not require the usual training of a practitioner of medicine, but do need a portion of that training, that could well be furnished by a selection from the courses leading to the medical degree, with some additions or amplifications as the need might be demonstrated.

The university department of medicine must be a place of liberal education, as well as a training school for special lines of work. The fact should be recognized that a liberal training in biological science is as possible in connection with man as with the lower animals, and therefore courses should be provided in this department that would be sufficient for the degrees of Master of Arts and of Science, Doctor of Philosophy and of Science.

If the broad conception of the medical department of a university I am endeavoring to emphasize be made clear, it is difficult to believe that objections raised to it will not disappear. The courses suggested for these degrees should be open to all who would be qualified to enter upon them in any other department of the university, not limited to those possessing a degree in medicine. The fact that they should be made up largely of laboratory courses, and must also probably be supplemented by and allied with courses in other departments of the university, would prevent this limitation. They must also, at present, be limited to the laboratory courses, for the reason that clinical teaching is not now available for such purposes; that it may become so in the not distant future is a hope of its best friends. Some of the lines of development by which this hope may perhaps be realized will be indicated later.

The discussion of such a project as is here outlined brings out a confusion of thought that it has been difficult to clear away — the distinction between "graduate instruction" from the university point of view, and "graduate instruction" as usually understood in medical education and illustrated by the many post-graduate schools and polyclinics that have come into existence of recent years.

The first takes as a basis for the word "graduate" the possession of the lowest — the bachelor's degree in Arts, Letters or Science; it means the student who has taken the first step in the company of scholars. It undertakes to provide for him the means for reaching any higher grade that the special facilities of medical science may offer, and to enable him to reach any academic degree that his inclinations and abilities may lead him to desire.

The second takes the meaning of the word "graduate" to be limited to a graduate in medicine, and undertakes to provide for such a graduate longer or shorter courses suited to his needs, in the clinics or in the laboratories as the case may be; by the very fact of such limitation the opportunities offered are limited in their usefulness.

From the university point of view the first is the most important meaning; from the medical, the second. But unquestionably the university standpoint is the broader; it therefore should be granted its prior claim upon the use of the term "graduate course," and courses in the suggested "Graduate School in Medicine" should include both those leading to degrees other than that in medicine, and those offered for the special benefit of medical practitioners. These latter should be made as full and as varied as the means at hand will permit; they should be extended and repeated so that the medical practitioner should be able at any time to satisfy his need for instruction in any direction. And side by side with them should be offered the more complete, the longer courses, that may from time to time be found worthy to lead to academic distinction other than that represented by a medical degree.

This medical degree, the doctorate, may itself be enhanced in dignity and value if the plain facts of the case should become recognized and the custom of the country be overcome. The revival of the bachelor's degree in medicine would secure this end. This bachelor's degree is the only one that is really necessary to insure a training fitting the student for the ordinary practice of medicine; the licensing boards and their examinations must act favorably to enable him actually to exercise the healing art. The doctor's degree in medicine should represent a higher training than this; but, as has been already pointed out, the century's practice to the contrary seems to make it impossible to reach this end at present.

This condition of public opinion, and indeed of the medical profession itself, is the main reason for an effort being made to satisfy the other demand that makes itself felt — the demand for training in the biological sciences best developed in a medical school but that shall free the student pursuing such training from the, to him, unnecessary and burdensome exercise in clinical medicine.

A further argument in support of a separate

executive board in charge of both kinds of graduate instruction spoken of, is that it would serve to enhance the dignity of what I have called the less important from the university point of view. All the better class of medical schools are busily engaged in developing this form of instruction, and in devising means for attracting this class of students, by offering advantages to the medical practitioner. This medical practitioner is a graduate, and there can be no doubt that it would prove a source of attraction to him that an institution offers him the opportunity to deal with a body concerned with his needs, separate and distinct from the undergraduate medical students. That this is so has been shown by the success of such independent institutions as have devoted themselves to this line of teaching, but whose work would undoubtedly have been strengthened if it had been affiliated with that of medical schools already established. The influence for good and the stimulation exerted would have been reciprocal.

A most important factor in advancing medical teaching of all kinds will be an expansion of the development of specializing in teaching that has already been referred to. It is the universal experience that the best results are to be obtained if an instructor devotes his entire time to his teaching and does not engage in practice. This has come to be recognized as a necessity in many branches — those in particular, that are concerned with laboratory work and laboratory research. The heads of such departments devote their entire time to the development of that department; it would be impossible for its work to be carried on satisfactorily under any other arrangement. The entire staff of all such departments should be under the same obligation, and sufficient living salaries should be offered to satisfy this end. Precisely the same principle should be extended to the clinical branches of instruction, and clinical teachers in the future should be required to give their entire time to the departments in which they may be engaged. They should use their hospital wards and clinics as the laboratory man uses his laboratory, as places of study, teaching, and research, in which the constant presence of the directing head shall serve as an inspiration to the students attracted thither. Most occupants of university chairs do this very thing; there is a constantly growing feeling against the holder of a professorship, and of lesser places as well, doing anything for pecuniary return that may curtail his time for teaching and research. The same principle should apply to clinical teachers in a medical department of a university.

Two objections have been urged against this suggestion. One, that a non-practitioner is not well fitted to teach how to practice; the other, that competent men cannot be found to accept such positions at any salary that the existing universities could afford to pay. The first objection is one due to long established custom and belief, and would disappear as soon as the experiment should be tried. So far as the practice of the healing art is concerned, its methods are now learned and taught in the hospitals, and have been so, ever since the old association of each student with some practitioner was abandoned. No student of the present day learns anything about how his instructor handles patients in private practice, except from what he sees in the wards, unless, as exceptionally occurs, he makes some private visits as a special favor. As a matter of fact, the treatment of patients, the practice of the art of healing, is more perfect to-day in any good hospital than in a home, and the instructor competent to fill the clinical positions here suggested would be a man also entirely competent to teach the necessary details of practice out of the wards, so far as they ever can be taught. The second objection is one that is even less serious than the first. If such positions were created, the dignity of a university chair, with control of hospital wards and of the teaching in the medical subjects covered by the chair, together with leisure and opportunity for study — all this would attract a number of men from whom a selection could be made. There is now no difficulty in finding candidates for the laboratory positions; the difficulty lies not in getting a man, but in making a selection of the best from among those available. The genius is no more common to-day than at any other time, but competent persons for such positions can be found, and that easily, at such salaries as are afforded for other university chairs. If this should prove not to be so, it would prove erroneous the belief that academic freedom, certainty, and dignity offer any advantages as against a possible overflowing purse.

Of course, for such a purpose, the university must have a hospital of its own, or at the least be so affiliated with a hospital managed in sympathy with its aims, that it shall have control of the appointments to the staff.

There are many kinds of hospitals and various functions to be filled by them. As this address is dealing with so many of the fermentations now inducing change in methods and means, it may not be out of place to remind its hearers what some of these functions are. The first and common duty of any hospital, the one that laymen and medical men understand everywhere, is to care for the sick poor. To help this function is at the bottom of the foundation of them all; the desire to help the sick poor is the reason for most of the donations and bequests given to them. This function has existed from the beginning, and that it was understood to be the primary duty of such an institution is indicated by the name itself, that the inmates were "hospes" — guests — and no fixed remuneration was exacted of those who received the benefits. This function will, of course, always remain a prominent one; but a second has been added that is almost as generally recognized to-day; this is the obligation resting upon a hospital to teach, and thus to spread more widely its beneficent influences by giving to others than the attending staff the benefits of the study and experience to be gained

within its walls. It is not many generations ago that no hospital was used for this purpose, and medicine was taught wholly by lectures. It was because the beginning in this use of hospital wards was made at Leyden that the great fame it attained as a center of medical learning was so early reached. And unquestionably it is largely because this function has come to be generally recognized that medical art and teaching have reached the position of dignity they now hold. There is, however, a broader application of this function of teaching that has not yet become widely known, and that must be applied specifically and broadly, as it is in occasional instances, in order that the best advantage of modern methods may be taken in developing and advancing our knowledge of disease. This consists in a union of the forces of the laboratory and of the hospital staff in a more definite and complete way than has yet been accomplished, and would require a unity of purpose and a sinking of individual position and privilege that might be difficult to secure.

There are problems in medicine — and the number increases — that cannot be solved by one man, or even by one department; they must be treated by a collection of the best men of the community having knowledge of the subject, brought together for purposes of consultation and sympathetic investigation. The hospital wards should furnish the material, the laboratories the means for study in this line, the clinicians using their knowledge for the binding together of the observations made. A way in which such collective investigations could be carried on is this, and it may be put in practice by existing hospitals or by new ones: Let the board in control turn its attention to some single problem pressing for solution, the question of typhoid fever, for example; why is it that, after so many advances in knowledge, the apparent mortality from typhoid fever is no less to-day than it was fifty years ago? (R. H. Fitz, Typhoid Fever. Boston M. & S. Journ., 1899.)

Certain wards might be set aside for the collection of cases of typhoid fever, or, in the case of a small hospital, its entire capacity might be devoted to the care of cases of this disease. Let it be understood that for a term of years nothing else would be received. Co-operation with other hospitals would secure sufficient material. The control of the wards should be placed not with a permanent staff, but with a set of specialists selected for their fitness to handle various parts of the problem. All needed laboratory facilities should be added, and then for a period of three, five, or more years, the whole of this complete force should be engaged in the study of the problem set before it. The advantages of such a method of collective study cannot be overestimated. From the point of view of the hospital — especially if small — the reputation and efficiency to be gained by such concentration of effort could not be reached in any other way; the patients would benefit by the attendance of men and the use of methods specialized and perfected to the highest degree; humanity in general would be likely to benefit by improvement in methods, the result of such combined effort and study concentrated upon one problem.

The partial benefits of this are seen in certain diseases in the results of treatment in the South Department of the Boston City Hospital, where known methods are applied by skilled experts to a limited series of diseases. The plan here suggested, however, involves the effort to penetrate unknown paths, and this upon a large scale with a clearly marked map of campaign.

Other problems could be taken up as their importance became apparent, and the attending staff could be changed to suit the requirements. If I have succeeded in making this suggestion at at all clear, I hope it may appeal to my hearers, as it does to me, as giving promise of most fruitful results if carried out.

The final fermentative suggestion I have to make is this: A most important development for freedom of learning will be an extension of agreement among university departments in medicine by which the migration of students may be fostered and encouraged. It will be impossible for any one institution to gather within its walls all the leaders in all branches of medical knowledge. But the best interests of the student — and of medicine — require that the learner should have the opportunity to profit by as much of the best as can be provided for him. This may be accomplished by creating such parallelism in medical teaching in a number of leading institutions that similar years of the course shall be practically equivalent; so that, if a student has completed a year's study in one institution, he shall be competent to continue his work in any one of a number of others. He should be allowed to do this without examination and upon simple certificate. If this could be carried out, it might happen that such a student would attend several different institutions in his course for a medical degree. He would be certain to go to more than one, unless the excellence of instruction in all departments of each should be more nearly equal than it is easy to suppose possible. The stimulation to teachers would not be the least of the benefits that would arise from the adoption of this plan.

I have thus endeavored to present some of the fermentative changes through which the future growth of medicine is to be influenced. I know that the accomplishment of some of the suggestions made is likely to be long delayed. Some of them, on the other hand, are nearing completion, and the prospects for progress, for liberal training, and for thoroughness are nowhere brighter than in medicine to-day.

According to *American Medicine*, M. Guien, agent for culture of the Colonial Society of the Upper Congo, has drawn attention to a native remedy for "sleeping sickness." It is an infusion of the wood called "iboga," which is common in the Gaboon. It is claimed that this infusion acts as a stimulant which counteracts the sleeping sickness.

PREVENTIVE MEDICINE: ITS ACHIEVEMENTS, SCOPE AND POSSIBILITIES.[1]

BY HERMANN M. BIGGS, M.D.,

General Medical Officer, New York City Department of Health; Professor of Therapeutics and Clinical Medicine and Adjunct Professor of Medicine, University and Bellevue Hospital Medical College, New York, N. Y.

THE terms sanitary science, public or state medicine, and preventive medicine have frequently been used as almost synonymous. The latter term, "preventive medicine," however, has sometimes been restricted in its application to the prevention of the infectious diseases. In the broad sense, preventive medicine comprises both general prophylaxis and individual prophylaxis, and applies to all forms of disease, not simply to the infectious diseases. Preventive medicine is an applied science, which deals with the preservation of the health, both of the individual and of the community.

No subject more vitally concerns the welfare of a community than that pertaining to its healthfulness. How the inhabitants live, and how and at what age they die, what is the extent and character of the morbidity occurring among them and what are its causes, are questions of momentous importance. They are essential features in the problem, whose solution will teach men how they may live longer, healthier, and therefore happier lives.

In rural districts the average healthfulness of the inhabitants depends largely on natural conditions, such as elevation, climate, soil, and, to a much less extent, on the artificial conditions produced by the handiwork of man. In densely populated cities, on the contrary, the natural conditions become relatively unimportant features in determining the degree of healthfulness, so much do they become subordinated in many cases to the artificial conditions which have resulted from the lives, labor and occupations of the inhabitants. It may be said with certain limitations that the inhabitants of any city in the temperate zone now have it largely within their power to determine what degree of healthfulness their city shall have. A high morbidity and a high mortality in any urban population depend largely on some remediable features of an unsanitary character, such as the sewerage of the city, the occupations, habitations, food and water supplies, and the habits of the inhabitants — all factors which lie to a great extent within their control. Hence, when any city in modern times has a high annual death-rate, for example, 30–35 per 1,000, as was formerly the case in New York, Liverpool and other cities, instead of a death-rate of 17–18 or 19 per 1,000, as now exists in London, Berlin and New York, it is because conditions are permitted to exist, partly from the neglect, indifference and ignorance of the people, and partly from the lack of proper facilities and necessary efficiency on the part of the authorities.

The achievements of scientific medicine have now placed at the disposal of the sanitary authorities such full knowledge as to the causation of so large a proportion of the diseases producing death, and of the means by which they may be restricted or prevented, that the determination of the average death-rate is in their hands. This statement is not, of course, intended to mean that it is now possible to prevent or stamp out local epidemics of influenza, pneumonia, cerebrospinal meningitis and some other infectious diseases, but it is intended to cover the average general death-rate of a city for a series of years.

The expectation of life at birth in certain manufacturing cities of England has been but little more than one half that of the healthiest districts of England. Until recent years it was twenty-five or twenty-six years in Liverpool and Manchester, thirty-seven years in London and forty-six years in Surrey, a healthy country district. Even at the age of thirty, the expectation of life was seven years more for England as a whole than it was for the inhabitants of Manchester. I have estimated that the expectation of life at birth in New York City in 1866 was only a little more than twenty-five years, while in 1903, calculated on the death-rate for that year, it had almost doubled, and equaled about forty-two years. For the seven-year period ending in 1873, the death-rate under five years in New York City was 123 per 1,000 of the population at these ages. For the year 1903 the death-rate under five years was fifty-six. On the present estimated population at these ages, this reduction equals a saving of more than 28,000 lives annually.

These considerations suggest the vast importance of the healthfulness of the community to the individual at every age, and to the community as a whole, for on this depends not only the relative freedom from illness, but also the probable lifetime of each member.

In the casual consideration of the healthfulness of communities as compared with the conditions existing in earlier times, we are inclined to think without investigation that there has been but little advance in modern times, and that while some diseases have been greatly restricted or entirely stamped out, these have been replaced by others equally as fatal to the human race. A little study, however, shows how erroneous are these views. In the seventeenth and eighteenth centuries the average annual death-rate throughout the civilized world was at least 50 per 1,000 of the population, and probably it was much more than this. From 1628 to 1635 in London, these years being free from pestilence, the average death-rate was 50 per 1,000, and the absolute annual mortality for twenty-four years, from 1620 to 1643, was over 70 per 1,000.

The death-rate during 1902 in London was only 17 and a fraction per 1,000. The mean expectation of life in London for the decennial period, 1771–1780, as calculated by Price's table, was nineteen and six-tenths years, the annual mortality being 51 or 52 per 1,000; while from 1831 to 1835, although an epidemic year

[1] Address on State Medicine at the fifty-fifth annual session of the American Medical Association at Atlantic City, June 7–10, 1904. By courtesy of *The Journal of the American Medical Association.*

is included, the death-rate had decreased to about 32 per 1,000. In 1894 the mean expectation of life at birth for all England had more than doubled that of 1780 in London, so that it was nearly forty-one years, and for London alone it was thirty-seven years. From 1771 to 1780 in London not less than five in each thousand of the population died annually of smallpox; in 1810 this mortality had sunk to 2 per 1,000, and in 1835 to 0.8, and in recent years it has been an absolutely insignificant decimal. Fever as a cause of death declined in almost the same ratio, from 6.21 in the decennial period ending in 1780 to 2.64 in 1810, and 1.14 in 1835. In the sixteenth century fever, plague, cholera and dysentery destroyed annually 31 out of every thousand of the population of London, or nearly twice the total deaths occurring now from all causes. These diseases at the present time, as causes of death, do not equal in London 2 per 1,000 annually of the population.

According to the English life tables up to 1875, 518 out of every thousand children in Liverpool died during the first five years of life; 351 died in London and 205 in the healthy rural districts of England, while in the whole of England 297 out of every thousand died during this period of life. In old New York City (comprising the boroughs of Manhattan and the Bronx), for the seven-year period ending in 1873, 616 out of every thousand children born died during the first five years of life. As computed by the death-rate under five in 1903, 280 would have died during these same five years. This mortality while still far too high, equals a reduction of nearly 60%, and as calculated for the estimated population at these ages, means a saving of about 20,000 lives a year in these boroughs. The death-rate in the period over five years of age has naturally shown a much smaller decrease, although it has fallen from 19 or 20, as it was in 1865 and 1866, at the time of the organization of the Department of Health of New York City as at present constituted, to about 14 for the year 1903, being a reduction of nearly one third. This has been accomplished, notwithstanding the fact that the old city has increased during this time from a population of about 750,000 to more than 2,200,000.

It does not seem necessary or desirable for our present purpose to consider in detail the causes of this decrease or the special diseases in which it has taken place, but the facts suffice to indicate the great achievements of preventive medicine during the past four decades. Expressed in human lives, it means in the boroughs of Manhattan and the Bronx a saving of over 30,000 lives a year, and, computed at the same rate for the whole city, a saving annually of more than 50,000 lives. I would not be taken as intimating that all of this has been accomplished through the agencies which we usually include under the head of preventive medicine, or that it has been the result solely of the action of the sanitary authorities. Such an interpretation would be very far from the truth, for many agencies have been at work in the production of these results. But preventive medicine, as I conceive its purposes and scope, should include all of those agencies which are essential and direct factors in the prevention of disease and the preservation of life. These agencies are not necessarily all under the direct control of the sanitary authorities.

In these introductory remarks, and in much that follows, I have taken many illustrations from conditions which exist in New York, because I have been familiar with the sanitary affairs there for many years, and the illustrations which it furnishes serve our purpose as well as if selected from many different states or communities.

It has long seemed to me that the work of the sanitary authorities in this country was too much restricted, and the general conception of the scope of their functions was narrow and out of harmony with the spirit and development of modern scientific medicine.

Sanitary work has been pretty well limited along certain old and well-defined lines, much to the detriment of the public health. The medical profession has unconsciously contributed no small part to this condition, because of the existence too often of a certain antagonistic attitude toward the action of the sanitary authorities and the feeling that the occupation of a larger field by them would be detrimental to the best interests of the medical profession. The latter has too often resented and opposed any movement to enlarge the field of preventive work, and has often insisted that its operations should be kept within the traditional narrow lines. Until in very recent years the operations of the health officers have been chiefly confined to the measures adopted for the prevention of the more readily communicable diseases, commonly called contagious. These usually included smallpox, diphtheria and scarlet fever, and, at intervals, yellow fever, cholera, epidemic dysentery and typhus fever. More recently typhoid fever and measles, and indirectly the diarrheal diseases of infants, have been generally added to this list. But even in regard to the diseases referred to, the measures adopted have been of an elementary and most unsatisfactory character. It must be admitted, however, that until our knowledge of the causation of many of the infectious diseases was rendered more exact by the discoveries in modern bacteriology, sanitary procedures were of necessity largely empirical, and disinfection was either entirely wanting or the methods employed were quite inefficient.

The scope of the sanitary measures in force with reference to the ordinary infectious diseases has in recent years been greatly broadened. More than ten years ago the Board of Health in New York assumed the position that all facilities and procedures looking to the prevention and cure of the infectious diseases should be afforded by the Department of Health. The establishment of the methods for bacteriologic diagnosis and the facilities for the serum treatment had

their origin there, and have since been widely followed.

General prophylaxis, or that portion of preventive medicine which should come directly under the supervision of the health authorities, has or should have a broader scope than that indicated, and should include the supervision, not only of those diseases which have generally come within sanitary surveillance, but also all the infectious diseases which from their nature are to a greater or less extent preventable, in addition to all other forms of disease which are the result of unsanitary living, occupations, habitations or surroundings, including those diseases arising from manufacturing, mining, or other industries, which, on account of their nature, are peculiarly or especially injurious to health. It should also include with greatly increased powers and breadth of jurisdiction, the surveillance of the water and food supplies and the sewage disposal.

To return for a moment to the consideration of the infectious diseases to be included in this list, there is a large class of different types of the infectious diseases which are well recognized as being more or less preventable which are not included in the registration returns. These are not dealt with at all by the sanitary authorities, or only to a very limited extent. Mention may be made in this connection not only of tuberculosis in all its forms, whooping cough, mumps, chickenpox and cerebrospinal meningitis, which have been included in the registration returns by some authorities, but have not, as a rule, been dealt with by them, but also of puerperal fever, erysipelas, pneumonia, the diarrheal diseases of infants, dysentery, malarial fever, influenza, the contagious diseases of the eye, and certain parasitic diseases of the skin, as well as some of the rarer diseases occurring in both animals and man, such as rabies, tetanus, anthrax and glanders.

The inclusion in the registration returns of such a long list of infectious diseases as has been here indicated requires considerable modifications and expansion of the ordinary sanitary procedures, and such action at first thought is likely to arouse opposition and unfavorable criticism from the medical profession. Such opposition and criticism, however, I believe is without proper justification, and arises from an erroneous conception of the proper scope and functions of the authorities and their relations to the medical profession and the people.

There has long existed a belief in the medical profession, and to a considerable extent it has also been a part of the conception of the sanitary authorities of their functions, that the registration of a case of any kind of infectious disease involved some surveillance of such case by the authorities. The slightest consideration would at once show that with relation to many of the diseases mentioned no such surveillance could be of any real service, and it might be a source of annoyance to the sick person, the family and the attending physician. Much good, however, would result, in my opinion, by such a broadening of the scope of sanitary work, without causing annoyance or being detrimental to any one. I should like, however, to point out that more than a year ago the Board of Health of New York City in the revision of its sanitary code included a number of new sections in relation to the infectious diseases, covering to a large extent the diseases above mentioned. These sections, with the accompanying notes, read as follows:

INFECTIOUS DISEASES.

SECT. 133. It shall be the duty of every physician to report to the Department of Health, in writing, the full name, age and address of every person suffering from any one of the infectious diseases included in the list appended, with the name of the disease, within twenty-four hours of the time when the case is first seen:

A. *Contagious* (very readily communicable). — Measles, rubella (rötheln), scarlet fever, variola (smallpox), varicella (chickenpox), typhus fever, relapsing fever.

B. *Communicable.* — Diphtheria (croup), typhoid fever, Asiatic cholera, tuberculosis (of any organ), plague, tetanus, anthrax, glanders, epidemic cerebrospinal meningitis, leprosy, infectious diseases of the eye (trachoma, suppurative conjunctivitis), puerperal septicemia, erysipelas, whooping cough.

C. *Indirectly Communicable* (through an intermediary host). — Yellow fever, malarial fever.

NOTE. In this provisional classification of the infectious diseases, arranged for practical purposes, the most readily communicable of these diseases, embracing the exanthemata and typhus fever, have been placed in a group by themselves and called contagious. This has been done with a view to emphasizing a distinction, which is not only of scientific significance, but of practical importance, in dealing with the sanitary features of administration. This distinction is furthermore of importance because it avoids the misunderstanding and alarm frequently caused by including in the same class the very readily communicable diseases (such as smallpox) and the much less communicable diseases (such as tuberculosis), which require very different sanitary measures for their control.

SECT. 134. It shall be the duty of the commissioners or managers, or the principal, superintendent or physician, of each and every public institution or dispensary in this city, to report to the Department of Health, in writing, the full name, age and address of any person suffering from any one of the infectious diseases included in the list appended, with the name of the disease, within twenty-four hours of the time when the case is first seen:

A. *Communicable.* — Influenza, lobar pneumonia, broncho-pneumonia, infectious diseases of the gastro-intestinal canal (dysentery, cholera morbus, cholera infantum, summer diarrheas of infants).

B. *Parasitic Diseases of the Skin.* — Scabies, tinea tonsurans, impetigo (contagious), favus.

NOTE. In this list of diseases reporting is required by the Department of Health in order that data may be obtained for general and special investigation of the modes and sources of infection and as to the prevalence and distribution of these diseases. The Department of Health does not propose to exercise a sanitary surveillance in these cases, but desires information with a view to the ultimate removal or improvement in the conditions which foster them. Notification is

required in certain of these diseases because of the liability to their extension among children in the schools.

It will be noted, first, that two main groups of diseases are specified. In the first group, including the more readily communciable diseases, and some others which are not so regarded, registration is compulsory in all cases coming under the observation either of a private attending physician or an institution. These are separated for convenience under three heads: (*a*) The contagious or very readily communicable; (*b*) the communicable, including diphtheria, typhoid fever, Asiatic cholera, tuberculosis and a number of others; and (*c*) the indirectly communicable, including only two diseases — yellow fever and malarial fever — which are transmitted solely through an intermediary host. In these three classes compulsory registration is required, because in all of the diseases in these classes preventive measures, properly executed, are certainly efficient to a very large extent. As to the propriety of the compulsory registration of all of the diseases included under the first heading, "The contagious or very readily communicable diseases," I assume that there can be no reasonable difference of opinion. Measles, rötheln, scarlet fever, varicella, variola, typhus fever and relapsing fever, certainly without question, should be reported to the sanitary authorities. The necessity for reporting rötheln and varicella rests more in the danger of confusion of these diseases with measles and varioloid, respectively, than because of the importance of the diseases themselves. Our experience in New York has shown again and again that outbreaks of smallpox have resulted from the failure of inexperienced physicians to recognize mild cases, these having been mistaken for varicella and treated as such. Every case of varicella occurring in the city must, therefore, be reported, and all cases occurring in adults are immediately seen by a trained diagnostician. I say all cases of varicella in adults, because experience has shown that very frequently varicella in an adult is a mild case of variola.

In the second class, called simply "the communicable diseases," there might be some question as to the propriety of the reports in some instances. There would be none, however, with regard to diphtheria, typhoid fever, Asiatic cholera, plague, tetanus, anthrax, glanders and leprosy. All of these diseases are under some conditions communicable and of the greatest importance, yet they are much less communicable than the first class, the contagious.

There cannot now be, nor can I conceive that there ever will be again, any serious question as to the necessity or propriety for the registration and sanitary surveillance of tuberculosis, although this has been a subject of very bitter dispute and although this disease has come actually under the close supervision of the sanitary authorities in only three or four cities in the United States, and of practically none in Great Britian or on the Continent. Pulmonary tuberculosis was included in the list of communicable and reportable diseases by the New York City Board of Health ten years ago, and the measures adopted for its surveillance have been gradually extended and the lines for its restriction have been drawn closer and closer as each year has passed. Some doubt, however, might properly arise as to the necessity of the inclusion of other forms of tuberculosis than pulmonary tuberculosis in the registration returns, because for the most part these other tubercular diseases are not communicable, or very slightly so. Bone, joint, intestinal and gland tuberculosis are practically never sources of infection in other persons, but cases of tuberculosis of the types mentioned indicate the previous exposure to infection of the individual, and they thus point out a probably infected site or family, concerning which the sanitary authorities should have information. Such cases may also disclose unrecognized instances of pulmonary disease. Furthermore, knowledge of all cases is absolutely essential to a comprehensive recognition of the extent and prevalence of the infectious disease, *tuberculosis*. During the past year measures to ensure the registration of tuberculosis in all its forms have been adopted in New York.

The importance of the registration of epidemic cerebrospinal meningitis arises not so much because of the evidence of its communicability as because of the importance of fuller information as to the conditions under which it arises and becomes disseminated. We have in New York City just been passing through an epidemic of this disease, the first serious one for thirty years. During the month ending May 15 more than 300 deaths occurred in New York City from this cause.

The infectious diseases of the eye — trachoma and suppurative conjunctivitis — should be included because of the importance of the adoption of preventive measures in the public schools. Few persons had any conception of the great prevalence of these diseases of the eye in the public schools of New York until after the Department of Health adopted some comprehensive measures for their surveillance. Such a vast number of cases was found that the Board of Health was forced to establish special dispensaries and provide special hospital facilities for their care. Only within a few weeks a second hospital and dispensary has been opened, and in the original one in connection with Gouverneur Hospital an average of about 500 patients a day were treated during the year 1903, and nearly 5,000 cases were operated on for trachoma.

Puerperal septicemia should be included in the registration returns because modern aseptic midwifery has shown that in most instances this is a strictly preventable disease, and, excepting rare cases of difficult or prolonged labor, its occurrence may be regarded as the result of uncleanliness, negligence or incompetence. The registration and the investigation of these cases by the sanitary authorities should soon result in the exclusion from practice of incompetent midwives,

restrict the work of the criminal abortionist, and foster the practice of aseptic midwifery.

No one, I fancy, would seriously question the propriety of including erysipelas and whooping cough in the registration returns. So far as this country is concerned I assume that typhus fever, Asiatic cholera, plague, leprosy and yellow fever are diseases which will never again call for anything more than occasional or emergency measures for the disposal of isolated cases or small groups of cases. But with reference to one disease in the third class, *i. e.*, malarial fever, some remarks may be in point to show the advantages which are likely to result from the interference of the sanitary authorities. We now all believe that malarial fever is not only an infectious disease and indirectly communicable through an intermediary host, but that it is also distinctly preventable.

The registration of cases of malarial fever should be required, not because close surveillance of individual cases is necessary, but because the sanitary authorities should know where the sites of infection are, where the breeding places of the anopheles mosquitoes are to be found, in order that they may adopt proper means for determining the cause of such areas of infection and the proper measures for their removal. In certain sections of New York City investigation has shown that in some instances almost every person living within certain small areas has suffered from malarial fever during the spring and summer months of a single season. Such outbreaks are without any question the result of local remediable unsanitary conditions, which furnish the breeding places for the mosquitoes. But without special information as to the existence of the cases, only to be obtained through the registration of malarial fever, knowledge of the presence of much unsanitary conditions and their removal may become difficult or impossible. The surveillance in their homes of the individual cases reported is, of course, not contemplated. That conditions similar to those found in New York exist in other communities, I have no doubt.

Section 134 of the Sanitary Code of New York, covering the second group, deals with infectious diseases of a somewhat different type, and in these the Sanitary Code requires the reporting to the department by public institutions of all cases coming under their observation; but it only requests physicians to report them and does not require such reporting.

Class (*A*), in this group, includes some of the more important acute infectious diseases of the upper respiratory tract, namely, influenza, lobar pneumonia and bronchopneumonia, and certain of the more common acute infectious diseases of the gastro-intestinal canal, namely, dysentery, cholera morbus, cholera infantum and the summer diarrheas of infants.

The acute diseases of the respiratory tract referred to should, in my opinion, be registered, because they are infectious, because they are of prime importance as causes of death, and in order that general and special investigation may be instituted for the collection of data bearing on the modes of infection and the sources and causes of their prevalence and their distribution. New York City has during the last winter experienced the greatest prevalence of these diseases which it has had for many years. In the first four months of the year more than 6,000 deaths occurred from influenza, lobar pneumonia, bronchopneumonia and acute bronchitis.

I firmly believe that these diseases can be to a very considerable extent prevented, but the means and the methods are yet to be determined, and it is hoped that registration will assist in the acquisition of knowledge for the attainment of this end.

A large new field has just been opened by recent observations with regard to the specifically infectious character of many of the cases of summer diarrhea and dysentery, both of infants and of adults. The results of the investigation of the sanitary authorities in recent years in many large cities have shown in the most conclusive way that these diseases are to a very large extent preventable, and it seems probable, or at least possible, from recent investigations, that some forms at least are preventable and curable by the use of a specific curative serum.

Investigations in New York and other localities have shown that serious outbreaks of diarrhea and dysentery have occurred in various institutions and in local areas which were probably, if not certainly, preventable, but concerning which the sanitary authorities have had no information. It seems evident, therefore, that these diseases should be made notifiable. A practical difficulty in this connection exists in the lack of definiteness as to what cases should be included and how the differentiation is to be made between the diarrheas due to simple digestive disturbances and those of a more serious nature caused by infection. This, however, is a matter for further investigation.

Notification of the parasitic diseases of the skin should be required, chiefly because of the liability to the extension of these diseases among children in the public schools.

There are certain very large and important questions of prophylaxis connected with the prevalence of typhoid fever and the milk and water supply of our large communities. The occurrence of great outbreaks of typhoid fever, such as the epidemics at Ithaca, N. Y., and Butler, Pa., during the last year, the prevalence in Philadelphia, Pittsburg and some other cities of the United States and the extensive distribution in the rural districts, constitute a disgrace to American preventive medicine and should arouse the sanitary authorities, the medical profession and the people to the provision of efficient measures and the enactment of suitable legislation for its prevention.

The annual cost of typhoid fever in sickness and death throughout the United States would be computed in terms of tens of millions of

dollars. All of this loss we know is certainly preventable. If only a small portion of the annual outlay made by the country for sickness and death from this cause were expended in the education of the people as to the cause and the methods of prevention of this disease and the provision of proper water and sewerage systems, typhoid fever might soon become a rare affection. Unfortunately the city sanitary authorities are often almost powerless in this matter, as their jurisdiction does not extend over the watersheds which supply with water the people under their care, and a supervision by them of the sources of the milk supply is also frequently absolutely impossible.

In New York City detailed investigations of all the cases of typhoid fever occurring within the city limits were instituted several years ago and have been continuously carried on. These show that at least 25% of the cases occurring in the city have *certainly* received their infection outside of New York City, and a considerable percentage more have *probably* received it outside. Five or 6% are the result of contact with other cases, and the remainder are, in all probability, almost wholly the result of infection through milk or oysters. Some more comprehensive measures are urgently demanded to extend the jurisdiction of the authorities in the supervision of the supplies of milk and oysters and other foods.

A serious objection which may be urged against the adoption of the measures here recommended in regard to the registration of many infectious diseases is the increased labor thrown on physicians which their enforcement would involve. The question may properly be asked: Whether the sanitary authorities in the interest of the general public may call on the medical profession for the expenditure of so much time and labor without making any compensation in return. There are 25 diseases included in the New York list. The English authorities pay a fee for the notification of each case of infectious disease, and I believe that this course might properly be pursued in this country; but this has not been the custom here, and the authorities generally are not now provided with the funds necessary for this purpose.

When the Department of Health of New York City established its bacteriologic laboratories in 1892, measures were adopted to make some return to physicians for their interest and labor in connection with the sanitary surveillance of the infectious diseases. A systematic plan was then inaugurated, and has since been consistently followed, to secure their co-operation, by offering free bacteriologic examination in the diagnosis and surveillance of various forms of infectious disease. This was first applied to Asiatic cholera in 1892, during the outbreak in New York Harbor, and has since been extended to all of the diseases in which existing scientific knowledge made it possible, cerebrospinal meningitis being the latest disease added to this list. The establishment of this system of free bacteriologic examinations in the diagnosis and surveillance of the infectious diseases, and the provision of facilities throughout the city for the collection of specimens and the sending of reports to physicians, constituted an entirely new departure in sanitary work and has been of the greatest value. The example of New York has been followed by the sanitary authorities in most of the large cities of this country, by many state authorities, and by authorities generally in Great Britain and to a certain extent on the Continent. These examinations constitute the return which the authorities here have made to physicians for the reporting of cases and for their assistance and co-operation in their care. This return has a very considerable money value, when we remember that for such examinations the usual fee is five dollars, and as physicians cannot, as a rule, make such examinations themselves, they must work without the assistance thus afforded, unless they appeal to the regularly constituted laboratories.

What now are the possibilities of preventive medicine as concerns the larger centers of population? In answering this question we may first take as the basis of our reply the conditions found in some of the large cities with the lowest death-rates, or still better, the conditions found in some healthy rural districts. In considering the crude death-rates, as ordinarily reported, however, one must not ignore the influence of the sex and age distribution of the population on the death-rate. As is well known, the death-rates in the periods of life between five and forty-five years of age are very low, and the death-rate among women is lower than among men. If, then, in a city there is a relative excess of the population in the middle periods of life, or an unusual preponderance of women, we may have a crude death-rate which seems very low, but which when corrected may be relatively high. For example, the death-rate of New York City, as corrected by the English life tables, would probably be at least three points higher than it is. For 1894 the gross rate was 22.76, and the rate corrected by the English tables was 26.46. The corrected death-rate of some of the large, rapidly growing Western cities would probably be five or six points higher than the crude death-rate reported. The death-rate of London at present averages about 17 per 1,000, and when corrected about 18.5 per 1,000, while the Berlin death-rate is somewhat lower than this. The crude death-rate of Surrey, a healthy rural district in England, is 14 and a fraction, and when corrected would probably be 15.

We can hardly use for a basis of comparison the conditions in any of the cities of this country with very low rates, because the rates have not been corrected, and the basis on which they are calculated cannot always be accepted as correct. Taking all the facts together, and judging of the duration of human life as we know it, we may accept a corrected death-rate of 14 or 15 in a large city as a goal toward which preventive medicine should strive and hope to achieve. If

we consider the question from another point of view, as to what is possible in the reduction of the death-rate from distinctly preventable diseases, we would reach a conclusion not unlike the previous one.

In New York City it may be assumed that the present tubercular death-rate of 2.7 may, under proper surveillance, with certainty be reduced to 1.2, and 1.5 points would thus be subtracted from the crude rate. The diphtheria death-rate, already reduced 65% by the use of antitoxic serum, should certainly be reduced to one third of what it is at present; it is now about .6 per 1,000 population. Similar reductions should be possible in the death-rate from typhoid fever, measles and scarlet fever. The diarrheal diseases of infants have already been reduced in the last twelve years to one half of their former prevalence, and should still be reduced more than 50%. Thus more than three points may be subtracted from the crude rate in New York, which in 1903 was 18.18. The rate would then be 15—. The rate for 1903 was the lowest in the history of the city.

The most fatal affections with which we have now to deal in New York are the acute respiratory diseases, including influenza, lobar pneumonia, bronchopneumonia and acute bronchitis. The average death from this group of diseases now exceeds 3 per 1,000 of the population, and in years when there is an epidemic prevalence of these diseases the death-rate may be 4 or more, as seems likely to be the case this year.

The advances in preventive medicine have as yet not only had no influence in reducing the death-rate from this group of diseases, but, on the contrary, there has been a slow and continuous increase. I cannot at this moment point out the method or the means by which a reduction is to be brought about, but still I firmly believe that with fuller knowledge such a reduction will become possible in the great cities where these diseases are so prevalent.

Something can be accomplished through the closer sanitary surveillance of the occupations and conditions under which the lower classes work, especially the noxious trades. Something, too, may be done through a closer supervision of foods to ensure their purity and freedom from adulteration.

A very difficult problem arises in connection with the diseases of the circulatory apparatus and the kidneys. My investigations have shown that in New York City a large increase has taken place, due to these causes, during the last twenty years. The acute respiratory diseases, cancer and diseases of the circulatory apparatus and the kidneys are the only important causes of death which have shown an increase during this period. The increase in cancer amounts to about 15%, and the increase in the acute respiratory diseases amounts to about 15%, while the increase in the diseases of the circulatory apparatus and kidneys combined equals about 40%. In making this statement I have taken fully into consideration the possible influence of greater accuracy in the death returns, *i. e.*, the inclusion formerly of these under other causes of death; but after making all allowances, it seems to me without question that an increase equaling 40% has taken place.

A very important sanitary problem is here presented to the health authorities. What are the factors in the lives of the inhabitants of our large cities (for I have found that similar increases less extensive, however, have taken place in London, Paris and Berlin) which have caused such a remarkable increase in the prevalence of these affections, and how are these factors to be removed?

The time at our disposal does not permit of more than this elementary and cursory review of the work in preventive medicine. Sufficient facts have, however, been adduced to show how great have been its achievements, and some of the directions have been indicated in which its scope should be extended. With such extensions, and many others not mentioned, the future possibilities of preventive medicine seem to be even greater than the past achievements, for almost every development in bacteriology opens up a new field of work for the sanitary authorities.

A CONTRIBUTION TO THE PATHOLOGY OF HYSTERIA BASED UPON AN EXPERIMENTAL STUDY OF A CASE OF HEMIANESTHESIA WITH CLONIC CONVULSIVE ATTACKS SIMULATING JACKSONIAN EPILEPSY.[1]

BY BORIS SIDIS, A.M., PH.D., AND MORTON PRINCE, M.D., ASSISTED BY H. LINENTHAL, M.D.

THE following observations are offered as a contribution to the pathology of hysteria. The experimental results obtained confirm the modern theory of the disease and corroborate the various and numerous observations which have been made of recent years in France, Germany, and this country. These researches have compelled us to recast our views of the pathology of hysterical phenomena, though a knowledge of this work has not yet found its way into textbooks. This is our reason for presenting this study before this Society.

The pathology as laid down in textbooks may be exemplified by the following references:

Walton (Wood's Handbook) states: "Post-mortem investigation gives no clue to the morbid process, and theoretic study of its nature has led, as yet, to little more than conjecture. . . . Most of the paralytic symptoms, for example, are best explained on the supposition of decreased irritability of the cortical centres, while the spasmodic symptoms allow of explanation in part on the ground of their exalted irritability, and in part on that of diminished inhibition."

Gowers in discussing the pathology states that "hemianesthesia must be ascribed to an inhibition of a sensory center relatively low," and that

[1] Read at the meeting of American Association of Physicians, May 10, 1904.

"this disturbance of lower centers has disclosed facts (!) hitherto scarcely suspected and of much physiological interest regarding this capacity for limited functional derangement." He then goes on to explain hemianesthesia by inhibition, and infers a fanciful arrangement for its arrest, etc.

Sachs, although referring in a footnote to Breuer and Freud's classic work, which has helped to change our conception of the disease, contents himself with the opinion that "there is much room for theorizing, but there are very few facts to guide us," and that "the transfer of sensory disturbances from one half of the body to the other would go to show that the two halves of the brain are evidently in sympathy with one another (to put it broadly) in this disease, and that they can be alternately affected."

Dana attempts no theory.

Oppenheim makes a feeble reference to the psychic factors, but no attempt at explanation.

Lloyd (Nervous Diseases by American Authors) considers that "the pathology of hysteria is among the unsolved problems of the infant science of psychology."

Among the latest textbooks, Church and Peterson quote a few recent definitions, but practically do not consider the pathology.

Binswanger in his extensive treatise on hysteria (Nothnagel's Special Pathology and Therapeutics) quotes the work of the modern French school, but apparently without comprehending it. He lays down the following metaphysical postulate which seems to be absolutely devoid of meaning: "The hysteric alteration consists in a disturbance of the normal exchange between the psychic and the material processes. This occurs in two ways: on the one hand, the psychic process fails to be awakened parallel with a definite series of material cortical excitations, or are only incompletely aroused; on the other hand correlated with a material excitement of the cortex an excessive amount of psychic activity takes place which excites every variety of reaction to the whole innervation process which arises in or is controlled by the cortex."

Strümpel thus reasons: "If the normal exertion and inhibition of the will-power be broken down, so that *unreasonable* will-stimuli are created and reach the muscles, we have hysteric convulsions, contractures or cramps. If there are present in the consciousness images of awaited or feared objects, and if these images be intensified by the conditions of the disease into *true subjective irritations* of consciousness, we shall have hysteric pains and neuralgias."

The following comment on this is fairly deserved:

"This piece of scientific speculation, as to its lucidity, reminds one of the definition of love given by a Platonist: 'Love is the ideality of reality of a part of the totality of the Infinite Being.'"

All these earlier speculations are not only trivial, but are now known to be erroneous, for recent researches have thrown a great deal of light upon the pathology of the disease, although much remains to be done to give a complete understanding of it.

The study of the case here reported is of clinical interest in that —

1. It confirms the work of previous observers in regard to the nature of hysteric anesthesia. That is to say, the anesthesia is not due to inhibition of sensory centers or any kind of suppression of their activity; in fact is not true anesthesia at all, but is due to a dissociation of consciousness, probably corresponding to a functional dissociation of systems of cortical neurons.

2. It shows the purely functional character of the epileptiform attacks and their origin in dissociated psychic states.

3. It emphasizes the importance of understanding the pathology of the attacks in order to effect a cure.

History. — Mr. M., aged twenty-one years, was born in Russia, and came to this country four years ago. His family history, as far as can be ascertained, is good. There is no nervous trouble of any sort in the immediate or remote members of his family.

The patient himself has always enjoyed good health. He is a very intelligent young man of good habits. He does not use alcohol or tobacco and gives no venereal history.

He was kindly referred to us by Dr. K. M. Davidson of Boston for epileptiform attacks and anesthesia of the right half of his body. The attack is preceded by an *aura*, consisting of headache and a general feeling of malaise. The aura lasts a few days and terminates in the attack which always sets in about midnight, but *when the patient is fully awake*. The attack consists of a series of spasms, rhythmic in character and lasting about one or two minutes. After an interval of not more than thirty seconds, the spasms set in again. This condition continues uninterruptedly for a period of five or six days (a sort of status epilepticus), persisting during the time the patient is awake, and ceasing only during the short intervals or rather moments of sleep. Throughout the whole period of the attacks the patient is troubled with insomnia. He sleeps restlessly for only ten or fifteen minutes at a time. On one occasion he was observed to be in a state of delirium as found in post-epileptic insanity and the so-called "Dammerzustande" of epilepsy. This delirium was observed but once in the course of five years. The regular attack is not accompanied by any delirious states or "Dammerzustande." On the contrary, during the whole course of the attack the patient's *mind remains perfectly clear*. He does not lose consciousness even for a moment, and not the least trace of emotional disturbance, such as fear, for instance, can be found. During the period of the attack the whole right side becomes anesthetic to all forms of sensations, kinesthesia included, so that he is not even aware of the spasms unless he actually observes the affected limbs. Otherwise he remains unconcerned, perfectly *placid* and unruffled, as if nothing special is happening to him.

The affected limbs, previously normal, also become paretic. After the attack has subsided, the paresis and anesthesia persist (as sometimes happens in true idiopathic epilepsy) for a few days, after which the patient's condition remains normal until the next attack. After his last attack, however, the anesthesia and paresis continued for about three weeks.

The first attack occurred five years ago, since which time, up to his last year, he has had every year one

attack which, very curiously, sets in about the same time, namely, about the month of January or February. During the last year, however, the attacks have increased in frequency, so that the patient has had four at intervals of about three or four months. On two different occasions he was in the Boston City Hospital for the attacks.

Examination.— Examination of the patient, made three weeks after the last attack, showed the following: Pupils are equal and react promptly to light and accommodation. Knee jerks slightly exaggerated. No ankle clonus. No Babinsky. There was a profound right hemianesthesia including the right half of the tongue, with a marked hypo-esthesia of the right side of the pharynx. All the senses of the right side were involved. The field of vision of the right eye was very much limited. The ticking of a watch could not be heard more than three inches away from the right ear. (Hearing in left normal.) Taste and smell were likewise involved on the right side. The muscular and kinesthetic sensations on the right side were very much impaired.

The patient's mental condition was good. He was well balanced, and did not give evidence of any emotional disturbances. He states that he has few dreams and those are insignificant, concerned as they are with the ordinary matters of his daily life. Occasionally he dreams that he is falling, but there is no definite content to the dream.

These findings were indicative of functional rather than organic disease. The *previous history* of the case was significant. The first attack came on after peculiar circumstances, five years ago, when the patient was sixteen years of age and living in Russia. After returning from a ball one night, he was sent back to look for a ring which the lady, whom he escorted, had lost on the way. It was after midnight, and his way lay on a lonely road which led by a cemetery. When near the cemetery he was suddenly overcome by a great fright, thinking that somebody was running after him. He fell and lost consciousness. By the time he was brought home he had regained consciousness, but there existed a spasmodic shaking of the right side, involving the arm, leg, and head. The spasm persisted for one week, during which time he could not voluntarily move his right arm or leg, and the right half of his body felt numb. There was also apparently a loss of muscular sense, for he states that he was unaware of the shaking of his arm or leg unless he looked and saw the movements. In other words, there was right hemiplegia, anesthesia, and spasms. For one week after the cessation of the spasms his right arm and leg remained weak, but he was soon able to resume his work, and he felt as well as ever. Since then every year, as already stated, about *the same month* the patient has an attack similar in every respect to the original attack, with the only exception that there is no loss of consciousness. Otherwise the subsequent yearly attacks are photographic pictures, close repetitions of the original attack.

This history, obtained from the patient himself and his family, was still further suggestive, though not a proof of the functional character of the attacks. Furthermore, even though functional, nothing was evident to show the deeper pathology of the affection; that is to say, the exciting and underlying cause of the attacks and the anesthesia.

A series of experiments accordingly was undertaken for this purpose. First, as to the *anesthesia*. If the anesthesia was hysteric, as is now well known, sensory impressions ought to be felt, even though the patient was unconscious of them, and we ought to be able to get sensory reactions of a wellknown sort.

Tests showing the functional nature of the anesthesia. Visual hallucinations.— The experiments which were made to determine the nature of the anesthesia produced interesting results. These experiments are of a wellknown class which have been frequently made use of to show that the anesthesia is not a true anesthesia, but that impressions from the anesthetic parts which seem not to be felt are really perceived subconsciously.

They may be made in several different ways. The method we made use of consisted in producing a visual hallucination whenever the anesthetic hand was touched. That is to say, if the anesthesia is functional, although the subject does not consciously perceive the tactile impressions, he sees the image of a number which corresponds with the number of times the hand is pricked or touched. This was found to be the result in this case. Whenever the hand was pricked a certain number of times successively, he always saw that number as an hallucination. The number was always correct, and showed that subconsciously the pricks must have been felt.

The details of the experiment were as follows: The anesthetic hand was placed behind a screen and the patient was told to look in a glass of water and tell what he saw there. Impressions made on the anesthetic hand gave rise to visual hallucinations symbolically representing the sensory stimuli. Thus, for example, when his hand was touched, very lightly, five times, he saw the figure five very vividly and described it in detail. He saw the number written; it looked very large; and he saw it written on the back of a hand.

The intensity of the hallucination was well brought out when, projecting the hallucinatory hand on a screen instead of in the water, the patient outlined it with a pencil. When one of us placed his hand on the screen by the side of the hallucinatory hand and the patient was asked to tell which hand looked more real, he insisted that both hands looked equally real, except that the hallucinatory hand looked a little farther away.

Other tests also showed that the *subconscious* reactions to impressions from the anesthetic hand were more acute than the conscious reactions to impressions from the normal hand. So we have the so-called "psychopathic paradox" that *the functional anesthesia is hyperesthesia.* (Sidis.)

It is perfectly evident then that there could be no inhibition of the sensory centers, or suppression of their activity, or whatever else it may be called. In spite of the apparent profound anesthesia the pin pricks were felt and perceived. The perception of them gave rise to hallucinations of a character that showed the pin pricks were counted and localized in the hand. The result of these tests is in accord with previous observations which have demonstrated that in hysterics all sensory impressions received from anesthetic parts, while they do not reach the

personal consciousness are, as it is called, subconsciously perceived. The accepted interpretation of such phenomena is this: Inasmuch as the sensations are perceived, the failure of the subject to be conscious of them must be due to a *failure in association*. The perception of the sensation is *dissociated* from the personal consciousness. More than this, these dissociated sensations are capable of a certain amount of independent functioning; hence the hallucinations, and hence the wellknown failure of hysterics to be incommoded by their anesthesia. This condition of dissociation is now recognized as that underlying hysteric anesthesia.

Study of the attacks.— For the purpose of studying the attacks themselves, the patient was hypnotized. He went into a deep somnambulic condition, in which, however, the *anesthesia still persisted*. This showed that the dissociation of the sensory impressions was unchanged. In hypnosis he related again the history of the onset of the trouble. But now his memory became broader and he was able to give the additional information, which he could not do in his waking state, that at the time he was frightened he fell on his right side. Moreover, he recalls what he does not remember when awake, that throughout the period of his attacks when he falls asleep, he has very vivid dreams of an intense hallucinatory character, all relating to the fright and fall of five years ago. In these dreams he lives over and over again the experience which was the beginning of his trouble. He again finds himself in his little native town, on a lonely road; he thinks some one is running after him; he becomes frightened, calls for help, falls, and then wakes up with a start, and the whole dream is forgotten. After he wakes he knows nothing of all this; there is no more fear or any emotional disturbance; he is then simply distressed by the spasms.

Subconscious reproduction of the attacks.— While testing the anesthesia during hypnosis, an attack developed; his right arm and leg began to shake, first mildly, and then with increasing intensity and frequency. His head also spasmodically turned to the right side. The movements soon became rhythmic. Arm and leg were adducted and adducted in a slow rhythmic way at the rate of about thirty-six times per minute. With the same rate and rhythm, the head turned to the right side, with chin pointing upward. The right face was distorted by spasm, as in great pain. The left face was unaffected. Pressure over his right side (presumably where he struck when he fell) elicited evidences of great pain. Respiration became deep and labored, and was synchronous with each spasm. The whole simulated Jacksonian epilepsy. It is noteworthy that the knee-jerk on the right side was exaggerated by comparison with the left during the attack. Consciousness persisted unimpaired, but showed a curious and unexpected alteration. When asked what was the matter, he replied to our surprise, in his native dialect (a German dialect), " I do not understand what you say." It was found that he had lost all understanding of English, so that it was necessary to speak to him in German. His answers to our questions made it apparent that during the attack, as in his dreams, he was living through the experience of five years ago which had originally excited his trouble. The attack was plainly an hallucinatory one. He said that it was now 1898, that he was sixteen years old, that he was in Rovno (Russia), that he had just fallen because he was frightened, that he was lying on the roadside near the cemetery, and that he wanted somebody to pick him up. The hallucinatory state developed further, the patient living through, as in a dream, the whole experiences that had taken place at that period. Now he was in a carriage, though he did not know who put him there. Then in a few moments was again home, in his house, with his parents attending on him as in the onset of his first epileptiform seizures. The attack terminated at this point, and thereupon he became perfectly passive, and when spoken to answered again in English. Now he was again twenty-one years old, was conscious of where he was, and was in absolute ignorance of what had just taken place.

Disappearance of the anesthesia and automatic reproduction of the attacks. — It was found that an attack could regularly and artificially be induced if the patient in hypnosis was taken back by suggestion to the period when the accident happened.

The experiment was now tried of taking him back to a period antedating the first attack. He was told that he was fifteen years old, that is, a year before the accident occurred. Now again he could no longer speak or understand English, he was again in Rovno, engaged as a salesman in a little store, had never been in America, and did not know who we were. Testing sensation, it was found that it had spontaneously returned to the hand. *There was not a trace of the anesthesia left.* The hand which did not feel deep pin pricks before now reacted to the slightest stimulation. *Spontaneous synthesis of the dissociated sensory impressions had occurred.* Just as formerly before the accident, sensation was in normal association with the rest of his mental processes, so now this association was re-established with the memories of that period to which the patient was artificially reduced.

The patient was now (while still believing himself to be fifteen years old) taken a year forward to the day on which the accident happened. He says he is going to the ball to-night. He is now at the ball; he returns home; he is sent back to look for a ring. Like a magic formula it calls forth an attack in which again he lives through the accident, — the fright, and the spasms. With the onset of the spasm, dissociation again occurs, the *hand becomes anesthetic* and remains anesthetic after the subject is awakened.

It was thus possible to reproduce an attack at any time with clock-like precision by taking him back to the period of the accident, and reproducing by an hallucination all its details. Each time the fright and the physical manifestations of the attack (spasms, paresis, and anesthesia)

developed. These induced attacks were identical with the spontaneous attacks, one of which we had occasion to observe later.

RELATION TO VARIOUS FORMS OF NEUROSES. — This case is similar to cases of this sort which had been studied by Janet in France, Breuer and Freud in Germany, and a number of cases studied in this country by Sidis and Prince.

The question is further raised by such cases as this, whether some of those cases of fear neuroses studied by one of us (Prince) in which there are manifested all the physical manifestations of fear, without the presence of the emotion itself — thus presenting a psychic paradox — whether some of these cases have not as a foundation a subconscious and unrecognized fear.

PATHOLOGY. — This analysis enables us to understand to a large extent the pathology of the attacks. At the time of the accident the intense emotional disturbance, the fright, acted as a dissociating agent, and dissociated the sensory and motor images of one half of the body in such a way that they were no longer in *rapport* with the personal consciousness. These dissociated elements were not, however, inhibited, or incapable of functioning, as is shown by the hallucinations and other phenomena brought out in the test experiments. In cases of this kind, dissociated sensory and motor images become what is called "subconscious" and capable of automatic activity. Sensory impressions are subconsciously perceived, and motor images subconsciously excited. The dissociation (through the influence of the emotion) of these sensory and motor images and their automatic subconscious excitation *is* the attack. The original emotion, fear, remains (unknown to the subject) dissociated in the subconsciousness as a fixed state. Here from time to time it acquires a separate and independent activity. At periodic intervals, as under the stress of some emotion, or by association of ideas, its dormant activity is awakened and, though still unknown to the patient, gives rise to the same sensory-motor disturbances which characterized the original experience. These subconscious dissociated states are so much more intense in their manifestations because of being cut off, by the very fact of their dissociation, from the inhibitory influences of the normal mental life.

The pathology of such cases as this and of hysteria in general, then, consists on the one hand in the dissociation of the mental (and cerebral) processes, and on the other hand in the independent and automatic activity of the disaggregated psychic (and cerebral) states. Dissociation and automatism are the two fundamental processes.

The case furthermore gives an insight into the nature of many of the cases of "traumatic neuroses," of "psychic" epilepsy, of hystero-epileptic seizures, and of some forms of insistent ideas and impulses.

TREATMENT (*reassociation*). — Once a case of this kind has been analyzed and its pathology determined, it is possible to bring about a cure by synthesizing the dissociated mental states with the waking consciousness; or, in popular language, by making the mind whole once more. For this purpose the dissociated lost memories are brought into the full light of the waking consciousness, which is thus made to have a complete knowledge of them. So long as normal associations are maintained between the *lost memories* (or mental states) and the normal mental life, the system which before was dissociated can no longer be thrown into independent activity, and the train of symptoms to which that activity gave rise can no longer appear.

That is what we did in this case: In hypnosis he was made to realize that he was twenty-one years old; he was given a knowledge of his present life, of the subconscious states with their attacks, and was made to realize the absurdity of his really being sixteen years old. In his waking life he was made to remember all the events of the incident. The subconscious and the waking memories were thus united. During the whole course of treatment by association, a course which covered a period of several weeks, the dissociated system was coming to the surface of consciousness more frequently, and in a fuller and more developed form. The attacks were more frequent, but of shorter and shorter duration, lasting but a few hours instead of several days. Finally the system became stable and permanently associated.

After the stability of association was effected, it was found that he could no longer be made to pass into that particular hypnotic state. The subconscious fear could no longer be excited. The attacks could no longer be artificially induced; indeed the anesthesia and the spasms could no longer be developed.

Although there is no reason to suppose that he is not cured, for a complete proof of a cure (a year or more must pass), still, as the attacks cannot be artificially induced, it is not probable that they can be excited by the associations which usually call them forth.

A CASE OF STONE IN THE BLADDER IN A BOY OF FIFTEEN.

BY RICHARD FROTHINGHAM O'NEIL, M.D., BOSTON,
Assistant Surgeon, Genito-Urinary Department, Boston Dispensary; Assistant Surgeon to St. Elizabeth's Hospital.

THE following case is reported as being somewhat out of the usual run, because of the age of the patient, the size of the calculus, the peculiarity of the nucleus, and of some of the symptoms.

A. B., fifteen years old, school boy, was referred to me by Dr. E. P. Joslin for treatment. The history ofwas as follows: Family history, mother died of phthisis when he was an infant; only child. Previous history, negative.

Present illness. — Eighteen months ago he began to have trouble with his urine. It began as a "burning and scalding," with pain at the base of the penis and in the suprapubic region. He said that at one time he had had a slight discharge from the urethra and had, on one occasion, passed blood from urethra. There was no other history of venereal disease or exposure. Six months after the onset of the attack, the right testicle became swollen, and he was obliged to stay in bed for a few days. He has been getting up from two to six times every night to micturate, and during the day he suffers more from imperative than from frequent micturition. He has pain before, during, and after micturition. Urine dribbles at times, and is passed sometimes with a good deal of straining and tenesmus. He is not made worse, to any extent, by exercise. He is able to play with the boys. His urine, according to his statement, "never stopped short in the middle of a full stream, but he was unable to pass it at times unless after taking nitre."

One day in my office he was only able to pass a little urine until he had made pressure on the base of his bladder through the rectum with his finger, after which he passed several ounces; this method he had only found out in the last few days. He said the urine at times was very thick, much more so than when I first saw him. He complained of a mucous diarrhea, and had passed some blood by rectum. He had not lost weight. Appetite good. He is greatly bothered by frequent and painful micturition at night, and shows the effects of loss of rest.

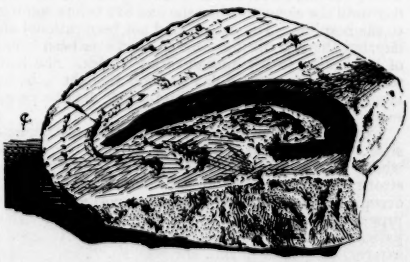
He has taken at various times solutions of potassium acetate and citrate, with tincture of hyocyamus.

Examination. — Well developed and nourished boy. Heart and lungs negative. External genitals large, nothing abnormal. Right epididymis slightly more palpable than left. Prostate a little enlarged and somewhat tender, more on the right. Urine very turbid, containing large shreds, much mucus and pus.

Chemical examination. — Pale, specific gravity 1012, acid, urea .69, albumen, trace.

Sediment. — Much pus, some bladder epithelium; no renal elements could be found.

Neither tubercle bacilli nor gonococci found after very careful search. Enormous number of mixed organisms present; the colon bacillus seemed to predominate.



There were two ounces of residual urine drawn with soft catheter. The tolerance of the bladder was between four and five ounces of irrigation fluid. There was a good deal of tenderness and resistance in the deep urethra. Examination under ether advised, the provisional diagnosis being either stone or tubercular disease.

On Feb. 22 patient entered the Deaconess Hospital, having been treated for a few days with bladder irrigation and urotropin, grs. viiss, twice a day, without benefit. Two days later, under ether, a stone was readily detected with the searcher; it was on the right side of the internal meatus, and seemed to be adherent. With the cystoscope (Nitze, size 22 being used), the rough white surface of the stone could readily be seen filling the entire field of the instrument, but the working space was so small that it was impossible to say whether or not in different fields we were looking at the same stone or multiple ones. The stone could not be felt bimanually.

Suprapubic cystotomy was decided upon and performed at once. The bladder was more distensible under ether. The peritoneum was found low down; it was pushed back out of the way, the bladder opened, and the stone delivered with some difficulty. It was found standing on end, so to speak, and had to be enucleated from a pocket it had made in the base of the bladder to which it was adherent for about two thirds of its length. This partial fixation accounts for his not having more trouble when taking exercise, the fact of the stone being a light phosphatic one probably had something to do with it also. The bladder was closed up tight around a half-inch rubber tube with plain catgut, the rest of the wound sutured with silkworm gut, and a small gauze drain put in the prevesical space. Syphon drainage was established and the bladder washed twice a day through and through by the urethra. After five days the tube was changed for a smaller one, and in four days more this was taken out, the wound drawn together, and urethral drainage established. The suprapubic wound leaked for forty-eight hours only after the tube was removed. The catheter was removed in six days and micturition was normal. The patient was up in three weeks, and out in four weeks after the operation, entirely relieved of all subjective symptoms.

Convalescence was uneventful, except on the second night after the operation, when there was a sharp reaction, due probably to infection of the raw surface of the bladder, the temperature going to 104° and the pulse to 116. There was spasm and tenderness over the left kidney and ureter. The urine was dark, and filled with blood and shreds of tissue, having the appearance of a severe hemorrhagic cystitis. There was a little albumen, but no renal elements could be found. The patient was given salt solution by rectum. The next day the temperature was 100° and normal from then on. On the fourth day the blood in the urine had disappeared. The twenty-four-hour quantity had always been sufficient, in fact a slight polyuria.

Two months after the operation the patient is perfectly well, except at times the urine is slightly turbid and contains a few shreds and slight amount of pus. This is probably due to a slight urethro-cystitis, which is gradually disappearing under urotropin and occasional irrigation. Can find no evidence of any trouble with the kidneys.

Longitudinal section of calculus. Actual size.

Examination of the calculus by Dr. R. L. Emerson of the Harvard Medical School is as follows: Dimensions, $2\frac{3}{8}$ x $1\frac{1}{2}$ x $1\frac{1}{16}$ in. composed of calcium phosphate with a little calcium carbonate, the nucleus being some gummy, resinous substance like a medicated bougie (see cut). I have been able to get no history from the pa-

tient as to how it came to be there. There has been no instrumentation of the urethra except on one occasion, a year after the onset of his symptoms, when a physician washed out his anterior urethra. The boy may have had an attack of urethritis and introduced the bougie himself as a curative measure.

I am very much indebted to Dr. F. J. Cotton for assistance during the operation. The early and excellent result obtained in this case was due in no small measure to the care with which the drainage apparatus was watched at the hospital.

A CASE OF LABOR IN AN EPILEPTIC.[1]

BY ANNIE LEE HAMILTON, M.D., BOSTON.

THE case I am to report this evening entered the New England Hospital Dec. 11, 1903, during the service of Dr. Marion Nute. The patient's physician had accompanied her because, he said, he wanted us to know that the case was one of epilepsy rather than uremia.

The family history was negative. The patient was a primipara, married; twenty-six years of age; whose general health was said to have been good excepting the epileptic attacks to which she had been subject for twelve years. The first convulsion occurred when she was fourteen years old, at her first menstrual period. The first two attacks were thought to be purely hysterical, as the patient did not lose consciousness, but twitched, struggled and threw herself about. With the third attack, she lost consciousness and foamed at the mouth. This time, it was considered true epilepsy, and since then the attacks have been more or less frequent, usually associated with the menstrual period. She sometimes had as many as two or three attacks in a week. During her pregnancy they were less frequent up to the sixth or seventh month, then rather more frequent between the seventh and eighth months.

Up to Dec. 8 (four days previous to her entrance), she had not had a convulsion for four weeks. On Dec. 8 she had three, and two or three on each ensuing day until the eleventh when she had five before coming to the hospital. The patient had not been rational all day, but this was the first time she had ever been "out of her head" to her husband's knowledge. She had seemed to be in pain all day and was thought to be in labor. She was about eight and a half months pregnant.

Examination showed the patient to be a medium-sized, dark-complexioned, young woman, face somewhat cyanosed; unconscious; rather restless; pulse strong, full, regular. Heart normal. The fetus occupied the right sacro anterior position, breech presenting. The heart was loud and strong. The patient's pelvic measurements were fairly good; external conjugate 19 cm., ant. sup. sp. 22 cm., crests 24.5 cm., between trochanters 29 cm. Internal examination showed the os dilated to the size of a quarter, with a small part presenting, and the diagnosis of footing presentation was made.

The patient resisted examination, throwing herself about on the table and appearing to have severe pain. Just as she was taken from the table she had another attack, lasting three minutes. A hasty examination of the urine showed specific gravity 1,030, reaction acid, merest trace albumin, urea 2.14%. At seven o'clock the patient had another attack lasting about three minutes. This appeared as follows: The eyes became fixed and staring, jaws tightly closed and whole body rigid; the face cyanosed, and the head turned to the left side. The breath held and finally caught with a great gasp. Then the twitching of face, hands and whole body began, at first fine, later of greater amplitude, then ceasing altogether. The face regained its normal color and the patient sank into a stupor, snoring loudly, foam escaping between the lips. There was no cry with this attack. She remained in this stupor for about an hour gradually recovering consciousness sufficient to answer questions in a stupid way. It was decided to dilate manually and deliver. As the patient now resisted manipulation very little and as it was felt that the smallest amount possible of ether should be given, the dilatation was started without an anesthetic and continued until nearly complete. As the pains now started in with renewed energy (they had been occurring at intervals of ten minutes all the evening) it was decided to see what work the presenting part would do in dilatation, and manipulations were stopped for the time. We did not wish to rupture the membranes, as the cord was coiled in the presenting pouch. At 11 P.M. she had another convulsion resembling the one described, but beginning with the true epileptic cry and lasting somewhat longer. The fetal heart remained strong, but we decided that it would be better to delay delivery no longer and, as soon as the patient's breathing and color improved sufficiently, started the ether, completed dilatation, ruptured the membranes and delivered a living male child somewhat asphyxiated but soon resuscitated by immersing alternately in hot and cold water and which cried quite vigorously. Child's weight 2,170 gm., about 4¾ lbs. The placenta and membranes intact were expelled five minutes later. There was no laceration. The patient's pulse was 132, strong and full. She soon apparently recovered from ether, but did not recover consciousness. Rested quietly until 3 A.M., when she had another convulsion lasting about three minutes, resembling those described. After this she slept five hours. At 8 A.M., Dec. 12, she seemed rational and gave clearly some of the details for the birth certificate, but could not remember her street or number. She took nourishment readily. In the afternoon she became more stupid and answered no questions except when asked if she had seen her baby, when she answered "No."

Dec. 13, third day, T. 98.6°, P. 68, R. 20.

Patient seemed more stupid to-day; her appearance has changed. In the morning she had a fixed stare and seemed to hold her face and jaw perfectly rigid. Her body was stiff and she clutched the bedclothes with arms rigidly extended. She drooled from the mouth. Respiration stertorous, could be plainly heard outside the room. Pupils even, rather dilated. Tongue slightly coated. When asked to show it, and chin tapped with the finger, the mouth was slightly opened and the tongue very slightly protruded. In the afternoon another change came. She became much more restless, the limbs moved constantly, and her whole body twitched, her face worked and her eyes rolled, with staring expression. Several times it was thought that she was about to have another convulsion, but she did not. She attempted to sit up in bed once or twice. Her breathing could still be heard outside the room. She did not show any intelligence whatever except when the baby was mentioned. When asked what she would name it she brightened up and said, "Charlotte." It will be remembered that the child was a boy. Evening, T. 99.4°, P. 92,

[1] Reported at the meeting of The Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, March 23, 1904.

R. 22. Catheterization necessary. There was no more albumin and the urine was reported normal. Feces were passed in the bed.

Dec. 14, fourth day, T. 99.2°, P. 56, R. 20. The patient did not sleep all night; was very restless but quieted by sodium bromide. Constantly moving all day, but did not speak until evening when she asked to see her baby. It was brought and she said she would name it Charlotte, she kissed it and showed considerable interest in what was going on around her. She passed urine and feces involuntarily. When the urine was not passed for eight hours she was catheterized. She took nourishment readily and would take a piece of bread in her own hand and eat it. P.M., T. 99.8, P. 68, R. 22.

Dec. 15, fifth day, A.M., T. 99.2°, P. 56, R. 20. Patient rested better during the night. In the morning the twitching had ceased and she lay perfectly rigid in bed. Did not appear as bright as last evening. Asked for her baby and showed interest in it. After dinner she began repeating short sentences over constantly to herself. She said, "I'm going to keep it, anyhow — papa won't let him come home, but I'm going to keep it, anyhow." Visited by her husband and sister, she recognized the sister, but did not admit that she recognized the husband; it was thought that she did, however. T. 99°, P. 60, R. 18, P.M.

Dec. 16, sixth day, A.M., T. 98.6°, P. 60, R. 22; P.M., T. 99.6°, P. 60, R. 20. Answered some questions in a rational manner, at other times stared vacantly at the questioner. Went to sleep at 10 A.M. and slept, except when wakened for nourishment, etc., the entire day and until early next morning.

Dec. 17, seventh day, T. 98.6°, P. 72, R. 20. Talked incessantly all day in an irrational way, was very restless, insisting upon sitting up, and once jumped out of bed. Dr. James J. Putnam was asked to see the patient in consultation. He thought no definite opinion of the case could be given as yet. It might be simply a post-epileptic condition which would clear up or possibly would develop into a puerperal mania. Advised very close watching. No special change in the treatment. With the next day came a marked change.

Dec. 18. Patient slept from 11.30 to 5.30, waked up quite rational, told of various affairs in her early life, and although she wandered a little at times kept to the line of thought remarkably well. After this she improved steadily and by Dec. 25 was "looking brighter than for some months," the family said. The pelvic condition was good from the first, and Dec. 22 the patient sat up in a chair and felt very well.

Dec. 29. In the morning while sitting in a chair reading, she had a convulsion and fell on the floor. This attack lasted about three minutes but was not severe; patient slept only fifteen minutes afterwards and then sat up apparently all right. When asked if she had had any warning of the attack, she said she had felt very well and had had no queer sensations such as she used to have before attacks. There was no cry.

Dec. 31. Patient sent home; general condition very good. Pelvic condition good.

With regard to the treatment while in the hospital it was chiefly symptomatic. Elimination was carefully looked after, the bowels moving several times daily. The nervous symptoms were treated with sodium bromide and hydrotherapy.

In response to a note sent to the husband I learn that since the return home her convulsions have been decidedly less frequent. This is no doubt due to the fact that she is kept under the care of her physician who is treating her with bromide.

The baby did very well for the first week, but after that looked badly and did not gain although he took his food well and apparently digested it. During the second and third week he failed perceptibly. When the patient was sent home, the child did not accompany her, but was cared for outside by a nurse, and lived only one week after leaving the hospital, dying in convulsions.

In looking in rather a hasty way over the literature of the past twenty-five years, I find very little reported with regard to this condition. It is apparently an unusual one as, although puerperal convulsions are unfortunately very common, they are, as a rule, due to uremia.

Edgar, in his "Practice of Obstetrics," says: "Epilepsy is a rare complication, because epileptics are usually sterile, and if gestation does occur are often free from an attack during pregnancy, the disease returning during the lying-in state. It may be confounded with an eclamptic attack. Children born of epileptics usually die of congenital epilepsy when quite young." Various other authors whose books I consulted do not speak of the condition, or only mention it in passing on to eclampsia.

Eben Duncan, Glasgow, who has made a study of the subject, says: "The discovery of albumin in the urine of a woman who has had several epileptiform convulsions is not necessarily evidence of uremia. It has been proved that albumin is the effect and not the cause of the fits."

In conclusion, I wish to thank Dr. Nute for permission to report the case, and Dr. Blanche Boyle, who was interne during the service, for her excellent notes from which I have drawn freely in writing this paper.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION. SECTION ON PRACTICE OF MEDICINE.

(Continued from No. 24, p. 654.)

SECOND DAY. JUNE 8. — (Continued.)

A STUDY OF ONE HUNDRED AND EIGHTY-SIX CASES OF MITRAL AND TRISCUSPID STENOSIS.

DRS. JUDSON DALAND and E. L. MCDANIEL, of Philadelphia, made a report on a heart showing mitral and tricuspid stenosis, and gave an analytical and statistical study of 186 cases of this affection that had appeared in literature from 1809 to 1904. In 157 cases the age of the cases, 14%, occurred between the ages of ten and twenty, 40% between twenty and thirty, 26% between thirty and forty, 12% between forty and fifty, 4% between fifty and sixty, and 1% between the ages of sixty and seventy. Males were afflicted in 21%. All cases occurred in the white race. In 21% of the cases it was distinctly stated that rheumatism was not the cause. From the observations made, the only important known cause of this affliction

was rheumatism. Difficulty in breathing occurred in 35% of the cases; dropsy occurred in 34%, cough in 9%. Pericardial pain and distress 12 cases, epigastric 3 cases, angina pectoris one case. Asthenia 10 cases. Hemoptosis 6 cases, vertigo 5 cases, embolism 3 cases, jaundice 3 cases, vomiting 3 cases. In 31 cases the apex beat was in the fifth or sixth interspace. Presystolic murmur was heard in the mitral area in 41 cases; in the tricuspid area in 11 cases. The systolic murmur was best heard at or near the apex in 30% of the cases, and over the base of the heart in 15%. In 31 cases a presystolic thrill was observed at the apex, and in 9 cases a systolic thrill. Aortic stenosis was discovered in 30% and aortic insufficiency in 16 cases. The average weight of the heart was 15.8 oz. Albuminuria was present in 37 cases.

PLEURAL EFFUSIONS IN HEART DISEASE.

DR. J. DUTTON STEELE, of Philadelphia, presented this paper. He said that he had already called attention to the fact that passive pleural effusion might occur in the course of failing compensation of the heart, before there was any tendency to external dropsy, and that this pleural effusion was very often unilateral, with a preference for the right side. This conclusion had been arrived at from a study of 75 autopsies and a series of 17 cases which Dr. Stengel's had investigated. It was the general opinion that hydrothorax was apt to occur before general edema, though many observers had reported isolated cases of right-sided cardiac hydrothorax. In deciding between cases of cardiac effusion and effusion from other causes, it was required that there should be decided evidence of myocardial disease and enlargement of the heart, and also that the cardiac condition should be predominant. A very interesting point shown by a study of these cases was that while right-sided effusions occurred with enlargement of the right heart, left-sided effusions were usually associated with the left side of the heart. The theory that appeared to explain most satisfactorily the preference of these pleural effusions for the right side, supposed that enlargement of the heart and especially of the right auricle could press upon the root of the right lung and obstruct the vena azygos major. However, the pressure of a dilated auricle upon the root of the left lung would not obstruct any large venous trunk analogous to the vena azygos major. He could not explain this, but could only call attention to the fact that left-sided cardiac dilatation seemed to bear some relation to left-sided pleural effusions. The effusion in certain cases was very obstinate, lasted a long time and returned quickly after aspiration. It was important that we should recognize that such effusions occurred in heart disease in the diagnosis of both cardiac and pleural affections.

PROLONGED DELIRIUM IN PERICARDITIS AND ENDOCARDITIS, WITH THE REPORT OF A CASE.

DR. E. M. GREENE, of Easton, Pa., said that all the authorities that he had consulted, while recognizing delirium as a frequent symptom in severe cases of pericarditis, especially where there was effusion, spoke of the delirium as being of short duration with marked cerebral symptoms, and usually associated with hyperpyrexia. He reported a case of acute rheumatism followed by endocarditis and with slight pleurisy with effusion. At the onset respiration ran up to 37 or 38 per minute, pulse to 100 to 108, temperature 100° to 101° F. Auscultation revealed symptoms of acute pleurisy and a systolic murmur over the pericardium, but more intense at the apex. His delirium lasted for five weeks; dyspnea was always present as was also cyanosis. The degree of fever was not sufficient to account for continuance of delirium through so long a period. Recovery took place slowly, but within a few months after the patient had returned to work, he was able to exercise at an elevation of 10,000 feet without discomfort, and subsequent physical examination revealed no marked lesion.

THE LIMITATION OF DIGITALIS IN MITRAL AND AORTIC REGURGITATION.

DR. FRANK JONES, of Memphis, Tenn., reviewed the anatomy and physiology of the heart. He said that the mitral valve located at the gateway between the great arterial reservoir, the left auricle and the arterial pumping station; the left auricle when it failed to close in systole threw its burden on various organs, the right heart, lungs, liver and kidneys. When compensation had failed or was failing the pathological picture was venous stasis. Edema and bronchitis would result in proportion to the degree of obstruction and stasis and the condition of the cardiac muscle. Nutrition was profoundly disturbed as a result of this stasis and engorgement. With this clinical picture there was no necessity of dwelling upon the marked effects of digitalis in mitral insufficiency with failing compensation. On the other hand digitalis was contra-indicated in aortic regurgitation. By anatomic location and physiologic action of the valves, when the aortic valve became incompetent and could not close with diastole, we had a backward column of blood thrown upon the left ventricle. In its effort to relieve the valve it becomes hypertrophied and there is a high blood tension. There frequently exists a well defined arteriosclerosis. He thought that to give digitials in such a condition was useless. Hyperemia venous stasis and dropsy are late symptoms, and in the majority of cases, when they do appear, the fault is at the mitral valve. The right and left ventricles are both so worn out that the administration of digitalis is useless or even harmful. Digitalis only increases the work of the ventricle while the ventricle calls for blood. When compensation fails the left ventricle goes to pieces. There was no justification for the use of digitalis in aortic regurgitation, no matter what might be the condition of the heart muscle. After a careful study of bountiful clinical material he was convinced that there was but one valvular lesion where digitalis was indicated, and that was mitral insufficiency, and then not until compensation had failed.

SOME POINTS IN THE ACOUSTICS OF RESPIRATION.

DR. CHAS. E. QUIMBY, of New York, presented this paper to demonstrate the following propositions: (1) The tracheal note represented the interference of pitch limit of respiratory sounds, and that limit might be defined by a letter of the musical scale, as might every other respiratory pitch. (2) In vesicular respiration, the inspiratory sound represented the superior pitch limit of respiratory sound. (3) The passage from vesicular respiration to bronchial breathing was attended, at first, by a lowering in pitch of the inspiratory note, and later by lowering of both inspiration and expiration. (4) In vesicular breathing the inspiration was of a higher pitch than expiration; in rude, bronchial and tracheal breathing, the inspiration was of a higher pitch than, or the same pitch as, expiration. There was no respiration resulting from consolidation in which expiration was of higher pitch than inspiration.

(To be continued.)

THE BOSTON
Medical and Surgical Journal.
THURSDAY, JUNE 23, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

REPORT OF ROYAL COMMISSION UPON HUMAN AND ANIMAL TUBERCULOSIS.

THE Royal Commission appointed by King Edward has, on May 16, 1904, published an Interim Report upon the following points:

(1) Whether the disease (tuberculosis) in animals and man is one and the same.

(2) Whether animals and men can be reciprocally infected with it.

(3) Under what conditions, if at all, the transmission of the disease from animals to man takes place, and what are the circumstances favorable or unfavorable to such transmission.

The greater part of this inquiry is directed to the view which had been expressed, that the bacillus which gives rise to tuberculosis in the bovine animal is specifically distinct from the bacillus which gives rise to tuberculosis in the human being, and that therefore the presence of the bovine bacillus in the milk or flesh of the cow, consumed as food by man, is not to be regarded as a cause of tuberculosis in the latter. To this point the Commission first gave its attention, and began the investigation, not by taking evidence, but by conducting experiments of its own.

The first line of inquiry may be stated as follows: What are the effects produced by introducing into the body of the bovine animal (calf, heifer, cow), either through the alimentary canal as food, or directly into the tissues by subcutaneous or other injection, tuberculous material of human origin, *i. e.*, material containing living tubercle bacilli obtained from various cases of tuberculous diseases in human beings, and how far do these effects resemble or differ from the effects produced by introducing into the bovine animal, under conditions as similar as possible, tuberculous material of bovine origin, *i. e.*, material containing living tubercle bacilli obtained from cases of tuberculous disease in the cow, calf or ox?

Material from more than twenty cases of tuberculous disease in human beings, was used in the experiments, including sputum from phthisical patients, diseased parts of lungs in pulmonary tuberculosis, tuberculous mesenteric, bronchial and cervical glands and tuberculous joints. The effects produced by these were compared with those produced by different strains of tuberculous material of bovine origin. In the case of seven of these strains of human origin, the introduction of the human tuberculous material into cattle gave rise at once to acute tuberculosis with the development of widespread disease in various organs of the body, such as the lungs, spleen, liver, lymphatic glands, etc. In some instances the disease was remarkably severe. In the remainder, the bovine animals were affected to a less extent, the disease being limited to the spot where the material was first introduced, or spread to a variable extent from the seat of inoculation along the lymphatic glands; but further transmission from these animals to other bovine animals ultimately gave rise in the bovine animal to general tuberculosis of an intense character. "We have very carefully compared the disease thus set up in the bovine animal by material of human origin, with that set up in the bovine animal by material of bovine origin, and so far we have found the one, both in its broad general features and in its finer histological details, to be identical with the other. We have so far failed to discover any character by which we could distinguish the one from the other; and our records contain accounts of the post-mortem examinations of bovine animals infected with tuberculous material of human origin, which might be used as typical descriptions of ordinary bovine tuberculosis." "The results which we have thus obtained are so striking that we have felt it our duty to make them known, without further delay, in the present Interim Report."

A further detailed report containing the results of experiments on more than two hundred animals, together with the discussions dealing with the influence of dose, of individual and of racial susceptibility etc., is in preparation. "Meanwhile we have thought it our duty to make this short report, for the reason that the result at which we have arrived, namely, that tubercle of human origin can give rise in the bovine animal to tuberculosis identical with ordinary bovine

tuberculosis, seems to us to show quite clearly that it would be most unwise to frame or modify legislative measures in accordance with the view that human and bovine tubercle bacilli are specifically different from each other, and that the disease caused by the one is a wholly different thing from the disease caused by the other."

The report is signed by all the members of the commission, namely, Professors Foster, Woodhead, Martin, McFadyean and Boyce.

DEDICATION OF THE NEW LABORATORIES AT THE UNIVERSITY OF PENNSYLVANIA.

WE commented some weeks ago on the prospective dedication of the new medical laboratories for the University of Pennsylvania. This dedication took place as arranged on the tenth of this month, and is to be regarded as one of the most significant events in the entire history of the university. Nearly twenty-two thousand invitations were sent to physicians in various parts of the world, among whom were included about six thousand graduates of the medical department of the university. The ceremonies were also so arranged that the members of the American Medical Association, which held its annual meeting at Atlantic City from the seventh to the tenth of June, could attend in a body.

In the absence of Dr. Weir Mitchell, it devolved upon Mr. J. Vaughn Merrick, a trustee of the university, to make the address of presentation. He drew attention to the extraordinary development of the institution during the time he had been connected with it as trustee, and expressed the hope and expectation that the new and extensive buildings would be the center of many useful discoveries in the future. The laboratories were formally accepted by Dr. Charles C. Harrison, provost of the university, who, in his felicitous remarks, forebore to urge the need of endowment which, nevertheless, he mentioned in a way to suggest to prospective benefactors a means of wise expenditure. Prof. H. P. Bowditch of Harvard University, in his address, spoke of the proper relation of the sciences, laying special stress upon physiology, the subject with which his name has been identified. In developing his subject, he alluded to the desirability of preceding the study of physiology by anatomy, and drew attention to the plan practiced in the Harvard Medical School since 1899, of devoting three half years successively to anatomy, physiology and pathology, thereby bringing about concentration of work and sequence of subjects. He maintains that this plan, now given four years' trial, has been successful. Dr. Bowditch proceeded to discuss the laboratory method of training and its limitations, and spoke a word in favor of the generally ostracized didactic lecture. He considered that both the laboratory and the lecture room were valuable as educational agencies, and that we should find a way of combining the two forms of instruction which should by no means completely do away with the lecture, and yet should give the practical laboratory instruction a large place.

Prof. R. H. Chittenden of the Sheffield Scientific School of Yale University spoke of the laboratory as a foundation stone upon which is to be reared our temple of knowledge, and urged the absolute necessity for the student, of personal work in laboratory methods. The history of physiological chemistry, a comparatively new science as applied to medicine, he sketched from its inception in about 1872 to its present wide development, both in this country and abroad. The importance of the subject, he ventured to prophesy, would continually increase in the near future, and come to occupy a more and more conspicuous position among the diversified branches of applied science. Dr. George Dock of the University of Michigan discussed the history of medicine from an early period down to the present time in succinct fashion. His special plea, coming down to the immediate needs of the present, was for a completer cultivation of pathological anatomy by the medical student and the physician, although he warned against the elevation of the laboratory in certain institutions as possibly leading to a top-heavy way of teaching by encouraging students to do advanced original work before their foundation was sure. He bewailed also the neglect, or at times objection to, autopsies, particularly in this country, in which he saw an inferiority to European methods. On this he said: "The difficulty in respect to autopsies does not depend on public sentiment alone, but on a certain neglect on our own part. I think we may hope that as pathology gets everywhere out of cellars and back rooms, and has localized habitation such as we see here, its cultivation will assume a broader and more independent character."

The formal exercises were brought to a conclusion by the address of Dr. Horatio C. Wood of the University of Pennsylvania. He, again, was somewhat retrospective, as no doubt the necessities of the occasion demanded, and also naturally spoke of the development of and necessity

for laboratories such as those now being dedicated. He spoke feelingly also of the burden of excessive teaching imposed upon men whose best efforts should be put into original investigation, a matter which should receive far more attention in our medical institutions than has hitherto been given it. Finally, he urged that we do not in the future forget laboratories in our eagerness to endow hospitals. It will not do to "prune the upper branches of that tree of knowledge which is for the healing of the people and to forget to keep alive the root which is the source of all continuing growth and fruitage."

In general, the occasion was memorable in more ways than one. It brought together a distinguished body of professional men; it emphasized, as has rarely been emphasized before in this country, the need and place of the laboratory in the general scheme of medicine, and enforced the lesson that, after all, the best medical education must come from the proper insistence upon the various methods of instruction rather than upon an undue devotion to any one. The addresses, the gist of which we have indicated merely, were peculiarly temperate in tone and represented the judicial frame of mind which has resulted from the ferment of the past few years.

MEDICAL NOTES.

A Centenarian. — Andrew Bradley, reputed to be one hundred and four years of age, died at the Soldiers' Home in Noroton, Conn., June 17.

Graduating Class of Johns Hopkins Medical School. — Forty-five degrees of doctor of medicine were conferred upon forty-two men and three women at the twenty-eighth commencement of the Johns Hopkins University recently held. The small proportion of women is worthy of note.

Smallpox in Chicago. — According to the bulletin of the Chicago Health Department for the week ending June 18, five cases of smallpox were discovered and removed to the isolation hospital during that week, none of whom had ever been vaccinated. The victims were all persons so employed as to be liable to spread the disease.

Boiler Explosions. — It is stated that statistical inquiry into boiler explosions during the year 1903, shows that the total number of explosions was 383, the total number of persons killed being 293, and the total number injured 522. This is a somewhat favorable showing as compared with previous years, but nevertheless is an extraordinary list of fatalities from a cause which might be regarded as preventable.

Railway Accidents. — According to *American Medicine*, during the last three months of 1903 the casualties on the railways of the United States amounted to more than 2,000 among passengers alone, 175 being killed. The casualties to employees were more than 12,000, about 1,000 being killed outright. The disproportion between the accidents to passengers and employees at least speaks well for the general care taken by the railway companies.

Philippine Government Exposition. — The largest single exhibit at the St. Louis World's Fair is the Philippine Government exposition. It is designed to combine a scientific interest for students of politics, civilization, economics and ethnology. It will also aim to demonstrate the grades of civilization of the various races found on the Island. The design of this exposition is to show what has been done and what is being done in the Philippines.

Honorary Degrees to Medical Men. — At the recent commencement exercises at the University of Pennsylvania the following honorary degrees were given to physicians: Doctor of Laws, Sir Frederick Treves, who has been on a tour through the western part of the country; Dr. H. P. Bowditch of the Harvard Medical School; Dr. H. C. Wood of the University of Pennsylvania. The degree of Doctor of Science was given to Prof. Russell Henry Chittenden of Yale University, and Dr. George Dock of the University of Michigan. It is of interest to note that of the seven honorary degrees conferred five went to medical men, due probably to the fact of their presence and participation in the recent opening of the new medical laboratories. It is, however, in general, observable that physicians have been honored by degrees in the past few years more widely than heretofore.

The Question of Doctors' Fees. — It is reported that a judge in St. Louis has recently given expression to the opinion that the financial condition of the patient should not be considered by the physician in his charge for professional services. The statement was that the character of the service, the seriousness of the complaint, the skill and time required, and the result reached, are elements to be considered, but not the wealth or poverty of the patient. This decision was handed down in a case against a physician for

an alleged exorbitant fee. However just such a decision may be theoretically, it is clear that its practical consequences would not conduce to complete justice. It would, for example, be an exceeding hardship to the poor, if only such considerations as those suggested by the presiding judge were taken into account. Doctors' fees, like lawyers' fees, must no doubt in general be determined by all the circumstances of the given case, among which the poverty or wealth of the patient must be given due weight.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 22, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 59, scarlatina 13, typhoid fever 15, measles 45, smallpox 0.

DONATION TO DARTMOUTH COLLEGE MEDICAL SCHOOL. — It is announced that the New Hampshire Medical Society, at its annual meeting, voted to donate $1,000 to Dartmouth College toward the erection of the new building for the medical school.

THE ADAMS NERVINE HOSPITAL. — According to the annual report of the resident physician of the Adams Nervine Asylum, the number of admissions during the year was 108, being eleven less than last year, and the total number under treatment was 149, or ten less than last year. It is stated that 86% of the present work of the year has been for patients who were wholly or in part beneficiaries of the asylum. The total number of free admissions was forty-five, the largest number in any one year since the asylum opened. The large amount of charitable work which this excellent institution does is not generally known in the community.

NEW YORK.

A NEW MEDICAL SCHOOL. — It is announced that in the autumn St. John's College at Fordham, Borough of the Bronx, which has hitherto not aimed to be classed as a university, will open a medical department. Later a law school is also to be established.

HOSPITAL FOR MALTA. — Mr. Henry L. Clapp, a New York merchant now residing on the Island of Malta, has announced his intention of erecting a hospital on American lines there, and has commissioned a firm of New York architects to prepare plans for the building.

THE LATE DR. J. M. POLK. — At the last meeting of the Medical Association of the Greater City of New York, Dr. Henry P. Loomis read an interesting obituary of Dr. John Metcalfe Polk, the son of Prof. William M. Polk of Cornell University, a young man of unusual promise, who died recently of pneumonia. He was graduated from Yale in 1896, and from Cornell University Medical College, with honor, in 1899, being a member of the first class graduated from that school. After serving for two years as interne in Bellevue Hospital he went to Vienna to perfect himself in pathology and medical diagnosis, and on his return from abroad was appointed Instructor in Medicine and Physical Diagnosis in the Cornell Medical College and Assistant Visiting Physician to Bellevue Hospital. Although not yet twenty-nine years of age, at the time of his death he had completed an exhaustive original study of pneumonia, and was about to publish a paper on the blood changes in that disease, which promised to bring to the attention of the profession some very important and original ideas.

WORK OF FRESH AIR DEPARTMENT. — The fresh air department of the New York Society for Improving the Condition of the Poor has recently opened a seaside tent-camp for young children suffering from tuberculosis of the bones and glands. It is situated in the vicinity of "Sea Breeze," Coney Island, the summer settlement of the Society, and at present affords accommodations for fifty patients. It is estimated that there are in the tenement houses of New York from three thousand to four thousand children under fifteen affected with non-pulmonary forms of tuberculosis. Dr. E. Franklin Smith is one of the committee in charge of the camp, and among the physicians and surgeons on the advisory board are Drs. E. G. Janeway, H. M. Biggs, N. M. Shaffer and V. P. Gibney.

Miscellany.

INCIDENTS OF THE BURNING OF THE "GENERAL SLOCUM."

THE bright features connected with the appalling catastrophe on the steamboat "General Slocum" were the heroic efforts of the watermen, the police, the physicians and the nurses, who saved hundreds at the risk of their own lives, the prompt and efficient aid rendered by all the city departments in an unusual emergency, and the generous response of the public to the Mayor's call for financial assistance. North

Brother's Island, where the burning boat was run ashore, it will be remembered, is the location of the Health Department's Riverside Hospital for contagious diseases. On it there is also now a tuberculosis hospital. Dr. Darlington, the President of the Department, was very early on the spot, and afterwards gave a graphic description of the events on the island. "I shall never be able to forget the scene — the utter horror of it," he said. "The patients in the contagious wards, especially in the scarlet fever wards, went wild at the things they saw from their windows, and went about screaming and beating at the doors, until it took fifty nurses and physicians to quiet them. Along the beach the boats were carrying in the living and dying and towing in the dead. We wrapped the living in blankets and gave them milk and whiskey. We used a barrel and a half of spirits to good purpose in reviving the sufferers and keeping the rescuers from getting so chilled that they could not go on with their work. One hundred and fifty doctors and nurses worked over the injured and remained at their posts all night — women and men alike. They did the work of heroes, and did it well." Efficient aid was also given by a number of the convalescents and tuberculosis patients. At the morgue and the neighboring dock of the Charities Department at the foot of East 26th Street, where hundreds of dead bodies were laid out for identification, many grief stricken persons attempted to throw themselves into the river, and it required the constant vigilance of the police to prevent such suicides. Of the injured some two hundred and sixty were taken to various hospitals after the disaster.

Correspondence.

ANNUAL MEETING, AMERICAN MEDICAL ASSOCIATION, JUNE 13, 1904.

BOSTON, June 17, 1904.

MR. EDITOR: The Fifty-fifth Annual Meeting of the American Medical Association, held last week at Atlantic City, presented a striking contrast to the Fourteenth International Medical Congress held a year ago at Madrid. In handling a large number of strangers, the Americans have the advantage of knowing how. For the abundance of hotel and railroad accommodation the Association is not responsible except that it chose such a favorable place. In Madrid practically all of the visitors had taken a long railway journey and very few of them could understand the language of the country. The lodging was inadequately handled, while at Altantic City even those who decided at the last moment to come found plenty of room, and no increased charge. The reduction of railway rate was substantially the same in each case. The foreign method of issuing tickets is a time-consuming process. Here in this country the delegates have not all become familiar with the details of the "certificate plan." Some who did not leave their certificates with the railroad office when they first arrived found some delay in getting them signed by the secretary of the transportation committee. The registration office was adequate and efficient even during the rush hours of Tuesday morning. The directions as to the meeting places of the sections were clear and explicit. Unfortunately, one of these had to be changed during the session, but the delay and confusion were inconsiderable. In Madrid the National Government was interested in the Congress and did its part well. The opening session in the royal opera house was a brilliant spectacle. The reception to delegates in the royal palace and the garden party for delegates and ladies were faultless in management and thoroughly enjoyable. The closing session at the hall of the University was somewhat marred by the feeling that there had been mismanagement in regard to the details of the Congress. At Atlantic City the arrangements for the comfort and convenience of members was excellent, the meeting places of the sections were good and not too far apart. The hall selected for the general meetings and the Section on Practice of Medicine proved to have very poor acoustic qualities. The Presbyterian church was substituted and proved adequate though not ideal.

The members in the different sections felt that the business of the session was being well taken care of by the house of delegates which met in the High School building. The efficient organization of each section and the hard work of the secretaries resulted in a program which could be carried out on time, thus leaving room for animated, entertaining and instructive discussion. At Madrid the very slender organization of the Congress — it meets but once in three years — made it very difficult for members to know when certain papers would be read. This was especially true of the general sessions. At Atlantic City the general sessions were the best features on the program.

The success of the convention was chiefly due to the committees of arrangement, the officers of the sections, and the members who read papers. Each and all put in *hard work*. The Association is to meet in Portland, Ore., next year and possibly the year after in Boston. The message of encouragement and inspiration which it sends to all who read the transactions is *work hard*.

One of the most earnest and practical gatherings was the symposium on Venereal Diseases held by the Section on Hygiene and Sanitary Science. It is destined to have far-reaching importance. The committee propose to regard syphilis and gonorrhea from the point of view of the innocent and not from the standpoint of prostitution. Indifference is the only method yet applied to these diseases, and that has been found wanting. By concerted action the State and Provincial Boards of Health propose to ask all physicians to report annually the number of cases of these diseases treated; whether male, female, married, or single. They also propose to furnish every physician with circulars issued under the sanction of the American Medical Association, which he may give to his patients if he thinks best. It is also proposed to conduct a campaign of education in every way that seems advisable. The amount of legislation required is not very great or very radical. The discussion showed encouraging signs of an awakening of interest among the profession and the public in the means at hand to prevent the spread of these two diseases.

Very truly yours,
CALVIN G. PAGE, M.D.

SANITARIUM vs. SANATORIUM.

WASHINGTON, D. C., June 18, 1904.

MR. EDITOR: The recent note in your JOURNAL on "Sanatorium and Sanitarium" led me to some dictionaries. The many sanitariums probably took the name without special thought, and one in Massachusetts lately changed from sanitarium to sanatorium.

The Standard Dictionary, published by Funk & Wagnalls, New York, gives as the first definition of sanitarium, "a sanatorium: sometimes restricted to a place where the hygienic conditions are prophylactic or preservative of health, as distinguished from one where therapeutic agencies are employed." From the Latin "*sanatorius*," health-giving.

The Century Dictionary, which is one of the best, says, "Sanatorium, a place to which people go for the sake of health; also, a house, hotel, or medical institution in such a locality, designed to accommodate invalids." It gives only one comment under sanitarium, "an improper form for sanatorium."

Yours truly,
A. ERSKINE MILLER, M.D.

Deaths reported, 2,919; under five years of age, 800; principal infectious diseases (smallpox, measles, cerebro-spinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 723; acute lung diseases 173, consumption 363, scarlet fever 25, whooping cough 12, cerebrospinal meningitis 60, smallpox 3, erysipelas 6, puerperal fever 9, measles 28, typhoid fever 41, diarrheal diseases 114, diphtheria and croup 62.

From whooping cough, New York 6, Chicago 3, Pittsburg 2, Beverly 1. From smallpox, Baltimore 2, New York 1. From cerebrospinal meningitis, New York 54, Chicago 1, Providence 1, Boston 3, Gardner 1. From typhoid fever, New York 5, Chicago 1, Baltimore 3, Philadelphia 16, Pittsburg 10, Springfield 2, New Bedford, Somerville, Waltham and Newburyport 1 each. From Erysipelas, New York 4, Philadelphia 1, Pittsburg 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending May 28, the death-rate was 15.4. Deaths reported 4,507; acute diseases of the respiratory organs (London) 80, whooping cough 163, diphtheria 41, measles 205, smallpox 4, scarlet fever 27.

The death-rate ranged from 3.9 in Kings Norton to 22.8 in Hanley; London 14.3, West Ham 13.7, Brighton 18.2, Southampton 10.7, Plymouth 20.1, Bristol 12.6, Leicester 14.2, Nottingham 18.9, Birkenhead 15.4, Liverpool 17.9, Bolton 19.0, Manchester 18.6, Salford 18.2, Bradford 19.9, Leeds 19.0, Hull 17.7, Sheffield 16.7, Cardiff 13.6, Rhondda 19.2, Wigan 18.3, Merthyr Tydfil 15.8, Northampton 11.4, Norwich 14.4.

METEOROLOGICAL RECORD.

For the week ending June 11, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

ERRATUM.

The statement in the JOURNAL June 9, p. 630, that Dr. E. L. Trudeau was present as a delegate from the United States at the International Tuberculosis Congress in Copenhagen, May 27, was incorrect. Dr. Trudeau did not go to Copenhagen.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING JUNE 18, 1904.

HART, G. G., acting assistant surgeon. Ordered to the "Reliance" for temporary duty, and on arrival of that vessel at Culebra, W. I., detached and ordered home to wait orders.

MINK, O. J., and F. E. PORTER, assistant surgeons. Appointed assistant surgeons with rank of lieutenant, junior grade, from June 7, 1904.

CHAPMAN, R. B., assistant surgeon. Detached from the naval hospital, Mare Island, Cal., June 27, and ordered to the Navy Yard, Washington, D.C.

BOOKS AND PAMPHLETS RECEIVED.

University of California Publications. Physiology. The Action of Cascara Sagrada. By John Bruce MacCallum. 1904.

University of California Publications. Physiology. The Possible Influence of the Amphoteric Reaction of Certain Colloids upon the Sign of their Electrical Charge in the Presence of Acid and Alkalis. By Jacques Loeb.

Concerning Dynamic Conditions which contribute toward the Determination of the Morphological Polarity of Organisms. By Jacques Loeb. 1904.

Medical and Surgical Report of the Presbyterian Hospital in the City of New York. January, 1904.

Modern Ophthalmology. A Practical Treatise on the Anatomy, Physiology and Diseases of the Eye. By James Moores Ball, M.D. Illustrated. Philadelphia: F. A. Davis Co. 1904.

Unconscious Therapeutics; or, the Personality of the Physician. By Alfred T. Schofield. Philadelphia: P. Blackiston's Son & Co. 1904.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, assisted by H. R. M. Landis, M.D. Vol. II, June, 1904. Philadelphia and New York: Lea Brothers & Co. 1904.

The Practical Medicine Series of Year Books, comprising ten volumes on the Year's Progress in Medicine and Surgery. Issued monthly, under the general editorial charge of Gustavus P. Head, M.D. Vol. VI. General Medicine. Edited by Frank Billings, M.S., M.D., and J. H. Salisbury, M.D. Chicago: The Year Book Publishers. 1904.

Third Annual Report of the Metropolitan Water and Sewerage Board. January 1, 1904.

University of California Publications. Physiology. Artificial Parthenogenesis and Regular Segmentation in an Annelid (Ophelia). By G. Bullot. June 1, 1904.

Addresses.

ANOMALIES OF THYROID SECRETION.*

BY FREDERICK C. SHATTUCK, M.D., BOSTON,
Jackson Professor of Clinical Medicine, Harvard Medical School.

MR. PRESIDENT, MEMBERS OF THE MAINE MEDICAL ASSOCIATION:

I thank you for the honor you do me in inviting me to address you this evening. Perhaps I should apologize for venturing to bring before you a subject which is not new. But all that is new is not true, and my subject is, at all events, replete with interest, practical as well as more strictly scientific, with well laid foundations, though the superstructure is still far from complete. Indeed, it seems to me there is nothing even in modern surgery more striking, I could say more dramatic, than some of the results which flow from our gain in knowledge as to the function of that little gland which is saddled across the trachea just above the root of the neck.

And we shall see that the surgeon's knife has lent its aid in fashioning the links of the chain of evidence, enforcing the lesson of the unity of medicine and of the interdependence of the physician and surgeon, the special work of each being based upon the general principles of anatomy, physiology, pathology and chemistry.

I hope it will not be a waste of time to briefly sketch the evolution of our present knowledge of thyroid function. Of the four chief ductless glands in adult life the adrenals were the first with regard to which we gained a definite knowledge, thanks to Addison's classic work which showed that their destruction is followed by mortal disease characterized by more or less well defined symptoms; that these glands, small as they are, are in some way indispensable to health and eventually to life. The far larger and usually single spleen is still something of a puzzle to-day. Its total extirpation seems to be compatible with the maintenance of good health even in the absence of one or more supplementary spleens. In case of necessity the bone marrow and lymph glands appear to be able to do the work of the spleen. Here we have a sharp contrast between the spleen on the one hand and the twin adrenals and Siamese twin thyroids on the other. If they are destroyed the organism seems to be unable to supply their place. The still smaller and single pituitary body is the last to yield up its secrets, in part, at least.

Enlargement of the thyroid gland — goitre — must have been recognized since anatomy, begotten of dissection, was born. Save in its mildest degrees it cannot escape notice. Atrophy of the gland, on the other hand, is not often easy to recognize in life, save indirectly through its symptoms.

While isolated cases of goitre occur everywhere it has long been notorious that in certain localities, some of the shut-in Alpine Valleys, for instance, it is far more common, so common in some places that its absence in an individual may be regarded almost as a deformity. And it was, furthermore, noted that where goitre is endemic a peculiar form of impairment, mental, physical or both, is rife, so peculiar as to deserve a special name — cretinism. Among the fanciful explanations for this endemic disease the drinking of water from melted snow was a favorite, winning credence alike from the profession and the laity. I well remember in 1869 my guide in the Tyrol trying to dissuade me from allaying my thirst from an icy mountain rill, and assigning the danger of goitre as a reason for his advice.

The connection between thyroid disease and cretinism was masked by the fact that there is no obvious relation between the degree of goitre and that of mental and physical health,— that one person with great thyroid enlargement might be otherwise well, while another with far smaller or no tumor might be a repulsive idiot, small in stature and asymmetrical in development. This, with dense ignorance as to the function or necessity of the thyroid gland, was the situation in 1873 when that great physician and acute observer, Sir W. Gull, published his paper entitled, "On a peculiar cretinoid state supervening in women in adult life." Note, please, here, the truly scientific mind. He described what he saw, fully, clearly. He indulged neither in hypothesis nor theory. Note also the word "cretinoid." His keen eye detected the broad resemblance of the acquired to the congenital state. Next Ord in 1877 first follows the trail to the autopsy table and introduces the term "myxœdema," on account of the remarkable mucin reaction presented by the puffy but non-pitting integument, so different from the ordinary œdema. He also discusses the relation between myxœdema and cretinism, sporadic and endemic, and notes thyroid changes in his fatal case. It is interesting that Curling and Fagge had already called attention to atrophy and absence of the thyroid in sporadic cretinism. Mark again Ord's purely descriptive term, expressive in one word of a definite group of symptoms from the true pathology of which we seemed to be still nearly as far away as ever. Next the great Frenchman, Charcot, in 1879 describes the condition and applies another purely descriptive name, "cachexie pachydermique," the thick-skinned cachexia. In 1880 Savage first recognizes the disease in the male.

Now surgery steps on the scene which shifts to Switzerland, a home of goitre. Safety, the daughter of cleanliness, had encouraged operative relief for the disfigurement and tracheal pressure of goitre. The unknown function of the gland and analogy seemed to warrant total extirpation, which also seemed better and easier surgery when the whole gland was involved. But it was found that in some of the cases thus operated on a train of symptoms began to develop and progressed producing a state to which the name "cachexia strumipriva" was applied. The publications by Kocher and Reverdin on this subject

* Oration before the Maine Medical Society at the Annual Meeting in Portland, June 2, 1904.

were almost simultaneous, and their experience led them to the resolution in future to leave a portion of the gland behind. The term "operative myxœdema" marks the recognition of the similarity of the symptoms following total removal of the thyroid and the myxœdema of Gull and Ord. It was not long before it was seen that they were identical. Thus was firmly established the pathology of myxœdema, and much light was thrown on the physiology of the thyroid gland. The report of the London Clinical Society, published in 1888, ably collected and analyzed the evidence, which was so complete that the experiments of Schiff and Horsley on dogs and monkeys, though affording highly interesting results, did not materially affect the main question.

We had now learned to recognize the condition resulting from the total absence or loss of thyroid function, congenital and acquired. We had also learned that the presence and activity of a portion of the gland, or of an accessory thyroid, prevents the development of the group of symptoms to the acquired form of which Ord's term "myxœdema" still remains attached. These symptoms when fully developed are so striking and distinctive as to permit probable diagnosis at a glance. Some years ago I was called to the suburbs to see a man with general peritonitis. While the family physician was going over the history the patient's wife came into the room. One look at her was enough to reach the diagnosis of myxœdema. Subsequent treatment cured a condition which had lasted for years, so near as to be practically in the "Hub of the Universe."

The story of myxœdema, like that of polyneuritis, is an illustration of how much easier it is to see what is pointed out to us than to see for ourselves — how rare is original thought. How many really obvious things now pass under our very eyes without penetrating beyond the retina!

The evolution of the therapy of myxœdema is scarcely less remarkable than that of its pathology. Transplantation of the gland was first practiced, and was followed by marked improvement which was, however, only temporary. The gland did not seem to live and persist amid strange surroundings; but the results showed that we were on the right track. In the first edition of Osler's Practice, 1892, we find "Unfortunately no satisfactory treatment is known. The patients suffer in cold and improve greatly in warm weather. They should, therefore, be kept at an even temperature and should, if possible, move to a warm climate during the winter months."

But while these words were going through the press the light was breaking. It was found that hypodermic, and even rectal, injection of the raw gland prepared and used under strict aseptic precautions was efficacious. Then feeding with the raw, the cooked gland, and, finally with liquid or dried extract of the gland was successively tried with the surprising result that the important active principle is, for practical purposes, unchanged either by the preparation without the body or by the digestive process within it. Thus was the battle won, and thus did we come into a position to readily recognize and cure the condition first described by Gull less than twenty years before, and which had been uncertain and obscure in pathology and hopeless in outlook.[1]

A year ago a middle-aged man came under my care at the Massachusetts General Hospital. His friends, weary of the burden of his support and care, were ready to send him to the poorhouse. He was practically an idiot, sluggish to the last degree both in body and mind. After several months' treatment he returned home, and his own mother failed to recognize as her son the man, active mentally and physically, whose bald head with here and there a long wisp of dry hair had become thickly covered with normal growth. I have seen him recently; he is perfectly well, self-supporting with steady work. I know nothing in medicine comparable to the change in a myxœdematous patient after treatment unless it be the effect of potassium iodide in certain cases of syphilis.

If the thyroid gland be congenitally absent or if it cease to act in early life, growth is seriously arrested and distorted. A child of eight, weighing twenty-three pounds, a typical cretin, entered my service this winter. Under treatment she has lost nearly six pounds in weight, but gained greatly in strength, intelligence and appearance. If the gland be destroyed by disease or extirpated in adult life certain nutritional and mental changes occur. Cretinism and myxœdema are essentially identical in nature, the only real difference lying in the period of life at which the cause begins to act. The relation of cause and effect is as certain as anything in medicine. But as to how the effect is produced we are still far from clear. The prevalent view is that the ductless glands secrete something which finds its way directly into the blood — internal secretion, so-called. However interesting it might be to touch upon the modern views as to the existence of an internal secretion also in glands furnished with ducts, nay even of the parenchymatous organs, such discussion would be aside from our present issue and would lead too far. I will mention only the relation of Langerhans' islands in the pancreas to, at least some cases of, diabetes. This seems established. The effects, then, of arrested thyroid secretion being so distinctive, what happens if, for any cause, secretion be excessive? For it seems highly probable that myxœdema is due to purely quantitative change. The failure of symptoms to develop if a portion of the gland remains active is one point favoring this view. With regard to this most interesting and important point — excess — we have not as yet succeeded in getting on as firm ground, though it seems as if more positive knowledge might not be far off.

There is one disease the symptoms of which are almost diametrically opposed to those of myxœdema and in many cases of which the thy-

[1] It is interesting to note that Englishmen took far the largest part in the solution of the mystery of myxœdema.

roid gland is manifestly enlarged. This enlargement, moreover, is capable of undgeroing such variations in size as to suggest that the enlargement must be in part, at least, due to actively increased blood supply, which, presumably, entails increased glandular activity. In passing, the thyroid enlargement — vascular — which occurs sometimes in connection with pregnancy and menstruation is worthy of note. I allude, of course, to that remarkable group of symptoms so obscure in origin until lately, to which the name "Graves' disease" is attached, though priority of description belongs to Parry. Parry's observations were lost sight of and, for convenience, I shall use the common English name. Contrast the facies of terror, the nervousness and tremor, the intolerance of heat, the moist skin and vasomotor instability, the emaciation of Graves' disease with the cow-like placidity, bodily and mental sluggishness, intolerance of cold, dryness of the skin and its appendages, scanty urine, and the swollen and puffy integument of myxœdema. The suggestion that symptoms so absolutely opposed must depend, at least in a measure, on opposed pathological conditions cannot but demand most serious consideration. I think it was Möbius who first, in 1890, maintained this view in print. How is proof to be secured? We *know* that myxœdema is cured by introducing into the system the thyroid of some animals, the sheep, for instance. Does such introduction produce Graves' disease in a healthy person? What is the effect on patients already the subjects of Graves' disease? For obvious reasons full experimental evidence on man with regard to the first of these questions cannot be secured. But that thyroid over-dosage does quicken the pulse, raise the temperature and cause loss of weight admits of no doubt. I have a lively recollection of a patient whom I nearly killed with thyroid extract some ten years ago. He was the first case I recognized as having partial myxœdema, a gentleman who had been treated for all sorts of things, "a dropsical tendency" among others. Though I felt sure of the diagnosis I asked Dr. J. J. Putnam to see and examine him without me and without knowing my opinion. He concurred. Putnam had just received the first sample of Parke Davis' dried extract which had reached Boston, and kindly placed it at my disposal. The patient took 15 gr. three times daily, and it was not many days before the pulse shot up from 70 to 140, the temperature from sub-normal to 103, and anginose pain was severe enough to require several half-grain hypodermics of morphia within a few hours. He has taken the extract ever since, occasionally intermitting its use for a short time; but never in 15-gr. doses. He is now seventy-nine. I have never poisoned anyone else to that degree. The cretin I alluded to before entered the hospital with a pulse of 70 and normal temperature. The pulse now runs 130–140, temperature 100–103, under one grain three times a day. By increasing or diminishing the dose, the pulse and temperature can be raised or lowered. A rapid pulse is the most constant single symptom of Graves' disease. Exophthalmos and goitre may be absent in severe and even, as Thomson has seen, fatal cases. The name "exophthalmic goitre" is, therefore, wholly inapplicable to the disease and should be dropped as it tends to perpetuate the error from which Kocher himself has not been able to free himself. As a surgeon he naturally sees only the cases with goitre and hence denies that Graves' disease can exist without goitre. This error reminds one of that of the great Hebra who maintained the identity of varicella and variola, I have always thought for the reason that he had seen but little varicella.

Thyroid extract, then, is capable of producing the most constant, if not essential, symptom — rapid heart action — and some of the minor symptoms of Graves' disease. Improvement in all symptoms often follows partial extirpation of the thyroid, as also it may follow ligation of arteries resulting in diminished blood supply, and hence, presumably, diminished glandular activity. These facts, taken together, constitute strong evidence as to an intimate relationship between the thyroid gland and Graves' disease.

It has been thought that the parathyroid glands may play something the same rôle in Graves' disease that the thyroid does in myxœdema, and keen investigators are studying the question. Extirpation of the parathyroids in animals is followed by acute and convulsive disorders — tetany, while extirpation of the thyroid alone is followed by chronic and nutritional disorders. The parathyroids were formerly supposed to be accessory thyroids and inconstant. They were discovered by Sandström in 1880, rediscovered by Gley in 1892. Positive clinical and pathological evidence with regard to the parathyroids in man is still meager, partly from the short time the work has been going on, partly from the inherent difficulties of the problem. Analogy would suggest that their action is essentially the same in the higher vertebrates. The known sequence of their removal in animals has suggested the possibility that the alarming frequency of pulse and respiration, too often fatal, which sometimes occurs rapidly after thyroidectomy for Graves' disease, may be due to removal of the parathyroids rather than to flooding of the system with thyroid secretion, poured out from the cut surface of the gland and rapidly absorbed from the extensive wound. If the parathyroid theory be true it would seem as if such cases should be invariably fatal, as they are not. The facts do not, as yet, warrant any final conclusion; but for the present, at least, the injunction by Jeandelize to make a point of sparing the parathyroids in thyroidectomy should be heeded by surgeons. MacCallum has fed the parathyroids to a patient with Graves' disease without appreciable effect. Whether the action of the thyroid and parathyroids is antagonistic, complemental, or unrelated we do not to-day know. But what evidence we have does not

seem to indicate a vital causal connection between the parathyroids and Graves' disease.

Let us then assume, for the sake of argument at least, that myxœdema and Graves' disease are both dependent on states of the thyroid gland, and that the former represents loss of function of the gland. Does it then follow that the latter — Graves' disease — represents excessive function or purely quantitive changes in secretion? We do not know. Qualitative change may or may not be operative. That glandular activity of any kind may be increased or diminished in greater or less degree, or even arrested, for considerable periods and simply from faulty innervation, we do know. The stomach tube which enables us to extract the gastric contents at any period of digestion has demonstrated to us the existence of both hypo- and hyperchlorhydria as phases of nervous dyspepsia, so-called. We have no such direct means of determining the amount and character of thyroid secretion, which, moreover, is probably far more subtle in its nature than that of the peptic glands. However plausible the theory that Graves' disease is the result of purely excessive thyroid secretion may be, proof is still lacking.

I have just received from my friend, Dr. W. H. Thomson, of New York, his most interesting monograph on Graves' disease, fresh from the press. He, as you know, doubts the causal relation of the thyroid gland to Graves' disease, and believes the main factor to be toxin absorption from the intestines. After study of his therapeutic results, which are better than any with which I am acquainted, it is hard to escape the conclusion that diet and mercurials are of great service, while we yet provisionally hold the view that morbid thyroid activity is the central and essential factor in Graves' disease. Thomson tells me that he prefers to get a bad case as his results in such are more striking.

It is certainly conceivable that intestinal toxins should have a peculiarly bad effect on the subjects of thyroidism. We are ignorant as to whether the thyroid puts something into the blood useful for constructive nutrition, though the fact that the earlier in life the gland ceases to act the greater the effect on growth would suggest this to be the case; whether its action is destructive toward toxins; or whether it acts in both ways at once. If the gland has a double action it is possible that either variations in the demand for the one or the other action, or variation in the supply to meet one or the other demand may occur in the complex conditions which constitute life. A double supply, a double demand; the extreme subtlety of the chemistry of the living body; and our fragmentary knowledge of the subject afford ample scope for speculation and hypothesis, which are in place in matters scientific, provided always that they be recognized for what they are.

Thus far I have had in mind fully developed cases of myxœdema and Graves' disease. They are easily recognized. But are we as a profession sufficiently alive to the fact that all grades of each exist? Do we recognize the "*formes frustes*," as the French call them? I think not as often as we should. Personally, I happen to have been interested in the subject, and during the past year I have seen at least four cases of Graves' disease in males and two in females, the nature of whose trouble had in some certainly, in others apparently, not been suspected by their previous attendants. These were, of course, cases entirely without or with only slight exophthalmos and goitre. Only yesterday a gentleman called with a pulse of 150, tremor, sweating. I have seen him at intervals of about six weeks for as many months and feel sure of the diagnosis. His return of rapid pulse of yesterday I think due to recent unavoidable business strain, for on the whole he is decidedly better than he was six months ago. Although the heart's action was violent as well as rapid, shaking nearly the whole chest, he was entirely unconscious of it, though he was conscious of his "nervousness."[2] If we keep clearly in mind the characteristic symptoms, minor as well as major, of myxœdema and Graves' disease, I feel sure we shall now and then encounter undeveloped cases of one or the other condition. Among the important symptoms of myxœdema a small renal secretion with a still smaller, proportionally, output of urea is not the least. Myxœdema, alike partially and fully developed, I think more rare than Graves' disease.[3]

In case there be doubt as to the diagnosis of these "*formes frustes*," tentative treatment, especially perhaps of the myxœdematous class, may confirm or negative our suspicions. Therapeutic truth lies at the bottom of a very deep well, deeper than the philanthropic drug and prepared-food manufacturers, distributing sample bottles, wish us to believe; and it is, of course, not safe to conclude that any gain following the use of thyroid extract is the direct result of its use and a proof of hypothyroidism, any more than that symptoms relieved after quinine were malarial; or that those disappearing after potassium iodide were syphilitic. At the same time a marked gain in physical and mental alertness with the return of a normal relation to cold are significant. Hertoghe seems to me to attach far more final value to the therapeutic test than it deserves.

The whole treatment of myxœdema is practically comprised in the administration of thyroid extract. It is safer to begin with moderate doses, say three to five grains twice a day for an adult, increasing the dose in size, frequency, or both, as the tolerance of the patient is developed. The presence of notable arteriosclerosis or of degenerative myocardial disease should make us

[2] Very recently I have seen a lady who was seen by my friend and assistant, Dr. W. H. Smith, some years ago. He tells me that at that time her somewhat rapid pulse and nervous manner led him to look for goitre which, as also exophthalmos, was quite absent. Under recent psychical perturbation the nervousness and tachycardia have greatly increased and goitre is manifest.

[3] We still need light on the interesting question as to how often thyroid atrophy, greater or less in degrees, results from thyroiditis complicating or following acute infectious disease.

very cautious as to dosage, at first at least.[4] It is easier to add to a deficient or to supply a lost thyroid secretion than to directly restrain or modify one which is excessive or otherwise morbid. The treatment of Graves' disease has long been unsatisfactory at the best. Real recovery is rare, though much may be done in alleviation if a quiet life without much nervous strain can be secured. A cool summer resort is very important. The improvement reported in some cases from mountain resorts and attributed thereto I believe should probably be credited to the temperature rather than to the altitude. Sexual excitement should be infrequent. A shrewd Canadian doctor once remarked to me that he had noticed aggravation of the symptoms of Graves' disease in the wives of commercial travellers coincident with the homecoming from trips.

The diet should be comprised mainly of fats, starches and sugars, with great moderation in or abstention from highly nitrogenous food; due regard being had, of course, to digestive peculiarities, temporary or fixed, of the particular patient. Oatmeal is probably the least desirable of the cereals from its excitant qualities. The bowels are apt to be either constipated or relaxed. Diarrhea, if genuine, may be regarded as an internal sweating and may be treated by some form of bismuth. Personally, I use Squibb's sub-nitrate in teaspoonful doses, less constipating than the smaller doses, perhaps, on account of its crystalline and hence scratchy nature. If there be constipation or any evidence of faulty intestinal chemistry I shall be tempted in future, acting on Thomson's suggestion, to give calomel regularly once or twice a week. And yet I have seen two cases recently, one with fifteen or twenty loose movements a day, the other with constipation, promptly acquire normal defecation under the neutral bromide of quinine alone.

Digitalis, far too frequently ordered under all sorts of conditions simply because the pulse is rapid, should not be used unless there be indication of insufficiency of the heart muscle. Strychnia is to be avoided. Three of the cases of Graves' disease seen lately had been taking digitalis and strychnia for longer or shorter periods without benefit.

Nearly four years ago my friend, Dr. F. Forchheimer of Cincinnati, told me of his results from neutral bromide of quinine. I have used it since and have thought it more helpful than any other drug I have used before. The toleration of quinine in Graves' disease is remarkable, and is seemingly proportional to the severity of the symptoms. I give it in five-grain pills three or four times a day. Two patients, cases of moderate severity, have now taken twenty grains daily almost constantly for more than three years without the least cinchonism, and with decided amelioration of all the symptoms, tachycardia and nervousness especially. A gentleman with acute Graves' disease, exophthalmos and goitre absent, was amazed that he could take twenty grains a day without discomfort, as he had always been highly susceptible to the action of quinine. Another similar case, a lady who has just come under my observation, gives the same testimony. At my suggestion the treatment has been largely used in the Out-Patient Department of the Massachusetts General Hospital with, as is reported to me, very satisfactory palliative results. The remarkable freedom from cinchonism and the small amount of bromide in twenty grains of the salt make it highly improbable that the latter is the active agent though, doubtless, as diminishing reflex excitability, it helps somewhat.

With thyroidectomy I have little experience, less, I am inclined to believe, than I should have considering my opportunities. The alarming symptoms and rapidly fatal termination after some cases of operation deter one from advising the knife in moderate cases, and the severe ones are bad subjects for serious surgery. On the other hand, a severe and chronic case perhaps justifies almost any risk. I have seen a few cases which have been greatly improved after operation, and Osler tells me within a day or two that they are having good results in bad cases at the Johns Hopkins operating under cocaine. A Massachusetts General Hospital case operated on by Mikulicz a year ago with distinct benefit has, I am told, since relapsed. I now regret not having advised operation in a very severe case in a young Jewess I saw some six months ago. All the symptoms were extreme. The prominence of the eye-balls was so great that corneal ulceration of a week's standing when I saw her had already destroyed her sight. It is the only case that I have seen of this disaster. Under such circumstances death is a true friend; but one shrinks from being the executioner.

With Rodagen, prepared from the milk of thyroidectomized goats or the serum, I have no experience.

To sum up: Graves' disease for the present is to be treated by rest, diet, climate, attention to the bowels and neutral bromide of quinine. If these measures are not followed by distinct improvement operation is to be seriously considered in severe cases, especially in patients whose circumstances in life are unfavorable for the general management of their disease.

In conclusion it only remains for me to thank you for the patience with which you have listened to me. If I have succeeded in imparting to my presentation a fraction of the interest which I feel in the subject, and, above all, which it merits, I shall be satisfied.

The fascination of the constant advance in knowledge tempts one, even in moments of weariness, to share the wish of Professor Hagen, the celebrated entomologist: "I wish I could be my own great-grandson."

[4] Larger doses are required, or may be used, to cause the disappearance of symptoms than to prevent their recurrence. The thyroid extract must, of course, be taken for the rest of life. A lady whom I saw in consultation eleven years ago came to see me within twenty-four hours about a friend. Under two grains, once, daily, she considers herself absolutely well, but experience has convinced her that this amount is indispensable.

THE SIGNIFICANCE OF THE TUBERCULOSIS CRUSADE, AND ITS FUTURE.[1]

BY EDWARD O. OTIS, M.D., BOSTON.

ORGANIZED effort for the purpose of fighting pulmonary tuberculosis is now being made in nearly every civilized country of importance in the world. It is called the "Crusade," the "Warfare," the "Struggle" against consumption. Governments and rulers, sanitarians and physicians, philanthropists and "the people" of all classes are taking part in this movement. It is singularly impressive to observe this great and widespread wave of combined effort against a single foe; and it would be difficult to find a parallel to it, comparable either in extent or activity, in any similar movement of the past. A brief enumeration of some of the principal anti-tuberculosis associations and special forms of activity in different countries may aid us in more vividly realizing the extent and magnitude of this crusade.

In Great Britain there is the "National Association for the Prevention of Consumption and other Forms of Tuberculosis," under the patronage of the king and the presidency of the Prince of Wales. Branches of this association exist all over England, and it has its own publication. At its instance there was held in London in 1901 the International Congress of Tuberculosis, attended by delegates from various parts of the world. As one result of this congress Sir Ernest Cassel placed at the disposal of the king $1,000,000 for the establishment of the King's Sanitorium now in process of erection.

In Germany anti-tuberculosis societies and associations for the erection of sanatoria exist in most of the cities, and about ninety sanatoria for the poor and working people, with accommodations for many thousands of consumptives, have already been erected. There is a German Central Committee for establishing sanatoria under the patronage of the empress, and an International Bureau for the Prevention of Tuberculosis has been organized in Berlin, with its special organ. In 1899 a tuberculosis congress of an international character was held in Berlin under the patronage of the empress. The German Workman's Insurance, which insures against invalidity, largely employs the sanatoria, either of its own construction or others, for its consumptives, on purely economic grounds, finding it more economical to cure or so improve such patients that they may resume their occupation rather than pay sick benefits for a longer period of time while they are slowly dying of the disease.

In France, both the government and the people are working together in various directions. In 1899 the government appointed a large commission to determine the preventive means to be adopted throughout the republic. There are seventy-eight anti-tuberculosis societies in the different cities, united in a national federation under the patronage of the president. The anti-tuberculosis dispensary was first inaugurated in this country, Dr. Calmette founding the first one at Lille. Several congresses for the study of tuberculosis have been held in Paris, and an international one is to occur there in 1905. In December last the *Figaro*, a leading Parisian journal, dedicated an entire issue to the fight against consumption.

In Denmark there is a national association founded two and a half years ago at Copenhagen, and through voluntary contributions from members of this society three sanatoria have been erected. National leagues likewise exist in Italy, Austria, Belgium, Spain and Portugal. In Russia many such leagues have been formed in various portions of the vast empire: at Moscow, St. Petersburg, Odessa, Sebastopol, Tiflis, etc. In Norway the government enacted in 1901 a very comprehensive law regarding the prevention and control of tuberculosis. In Sweden, on the occasion of the twenty-fifth anniversary of the King's reign, the sum of $644,000 was raised by a national subscription and presented to him; this amount, together with $238,000 voted by the Reichstag, was applied to the erection and maintenance of three sanatoria in different parts of the kingdom. The educational propaganda, by means of popular essays and the press, has been very active in this country. The official almanac, which enters every household, has for the past two years contained a brief account of tuberculosis and practical rules for the government of the consumptive and his household.

In Switzerland almost the entire population, one can say, is taking part in the struggle. In most of the important cities various organizations exist for the purpose of aiding the tuberculous poor and disseminating anti-tuberculosis literature. More than a dozen popular sanatoria have already been established in this little country, and twenty paying ones. There are also several sanatoria for tuberculous children. In Holland there is a national association for the creation of sanatoria for the poor, with subcommittees in the principal cities. The queen-mother Emma has taken an active interest in this movement, and has made substantial contributions. In Turkey, Hungary, Bulgaria and Roumania, both the government and various societies are at work with the same general objects in view as in other countries. In South America leagues exist in Brazil, Argentina, Chili, Uruguay, Paraguay, Bolivia, Equador and Cuba. A general Latin-American congress met at Santiago in 1901 and formed a permanent international commission to direct the crusade in these countries.

In Canada, there is the Canadian Association for the "Prevention of Consumption and Other Forms of Tuberculosis," whose honorary president is the Earl of Minto, the governor-general. Ontario and Montreal also have their leagues. In the provinces of Ontario and Quebec sanatoria have been established. In Mexico, Central

[1] Read before the American Social Science Association, Boston, May, 13, 1904.

America, Australia and New Zealand similar anti-tuberculosis agitation is in progress; and in Japan the imperial government has created a large hospital for the study and treatment of the disease. In the United States there are various state and local associations. The first one of the kind was the Pennsylvania Society for the Prevention of Tuberculosis, founded in 1892. Quite recently Mr. Henry Phipps of New York donated $1,000,000 for the establishment in Philadelphia of an institute for the study, prevention and treatment of tuberculosis.

This great crusade is of comparatively recent origin, dating back hardly more than a decade, and its incentive is the result of a *discovery* and a *fact*. The discovery is the finding or isolating of the tubercle bacillus and the proof that this micro-organism is invariably the cause of the disease, or, in other words, that pulmonary tuberculosis is communicable or infectious. The fact is, the enormous prevalence of the disease, and, further, that its greatest mortality is at the best period of a man's life, between fifteen and forty-five years of age; of all who die during this period fully one third die of pulmonary tuberculosis. Possessing this knowledge of the cause of the disease and the method of its communicability, it is at once apparent that it is preventable, if we can find a sure and ready way of controlling the cause, *i. e.*, the infecting germ. Happily, this is easy, for it is through the sputum alone of the consumptive that the contagion is conveyed. The breath, the perspiration, the other discharges from the body, do not contain the specific germ, only the sputum; and this is dangerous only when it becomes dry and releases into the air the infecting micro-organism. The conveyance of the disease by animals suffering from it is still under discussion, the weight of evidence so far being in its favor. If it is a fact, it counts for relatively little in comparison with the sputum cause of infection. Few, if any, phthisio-therapeutists would, I think, agree with Von Bering that everybody has latent or active tuberculosis caused by the ingestion of milk during infancy.

The tubercle bacillus is a vegetable parasite, a seed, and, like other seeds, requires a favorable soil for its germination and growth. Furthermore, it resembles other seeds in the characteristic of exhausting or changing the character of the soil in producing the crop. Tuberculosis, by its growth, not only feeds upon the normal lung tissue and renders it incapable of performing its proper respiratory function, but so changes its structure that it becomes a ready prey to other destructive micro-organisms.

It is at once evident, then, that not all individuals exposed, even for a prolonged period, to the tubercle bacilli, contract the disease, provided their tissues are sufficiently resistant; and in this fact lies the whole theory of the present method of the treatment of the disease,— to convert a previously receptive organism into a resistant one.

It was the stony soil which afforded no depth of earth to the sower's seed, and "because they had no root they withered away." So the tubercle bacillus will not grow in a healthy organism. But the seed falling into good ground produced an ample crop, thirty, sixty, an hundredfold. So it is the conjunction of the bacillus and the favorable soil whose fruition is pulmonary tuberculosis.

The favorable soil is the human organism depressed below its normal standard of health by many and various influences and conditions, either chronically or temporarily. Here comes in the influence of heredity as a factor in producing this favorable soil. Whereas consumption is not inherited, for a contagious disease is caught not transmitted, yet experience indicates that a "tendency" to it, a special sensitiveness to the tubercle bacillus, appears to be inherited in a certain proportion of cases, not, by any means, in all.

The causes working to prepare this favorable soil are all those which we class under the head of unhygienic life and environment, or, in other words, they are the evil resultants of civilization. It is hardly necessary to enumerate them. Unsanitary dwellings and workshops, alcohol, unwholesome occupations, excessive labor, insufficient and improper food, and, more potent than all the rest, vitiated air. "He who has been the free child of nature," says Mr. Edward Carpenter,[2] "denies his sonship; he disowns the very breasts that suckled him." He deliberately turns his back upon the light of the sun, and hides himself away in boxes with breathing holes (which he calls houses), living ever more and more in darkness and asphyxia, and only coming forth, perhaps once a day, to blink at the bright god, or to run back again at the first breath of the free wind, for fear of catching cold."

Tuberculosis is an ubiquitous disease, and no region, whatever its climate and latitude may be, is exempt from it. The countries of the north and the tropics are alike swept by its ravages. Wherever human beings congregate, as in thickly settled portions of great cities, or wherever they shut themselves up in a vitiated atmosphere, like the Scandinavian farmers of Minnesota, or the peasants of Brittany, there it is most prevalent.

The yearly holocaust is appalling, but we have become so inured to it that it no longer startles us like some sudden catastrophe which destroys a few hundred lives. The annual sacrifice to it in France, for instance, is one hundred and fifty thousand lives, equal to the number of inhabitants of the city of Rouen. In this country it claims an equal number of victims, and so on in much the same proportion throughout the civilized world.

Is it any wonder that at last men are awakened to the realization of the destruction caused by this grim monster? Now that we know its cause through the transcendant discovery of Koch, and are able to control it, the enemy is no longer veiled in mist, but stands clearly revealed before

[2] Civilization, Its Cause and Cure, by Edward Carpenter.

us. It is only a matter of the selection of weapons, the mobilization of forces, and the persistence of the warfare to defeat the enemy, to exterminate this "great white plague."

It will be instructive now to consider some of the weapons and the different lines of attack employed in this warfare. There are five main lines along which the advance is being made: the Educational, Social, Isolation, Governmental and Medical.

Under Educational is comprehended the various methods of instructing the people in the simple facts regarding tuberculosis, its prevalence, cause, communicability, prevention, curability, conditions producing the favorable soil symptoms suggestive of its presence. This is accomplished by means of popular lectures, pamphlets, illustrations, placards and the like. Existing organizations of all kinds are asked to furnish audiences, or they themselves ask for lectures and information upon the subject. The schools, labor unions, lodges, educational centers, clubs, churches, neighborhood settlements, employees in great department stores, — are all available for audiences. Physicians, sanitarians, laymen who have had exceptional opportunities to become conversant with the subject, like Professor Fisher of Yale College, are available for lecturers. Leaflets, pamphlets, or more elaborate productions are furnished gratuitously by boards of health, dispensaries, anti-tuberculosis associations, or philanthropic individuals or societies. Tuberculosis exhibitions for conveying knowledge upon the subject in a popular form have of late been instituted. Such an exhibition was recently held in Baltimore lasting a week. Here were sections devoted to statistics: tenement houses, sweat shops and factories, state and municipal prophylaxis, hospitals and sanatoria, pathological anatomy and bacteriology. Small groups from all classes of society — students, nurses, teachers, working women's clubs, charitable societies and associations were conducted through the exposition and the various exhibits explained. Daily popular lectures were also given.

Similar exhibitions have been held in Moscow and St. Petersburg, and one is to take place in St. Louis during the Fair. In June of last year the International Tuberculosis Museum was opened in Berlin, "intended," as Dr. Kayserling says, " to be a popular object lesson, and to represent one of the means for enlightening the people as to the nature of tuberculosis." There were divisions upon the history, prevalence, cause, prevention and treatment of the disease, the whole subject being exhaustively portrayed in this way.

Another educational means is the use of the press, by popular articles on consumption in the daily and weekly papers and monthly magazines, such as the admirable article by Professor Fisher in the *Outlook*, or those of Dr. Knopf in some of the New York daily papers. Reports of lectures upon tuberculosis, the transactions of anti-tuberculosis associations, and other articles upon the subject in special publications like *Charities*, the *Club Worker*, nurses' magazines and the like — all have an educational value.

Under Social are included all efforts towards the general betterment of the masses, the workingman, the tenement-house dweller, the factory operative, child life. Indeed, the social condition of the individual has such a direct influence for or against one's receptivity to tuberculosis, that it has been called a " social disease." The question of housing, overcrowding, intemperance, the feeding of infants and adults, wages and labor, — all have a more or less direct bearing upon the prevalence of tuberculosis. The decrease of the disease prior to the active warfare against it now in progress is undoubtedly largely due, as Hoffman says, to the improvement in the mode of life of the masses. By an amelioration of the conditions of their life they become more resistant to the disease, and, as the great Genoese investigator, Maragliano, has recently said,[3] "the victims of tuberculosis will diminish in number, in proportion as the human organism is in condition to resist the disease."

As the modern surgeon now realizes that absolute cleanliness is really the cause of his marvellous results after operation, and that all his antiseptic precautions are only a means to this end, so in the ultimate analysis, the social problem is the struggle towards cleanliness. Clean bodies, clean houses, clean workshops, clean air, clean water and food, and clean minds are the essential factors involved in the solution. Indeed, we even use the word as indicative of character, and the phrase, a "clean man," conveys a very fair estimate of the moral status of the individual.

Again, under Social may be included the various methods of relief and control of the poor tuberculous individual by frequent visitations at his home by visitors or nurses under the direction of anti-tuberculosis associations or dispensaries. Through this instrumentality the victim of the disease and his family are instructed as to the proper disposal of the sputum, and the general care of the patient. Material aid in the form of food or other necessary articles is also furnished when needed.

Anti-tuberculosis dispensaries, previously referred to, perform a very important social rôle, as well as therapeutic. The consumptive who applies to such an institution is not only given medical care, but is kept under constant observation by the visitor or nurse. He is supplied with sputum receptacles, and generally guided in his plan of life when possible. Opportunity for change of occupation, if considered desirable, or of residence, or entrance into a sanatorium or hospital is provided for.

As it is the task of the engineers of an army to collect information regarding the enemy and to discover the topography of his country, so, under the social side of the tuberculosis problem are the various statistical investigations regarding the disease and its social relations, such as has been so admirably made by Miss Lillian

[3] Medical News, April 2, 1904.

Brandt, the statistician of the Committee on the Prevention of Tuberculosis, of the Charity Organization Society of New York. Such information enables one to prosecute the siege more intelligently, more effectively, and at more points of attack. "The struggle with tuberculosis," said M. Casmir Périer at the meeting of the Central International Tuberculosis Committee, in Paris, last May, quoted by Miss Brandt, "is intimately bound up with the solution of the most complex economic problems, and no plans will be complete which have not for their basis the material and moral improvement of the people. The struggle with tuberculosis demands the mobilization of all social forces, public and private, official and voluntary."

Isolation. — Under this head are included all measures of prevention dependent upon the segregation of the tuberculous individual when he becomes dangerous to those about him through the dissemination of the infecting sputum. This is accomplished through the instrumentality of boards of health, sanatoria, consumptive hospitals, and various "homes," or almshouses. In some countries, as Norway for instance, and in many cities, compulsory notification of the disease is required by law, and the same authority can be exercised in dealing with it as with any of the other contagious diseases; that is, the government or board of health can remove a consumptive from his abode when in their opinion he is a menace to those about him. This usually happens in the later stages of the disease. Consumptive hospitals for advanced cases of consumption are sadly needed in our American cities, and it is one line of attack and an exceedingly important one to arouse public opinion so that they will demand of the municipality the establishment of such institutions. It is no hardship to remove a poor consumptive to such a hospital, for he will receive far better care than is possible in his wretched abode.

Sanatoria also effect isolation, although their primary object is to cure. The workingman in the earlier stages of the disease and still able to pursue his avocation may be quite as dangerous to his fellow-workmen as the more advanced case. By his entrance into a sanatorium he obtains the benefits of treatment and has the chance of cure, while at the same time he is isolated. From obvious reasons isolation at one's home is hardly practicable.

Governmental. — Whatever anti-tuberculosis regulations originate from or are executed by the authority of the government, central, state or municipal, may be included under this division. Such are compulsory notification, already referred to; inspection and disinfection of infected abodes; free examination of sputum by state or city boards of health; ordinances against promiscuous spitting now in force in so many countries; sanatoria established and maintained by the government, as that of the United States Marine Hospital Service in New Mexico, and various similar state institutions, a most conspicuous example of which is the Massachusetts State Consumptive Hospital at Rutland. When the government is paternal, other measures for the prevention and control of the disease emanate from the central authority, and many of the national associations for the prevention of tuberculosis receive the endorsement and enjoy the prestige of the ruler of the country in which they are situated. As in Germany and England, — indeed in almost every country in Europe, — the rulers and government have shown themselves most intelligent and progressive in zealously supporting and aiding this great crusade. It is to be hoped that shortly a national association will arise in this country with the approval and co-operation of our government.

Finally, under Medical or curative are embraced all means instrumental in curing or arresting the disease, the chief of which is the modern sanatorium. As consumption is, for the most part, only curable in the early or incipient stage, only such cases are generally received into a sanatorium as appear susceptible of a cure or of such improvement as will enable them to again resume some occupation. The distinction between a sanatorium and a consumptive hospital is to be noted: the function of the former is to cure or improve, while that of the latter is to care for and isolate the hopeless cases.

The sanatorium treatment, also called the hygienic, dietetic, or open-air treatment, is based on the principle of increasing the resisting power of the consumptive to the tubercle bacillus. This, in brief, is accomplished by constant exposure to fresh air, abundant feeding, and mental and physical rest. Such treatment has been so preeminently successful that sanatoria are springing up all over the civilized world with amazing rapidity, as has been noted earlier in this paper. From present indications it will not be very long before every state in our own country will have one or more such establishments. It has been determined from experience that it does not matter very much what the climate is where the sanatorium is situated, provided fresh, pure air is obtainable. Both private and governmental initiative or a combination of both is active in founding such beneficent curative institutions.

Incidentally, as has been referred to above, the sanatorium exercises a preventive influence of no small degree by isolating its patients. Another very valuable incidental influence of the sanatorium is the educational propaganda carried on by its graduates, or cured patients; as they return to their homes they become apostles of fresh air and wholesome living to their less enlightened neighbors. This result of the sanatorium training has been strikingly exemplified in the state of Massachusetts.

In this connection I may again refer to the anti-tuberculosis dispensary as a curative instrument of no mean value. But comparatively few consumptives from the great mass of them can go to sanatoria, and for one reason or another they must remain at home, and these home con-

sumptives the dispensary looks after. Through its visitors or trained nurses it keeps in constant touch with them, enables them to obtain proper food and fresh air by various expedients, such as sleeping on a piazza, or an improvised platform, and by day in the open air in parks, or roof gardens. Thus many economic cures at least are effected, and often while the patient, perforce, continues at his occupation.

In the foregoing I have briefly and imperfectly, it is true, considered the various lines of attack and the weapons at present in use in this great warfare, and it remains to forecast the probable results of the struggle. What of the future? Theoretically, consumption is a perfectly preventable disease, and I believe it will be proved to be practically so. If, by the general improvement of the mode of life of the masses, the mortality from tuberculosis has been so materially reduced in the past, as it has in those countries where sanitary efficiency is high, it is reasonable to suppose that the continuation and increase of this general betterment of the masses, in conjunction with all these specific and special agencies now in operation, will cause the diminution of the disease to progress at a far greater rate from this time forward, and the evidence at hand corroborates this inference.

In Germany, if the decline in the mortality from tuberculosis continues at the same rate as at present, the disease will be exterminated in less than thirty years, and in England in about forty. The striking drop in the Prussian tuberculosis death-rate from 31 per 10,000 inhabitants in 1886 to 21 per 10,000 in 1900 is attributed to three causes: (*a*) The widespread knowledge as to the infectious character of tuberculosis; (*b*) the provision for a large number of sanatoria for the working classes; (*c*) the early and systematic resort to sanatoria which the workingmen's State Insurance Department in Germany encourages and assists. In Belgium the mortality which in 1888 was 38.4 per 10,000 inhabitants was reduced in eleven years to 24.5 per 10,000 in 1898; a diminution of 36%. In five eastern states and ten other cities of the United States the mortality has been reduced from 27.2 per 10,000 in 1887 to 21.2 per 10,000 in 1900, a diminution of 18%. In Massachusetts from 1892 to 1902, a period of ten years, the diminution has been from 24.5 to 15.8, or a little over 35%. In New York city the diminution from 1886 to 1901 has been more than 30%, and Dr. Biggs of the department of health of that city, in quoting this diminution, says that it is his belief that with a complete and efficient scheme for dealing with tuberculosis, including suitable hospital accommodations, and the proper enforcement of precautionary measures, the death-rate from tuberculous diseases in New York City may be further reduced one third within a similar period, which would mean the saving of three thousand lives annually.

It is to be borne in mind that the beginning of this rapid diminution is coincident with the diffusion of the knowledge of the present facts regarding tuberculosis, and when the special methods of fighting it were beginning to be operative. Koch discovered the bacillus in 1882, and in 1886 the results of the direct attack were beginning to be appreciable.

The process of civilization, from a sanitary standpoint, at least, has been painful and costly, and it is still a debatable question in many minds whether the present manifestation of it is worth the cost. In its past, by its ignorance and filth, it has inflicted upon the human race many and frightful pestilences. By its increasing enlightenment in sanitary science and preventive medicine it has shaken itself free from the majority of these enemies. Tuberculosis still remains to mock it with its ghastly smile. It is evident, however, from the present weighty movement in progress, that there is a determination to fight it to the death. From the constant increase of anti-tuberculosis associations, the universal dissemination of the facts concerning the disease, the rapid increase of sanatoria, it is apparent that this great movement gains daily in momentum and power. The great awakening is at hand, and from every indication it seems destined to grow and grow until the final consummation is achieved and the "Captain of the men of death," this great white plague, is exterminated.

THE PHYSIOLOGY OF THE URETER.

BY BYRON ROBINSON, B.S., M.D., CHICAGO, ILL.

THE physiology of the ureter is practically comprised in three functions, viz.: (*a*) peristalsis; (*b*) secretion; (*c*) absorption. All visceral muscles must contract and relax, execute rhythm or atrophy. All epithelial surface — mucosæ — absorbs and secretes. The object of ureteral function is to conduct the urine from the kidney (a urine secreting organ) to the bladder (a urine reservoir), and to prevent its return from the bladder into the ureter (trigonum vesicæ). The method utilized by the ureter in transporting urine from kidney to bladder is by means of periodic rhythm or peristalsis. The ureter in passing from the kidney to the bladder is forced to assume a sinuous course from pressure of adjacent structures which impose on the ureter an irregular form consisting of ureteral dilatations (urinal reservoirs) and ureteral constrictions (isthmuses, spincters).

First, I shall assume from the distention of one hundred and fifty ureters three constant main isthmuses, viz.: (*a*) one adjacent to the distal kidney pole which I shall term the *proximal ureteral isthmus* (ureteral neck); (*b*) one at the arterio-ureteral crossing of the vasa iliaca and ureter, terming it the *middle ureteral isthmus* (flexura iliaca ureteris); (*c*) one at the entrance of the ureter into the bladder, demonstrating it as the *distal ureteral isthmus* (vesico-ureteral sphincter or vesico-ureteral valve).

Second, consequently I shall assume three

ureteral dilatations or urinal reservoirs, viz.: (*a*) one consisting of the calyces and pelvis, the *proximal ureteral dilatation* or reservoir; (*b*) the main lumbar, middle ureteral dilatation or *lumbar spindle;* (*c*) the main pelvic ureteral dilatation or *pelvic spindle.*

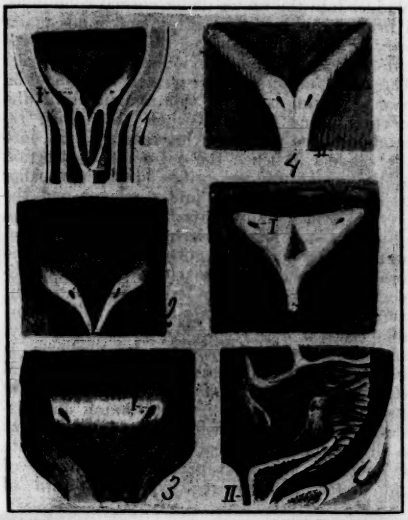

FIG. 1.

The strictures, isthmuses, dilatations, and reservoirs endow the ureter with a definite form which adds interest to its physiology. The chief ureteral constrictions and dilatations are undoubtedly mainly due to the physiology or functional activity of the ureter and the environments of erect attitude. However, ureteral constrictions and dilitations are a heritage of the irregular calibered Wolffian ducts. It is of practical importance to call attention to the fact that ureteral constrictions or isthmuses obstruct ureteral calculus, and also that the ureteral strictures or isthmuses may be mistaken for pathologic ureteral strictures. I will also call attention to the fact that, frequently, apparently physiologically, the ureteral constrictions and dilatations may become exaggerated; however, it is the ureteral dilatations alone which have become chiefly increased, for the ureteral isthmuses yield comparatively little. The ureteral catheterizer perceives the ureteral constrictions from obstruction to the ureteral catheter and the ureteral dilatation from the freedom of the ureteral catheter and excessive flow of urine while the instrument is in the dilatation.

EXPERIMENTAL OBSERVATION.

If one takes a spare dog of some twenty pounds, anesthetizes him in a room of 75°, incises the abdomen from the xiphoid cartilage to the symphysis pubis, and with warm towels separates the abdominal viscera in order that the ureter may be noticed shimmering through the dorsal peritoneum, the following phenomena may be observed: every three to five minutes a peristaltic wave passes from the proximal to the distal end of the ureter. The rhythmical movements begin in the ureteral pelvis and calices. The time required for the ureteral rhythm or wave to pass from kidney to bladder is ten to fifteen seconds.

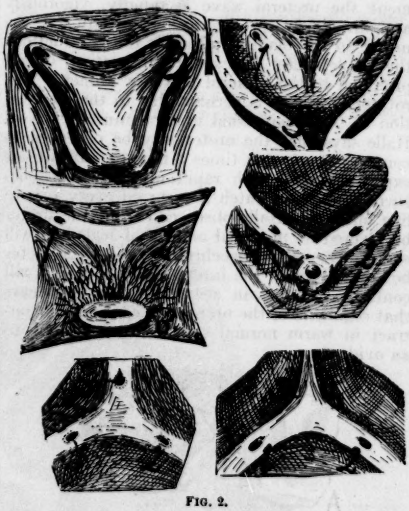

FIG. 2.

The phenomena observed during the passage of the ureteral rhythm are: (*a*) rapid circular, muscular, ureteral contraction; (*b*) longitudinal muscular contraction; (*c*) a white circular band due to exsanguination at the point in the ureter where the rhythmical wave is traveling. The caliber and diameter of the ureter at the point of the passing wave is smaller and more cylindrical than at adjacent segments; (*d*) the periodic ureteral peristalsis is of extreme vigor and brusqueness as one may perceive by sight and by holding the ureter between the finger and thumb during the distalward movement of a ureteral wave. The brusque, energetic, vigorous ureteral rhythm differs from that of all other glandular exit ducts. It resembles more the peristalsis of the tractus intestinalis. Yet it also resembles in its brusqueness the vigorous cardiac contractions. The phenomena are modified by environments, viz.: temperature, kind, degree and length of anesthesia, trauma, visceral exposure, fatigue, irritation of ureter, electricity, blood supply, amount and composition of urine secreted, vigor of subject, etc. The periodic peristaltic wave proceeds, regardless of the position of the subject, hence, force of gravity may practically be disregarded. The ureter appears to begin to contract at about the distal pole of the kidney, near the proximal ureteral isthmus. The ureter existing as a white or bluish gray cord suddenly assumes a cylindrical form, its lumen and volume diminish, its color

becomes a pale white for about three quarters of an inch, from exsanguination. Its muscular bundles, acting like living ligatures, limit the blood, exsanguinate the current, in the ureteral wall. A fine oscillating movement begins at the proximal ureteral isthmus, the sensitive segment of the ureter, and in a moment the ureteral pelvis contracts; whence at the same moment the ureteral wave is rapidly, vigorously and brusquely propagated distalward on the ureter to the bladder. During the contractions the whole ureter appears to be erecting, drawn proximal to the ureteral pelvis or kidney. The rotatory erection is perhaps due to the contraction of the longitudinal ureteral muscles. Noel Halle says that the ureter may be observed to contract two to ten times a minute. In all our experiments no such rapid ureteral waves occurred. By the watch it recurred every two to five minutes. Halle observes that if the ureter be severed its proximal and distal segments will continue to contract isochronous, and if the ureter be severed twice the intermediary segment will contract. This is in accord with experiments that segments of the ureter will continue to contract in warm normal salt solution, similar to an oviduct.

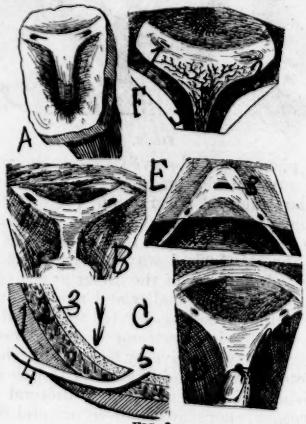

FIG. 3.

THE CAUSE OF THE URETERAL PERIODIC URETERAL RHYTHM.

The periodic ureteral peristalsis, rhythm, is due to the sympathetic nerve ganglia located in the wall of the ureter, especially in the tunica fibrosa ureteris, the cellular tissue framework support. The ureter, like all other viscera, has its own peculiar periodic peristalsis, rhythm, ruled by what I shall term the automatic ureteral ganglia.

A VESICO-URETERAL VALVE.

Physiologic Data from Cystoscopic Inspection of the Distal Ureteral Orifice in Woman. — The cystoscope reveals the most practical physiology of the distal ureteral orifice and its relation to the bladder. The distal ureteral orifice is practically vesical mucosa and is subject to the same laws as the vesical mucosa. The normal function of the ureter is to convey urine from the kidney to the bladder and to prevent its regurgitation or return into the ureters. It is impossible for the urine to regurgitate from the bladder into the ureter under normal conditions. I proved this by injecting air and fluids under varying conditions into the bladder. The urine enters the bladder by periodic spirts and jets. The distal ureteral orifice presents no material change during ureteral contraction until the spirting urine appears, when the orifice retracts and the column of urine is projected into the bladder, whence the vigorous contraction of the distal ureteral orifice obstructs further passage of urine. The ureter relaxes and the ureteral orifice resumes its normal location and state of rest. The wonderful adjustible vesico-ureteral valve, a non-regurgitant valve, is the location around which is clustered vast physiologic functions, and from lesions and consequent bacterial disease it becomes the atria of innumerable ureteral and renal infections. Practically, the chief ureteral physiology, for medicine, is located at the distal ureteral orifice. The vesical segment of the ureter changes its form and caliber under varying conditions, contraction and distention of the bladder (diastole and systole), but in all the changing vesical panorama one can note distinct provisions for guarding the lumen of the ureter whereby regurgitation, return of

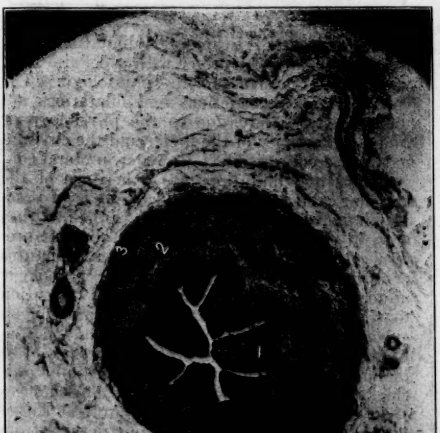

FIG. 4.

urine in the ureter, is prevented. In the distended bladder the ureteral valve is markedly oblique. In the contracted bladder the ureteral valve is relatively extended. Besides, during ureteral peristalsis the distal ureter puckers its mouth like a contracting anus. However, the guard to prevent urinal regurgitation into the ureter is the physiologic action of the vesico-ureteral valve, for this valve adjusts itself to all intra-vesical pressure, to all physiologic conditions of the bladder. The vesico-ureteral valve is the guard, the sentinel for the ureter and kidney, it is the policeman for the ureter and kidney. Its integrity alone prevents ascending infection. The health of the ureter and kidney depends absolutely on the protection — non-regurgitation — of the vesico-ureteral valve. Its physiologic integrity decides the limits of health and life.

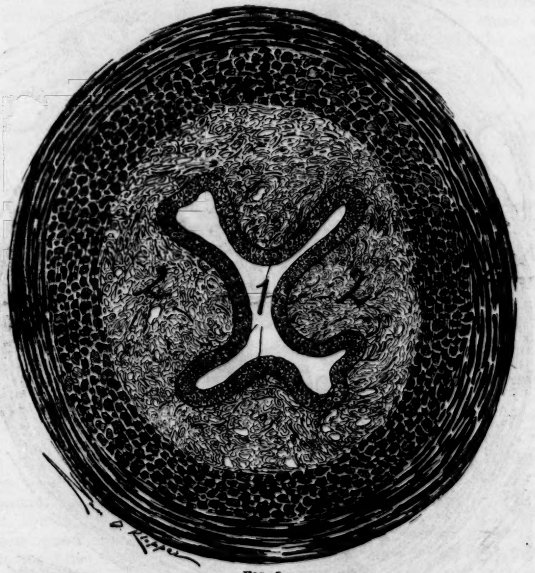

FIG. 5.

FIG. Dog. (Author.) Ureter of dog, drawn under tunica mucosa. 2, Tunica propria. 3, Tunica muscularis longitudinale (internal). 4, Tunica muscularis circulare (external). The tunica propria is more extensive in dog than in man and has a more definite contour. The longitudinal and circular layers are more definitely isolated in dog than in man. The tunica mucosa ureteris is almost an unchanging structure in all animals.

Physiologic experiments demonstrate that the ureter possesses certain conditions which explain its functions.

SENSIBILITY.

The ureter possesses sensitive nerves, as may be noted by irritating it. The tunica mucosa is excitable. Some years ago I ligated quite a number of ureters of dogs to note resulting obliteration of renal function. I observed that such ligature was painful — however periodically. All observers note the ureteral calculus is painful. The terrific pain of some ureteral calculi is sufficient to indicate that numerous sensitive nerves reside in the ureter, and especially in the tunica mucosa. The pressure of urine on the mucosa of the ureteral pelvis and calices appears to interrupt rhythm. However, ureteral segments with no urine on the mucosa will contract rhythmically.

CONTRACTILITY.

The ureter is provided with contractile power from the possession of a muscular wall. One can distinctly observe the peristaltic wave in dogs. According to my records of experiments it repeated itself on the average every three to five minutes. Boari notes that it may repeat itself several times a minute. In none of our experiments did such contractions occur. The physiologic peristaltic ureteral wave is very energetic in dogs, as one can perceive while manipulating the ureter. The mechanically induced contraction is less vigorous; it is more diffuse, irregular in rhythm and direction. The peculiar energetic brusque and vigorous ureteral rhythm may be observed in the consequent dilatation of the ureter proximal to a ureteral stricture.

The summation of factors influencing ureteral contraction, are:

(1) Sympathetic nerve ganglia located in the ureteral parietes, especially in the tunica fibrosa ureteris.

(2) The flowing and pressure of urine on the tunica mucosa ureteris (similarly as food on the

mucosa of the tractus intestinalis induces peristalsis).

3. The tunica mucosa ureteris is excitable, sensitive. This is demonstrated by violent ureteral peristalsis induced by ureteral calculus, concentrated or morbid urine or the ureteral catheter. Also by ureteral obstruction as ureteral stricture, flexion, pressure.

(4) The ureteral contractions increase with increased quantities and concentration of urine, which demonstrates that urine pressure plays a rôle.

(5) Diaphragmatic contractions. (6) Vascular peristalsis. (7) Peristalsis of the tractus intestinalis. (8) Temperature. (9) Condition of muscle (fatigue or quietude).

If urine pressure or ureteral irritation be excessive, the ureter relaxes from fatigue and slows its rhythmical wave.

(10) Mechanical, chemical or electrical irritation. (11) Tumor pressure as in pregnancy. (12) Cerebral activity or irritation.

(13) The renal function has a capital influence on the physiology of the ureter, especially as regards quantity and condition of the urine.

(14) The ureteral pelvis usually holds several teaspoonfuls of urine and hence will experience the greatest intra-ureteral pressure. Microscopically the ureteral automatic ganglia are difficult to demonstrate, requiring usually numerous trials.

PHYSIOLOGIC AND ANATOMIC INDEPENDENCE OF THE URETER.

The ureter is an independent organ, physiologic and anatomic, performing its function as independently as the heart, uterus, oviduct, intestine, liver and pancreas. If the oviduct be extirpated, immediately placed in warm salt solution and gently irritated, it will pass through its rhythmical motion for about a half hour. Similarly, if a segment of severed ureter be placed in normal salt solution at 100° F., the ureter being gently irritated, it will continue its rhythmical, periodic contractions. The ureter is independent of the bladder as the ureteral rhythm is propagated to or from the bladder, demonstrating independence of vesica urinaria and ureter. I found by repeated dissections that the ureter is anatomically independent of the bladder wall, for it is separated from the vesica urinaria by a stratum, a cylindrical sheath of connective tissue, in exactly a similar manner that the ductus choledochus communis is separated from the caput

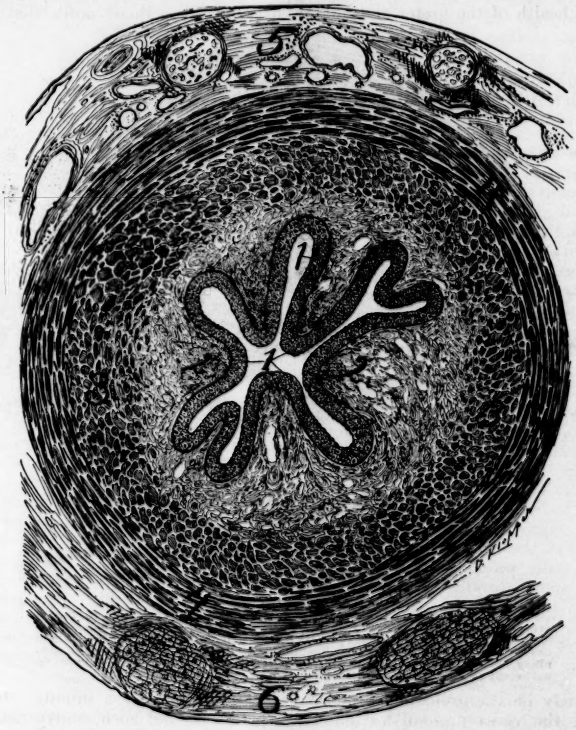

FIG. 6.

pancreatis as it passes in its journey to enter the duodenum. The ureteral and vesical muscularis do not blend. The ureter penetrates the bladder obliquely with its three tunics. The intravesical pressure perhaps does not influence the pressure in the ureteral pelvis. Regurgitation of urine into the ureter is impossible, as the vesical mucosa forms a valve, and the more urine in the bladder the more secure becomes the valve (hence the greater pressure); by coaptation against regurgitation. Slow pressure may produce extensive ureteral dilatation from constant physiologic efforts. The resistance of the ureteral sphincter — uretero-vesical valve — is remarkable. In pathologic cases the ureteral orifice participates in the dilatation. The ureteral orifices may be patent, patulous, admitting a sound. When the obliquity of the ureteral orifice — the valve — is deficient, the ureter and bladder communicate freely as one tract, one continuous channel.

DIRECTION OF THE URETERAL PERISTALSIS.

Physiologically, the peristalsis moves distalward. It begins in the region of (*a*) the distal ureteral pelvis; (*b*) the proximal isthmus; (*c*) the calices. The regular physiologic ureteral rhythm travels from the proximal ureteral end (kidney) to the distal end (bladder). The three-quarters inch of longitudinal, whitened, exsanguinated ureteral zone representing the segment of the ureter immediately proximal to the ureteral wave, represents phenomena quite different from intestinal or genital peristalsis. Thomas Engleman, the celebrated Berlin physiologist, noted that artificial irritation of the tunica mucosa does not induce ureteral contraction. The irritation must involve the tunica muscularis. This does not accord with conditions causing pain, with ureteral colic, induced by calculus irritating the tunica mucosa. Mechanical irritation may induce anti-ureteral peristalsis. Boari reports that the injection of sulphate of indigo in the veins produces visible ureteral rhythm (in rats and rabbits).

PHYSIOLOGY OF THE URETER CALICES.

The function of the ureteral calices is to collect and conduct urine from the renal pyramid to the ureteral pelvis. This continues uninterrupted through life, if no obstruction is offered. Any obstruction is liable to disorder the function (peristalsis) by depositing urinal residue in the lumen, which serves as a bacterial medium, whence, from deposits, calculus arises.

The calices have resting and acting periods. They act rhythmically. The urine secretes continually, but the ureteral calices act only when sufficient quantity of urine is collected to produce by pressure a peristaltic wave of the calices.

The main disease of the ureteral calices results from mechanical obstruction. The movements of the diaphragm and liver on the kidney aid the ureteral calices to empty themselves. Also, the contractions and dilatations of adjacent organs aid in promoting ureteral peristalsis. The ureter is a muscular conduit, and hence possesses rhythmical waves. Force of gravity may aid slightly, but the ureter would force the urine in the bladder with the subject standing on the head. As the urine collects on the mucosa of the calices it induces relax action and a rhythm. The ureter is contractile, as one can observe regular peristaltic waves on animals. Electrical application to the ureter induces ureteral contraction. The irritability of the calices is influenced by temperature, composition of urine, repose, activity and the quantity of fluid poured on their mucosa. Doubtless the chief cause of calicular rhythm is urine pressure on the mucosa, as food on the mucosa of the tractus intestinalis is the chief cause of its peristalsis. Also pressure of urine in the calices releases peristalsis.

CONSERVATIVE SURGERY OF THE UTERINE APPENDAGES WITH ESPECIAL REFERENCE TO THE OVARIES.*

BY EDWARD L. TWOMBLY, M.D., BOSTON,

Gynecologist to Saint Elizabeth's Hospital and Boston Dispensary.

In bringing this subject before the Society, it is not to take an extended survey, for it has already been very ably done by distinguished observers like Dr. A. Palmer Dudley in his chairman's address before the American Medical Association at New Orleans; by Dr. Howard A. Kelly in his book; by Dr. H. C. Coe on "Secondary Laparotomies"; and by Dr. W. L. Burrage who has very carefully tabulated 187 cases. My point is not to present statistics at this time, but to call attention to one important factor in the conservative operations on ovaries alone, without reference to tubes or their complications.

The pendulum of surgery in women's diseases swings back and forth. In former years, it was for the complete removal of all diseased organs, but now it is for the preservation of the same and of any part which may perform its function again. Since 1897, our best operators in gynecology have advocated very conservative measures, and I believe that all our gynecological staff at St. Elizabeth's Hospital are in accord on this subject.

While each man has his individual way in doing his work, we are harmonious in the following conclusions:

For myomectomies by the abdominal route, no deaths or bad results have been noticed, and the animal suture has invariably been used. If one ovary is diseased, and the other ovary healthy, the diseased one is generally removed. Where both ovaries are diseased, resection of one or both is practiced. Whatever healthy ovarian tissue there seems to be, however small, is left. Dr. F. W. Johnson reports one secondary operation after both ovaries had been resected. Dr. R. A. Kingman reports none. Dr. W. L.

* Read at the meeting of the Section for Obstetrics and Diseases of Women of the Suffolk District Medical Society, April 27, 1904.

Burrage reports that in a large number of cases (85) which he has tabulated for a number of years, five secondary operations have been done, and in four more cases, another operation is needed. In my own 42 cases, seven secondary operations are indicated, but only two have been done. It is very true that all our chickens do not come home to roost, so that it is fair to infer that the proportion of secondary operations is larger than appears.

Dr. Burrage very aptly replies to my question, "How many secondary operations because of conservative work on the ovaries," by saying, "None 'because of,' but I can recall several cases in which secondary operations have been necessary owing to the development of further lesions."

Dr. H. C. Coe remarks that a secondary operation does not imply careless or imperfect work on the part of the former operator. He says, "An ovary which appeared perfectly normal has undergone cystic degeneration or become the seat of a large tumor, and develops rapidly from apparently healthy organs after a primary operation." He queries whether it may not be "circulatory disturbances after ligation of large vessels." Conservative work on the tubes has not thus far proved very satisfactory, especially in gonorrheal cases. I prefer to remove them by the V-shaped incision into the horns of the uterus, and leave the uterus when possible, although many operators advocate removing the uterus as well.

I wish, however, to-night, to limit my paper to the discussion of the preservation of the ovaries or resection of the same as the best surgery of the present day. In some of my cases which I shall mention in brief, I have been ultra-conservative, and so have a larger number of secondary operations indicated. I believe that the procedure, which I wish later to emphasize, will do away with a number of such operations in the future.

When is a conservative operation *not* indicated?

(1) In women forty years and over, or in other words, those who are at the menopause. Dr. Burrage further limits this class in his paper to "pronounced neurasthenics."

(2) In gonorrheal affections, where the pain and distress and repeated flare-ups in diseased tubes and ovaries cause a life of continued suffering.

(3) In malignant disease of one ovary, such as a papilloma, sarcoma, or carcinoma. Dr. Kelly disagrees in this conclusion saying, "If such a disease as a superficial papilloma is seen at the very beginning and the other ovary appeared perfectly normal, I should without hesitation save it in a young woman with the expectation of carefully watching the patient for several years, and of operating at once upon detecting the slightest evidence of disease."

(4) In tumors that involve the whole organ.

(5) In tuberculosis of the ovary.

In all other cases, and especially in young women where some risks must be taken to preserve the menstrual life, Dr. Kelly says in his admirable chapter on "Conservatism," the surgeon should act as if the patient were "his nearest relative, and try hard to avoid mutilation." In other words, the conservative operation should be done.

What are the diseases which attack the ovaries, and where can we resect them without great danger of their recurrence? The two great divisions are cystic and solid. The solid tumors are fibromata, sarcomata and carcinomata — 5% of all cases. They are malignant types, or may become so in the case of fibromata, and there is no question of not removing them entirely.

The cystic tumors are divided into simple, proliferating, dermoid, and parovarian. We have especially to do with the first three. Cysts may originate in any part of the tubo-ovarian structure, that is, in the medullary or parenchymatous portions of the ovary. The surface of the cyst varies from the bluish white or greenish, to brown, yellow, or glistening white.

The follicular cysts and those of the corpus luteum are simple and easily dealt with. The best treatment is to let them alone. Sometimes fifteen to twenty follicular cysts are found (dilated Graäfian follicles) which rarely attain great size, although some may enlarge to the size of a goose egg. This disease is generally bilateral, and there is pain at the catamenia and to the touch, so extensive resection is indicated.

Dermoid cysts originate in the parenchyma and often occur with large glandular or proliferating growths. All operators can testify to the irritating qualities of their contents, so every precaution should be used to prevent rupture, and the escape of their contents into the abdominal cavity. Teratoma have been classed with dermoids, and are a malignant and gigantic growth.

The proliferating cysts form the greatest class of ovarian tumors, and originate both in the parenchyma and in the hilum which is richly supplied with blood vessels. They are the glandular and papillary growths, and the latter are often seen bursting through the connective tissue from which they may also spring, forming tufts, and infecting the general peritoneal cavity.

In these proliferating cysts, there is always danger of malignancy, and if both ovaries are in anywise affected, both should be removed. "One ovary being affected, it is justifiable to remove both, although not always advocated." (Pozzi.)

We are thus narrowed down to a small class of tumors in which resection should be done, namely: — the non-proliferating cystic tumors which have their origin in the parenchymatous zone or cortical portion. If seen early, much of the ovary may be saved. If seen later when much of the cortex is involved, and the germinal epithelium of the cyst has proliferated to form glandular structures, we have the so-called adenoma which is very common and may attain a great size. It is made up of numerous small cysts and the whole ovary will have to be sacrificed.

It is taken for granted that conservatism on the ovaries is far more satisfactory than such work on the tubes, therefore such operations should be performed upon the class mentioned, although the general adoption may be a cause for more secondary operations.

The patient should be made to understand that possibility, but she is given the additional hope of the preservation of ovulation, menstruation, and the chance of bearing children. In no case should we make a promise to our patients to save an ovary or ovaries that will render our operation useless and of no value.

To the question, "In a doubtful case, would it not be wiser to let an ovary alone, if we do not feel justified in removing it," I would reply, decidedly, " No." In any young woman, a suspicious ovary should be incised, examination of its interior be made, and if healthy, it can be sutured again with fine cat-gut without harm (according to my belief). I think this is best done by splitting longitudinally on one part of the convex border down to the hilum, and, if necessary, enlarging the incision in the longitudinal direction so that the diseased portion or cysts can be excised. Careful approximation and closure of the incision with fine cat-gut should follow afterwards. Simple puncture of cysts with cautery or the knife, unless very superficial, give rise to pain, swelling, and enlargement from slight hemorrhage which takes place and is often overlooked. I do not recommend this procedure. Secondary operations are reported where the cysts had been previously thus treated.

My plea is,—that an exploratory incision should be made in an ovary which has been the seat of constant pain, with exacerbations during the menstrual periods, even if it appears normal or slightly enlarged. The same procedure should be done in both ovaries where there have been constitutional symptoms pointing to the ovaries, when they seem normal, or large but otherwise healthy. As a large cyst involving the ovary is likely to be duplicated on the other side, I advise the exploratory incision in the second ovary, thereby lessening the chance of recurrence, and saving a secondary operation, often finding and removing by resection a similar growth beginning in the apparently unaffected ovary. Careful resections of the ovaries presenting any abnormalities would eliminate many a cyst and the ovaries still perform their functions. I am convinced that pain would be relieved by a wedge-shaped incision and the wedge removed in thickened capsules; and, by a more careful approximation, adhesions, which are stated to be the greatest cause of secondary operations, would be more and more avoided.

I wish to illustrate my position, by giving briefly the outlines of a few of my cases.

Case I. Where incision probably saved years of suffering. E. G., fifteen years. Single. Backache and pain in abdomen. Sharp pains in right inguinal region. Dysmenorrhea.

Diagnosis: Retroversion with prolapsed ovaries, right one enlarged.

Operation Aug. 28, 1900. Curettage, resection of right ovary and suspensio uteri. Conditions above noted were found, and right ovary somewhat cystic. Incision made and carried deeper to find a small dark-blue cyst in the center of the ovary which was removed without rupturing. It proved to be a dermoid cyst with hair and part of a tooth. Recovered well from operation and was free from symptoms for a year. April, 1904, her physician reported that the pains had returned gradually and that he had found the uterus retroverted, and ovaries normal. Office treatment for six weeks for retroversion had caused all symptoms to disappear.

Case II. A. P., twenty-four years. Married, one child. Menstruation profuse and painful. Enlarged left ovary. Operation July 12, 1900. Curettage, removal of left tube and ovary which was disorganized by a large cyst, size of an orange. Many adhesions. She was better for a time afterwards but is under my care now for a large mass involving both ovary and tube on the right. She has never been well. I believe that I could have saved her much suffering by resection of the right ovary, which should have been investigated further, at the first operation.

The next two cases show that I was ultra-conservative, with poor results.

Case III. V., seventeen years. Single. Always delicate. Constant pain in back and in both ovarian regions. Headache. Menorrhagia. Prolapsed and slightly enlarged ovaries.

Operation Nov. 10, 1897. Curettage, suspension of uterus and ovaries. The ovaries though somewhat large did not appear either cystic or diseased. They were equal in size and I contented myself by suspending them close to the uterus, shortening the ovarian ligaments. Good recovery but relief very short. 1900. Examination showed right ovary twice as large as the left, with the same pains, and general health only slightly improved. Febuary, 1904. Patient married and four months pregnant, but reports backache, " hard time with her stomach," and general weakness. She is afraid that she will not be able to go to term or " ever do anything like other girls."

A resection of both ovaries or even removal of one ovary and resection of the other would have saved her these years of discouragement.

Case IV. B. L., single, twenty-three. Backache for two years. Menorrhagia every two weeks. Retroversion and small cyst of left ovary.

Operation July 30, 1900. Curettage. Cyst of left ovary punctured, and hydatid of morgagni tied off. Suspensio uteri. Good recovery, but six months afterwards, she writes that the same symptoms persist, although menstruation is regular. She is unable to work. September, 1902, she reports, " Able to work most of the time, but far from well. Backache all the time." The cyst of the left ovary was quite deep and bled freely. It should have been resected or removed, and the right ovary investigated.

Case V. E. H., thirty years. Married, one child. Backache, menorrhagia. Right ovary large as a hen's egg. Operation Nov. 4, 1902. Curettage. Right ovarian cyst removed with its tube. Left tube and ovary tied down by adhesions, but freed and left in. Appendix normal.

July, 1903. Patient felt very well until she went in surf-bathing, when she noticed pain and swelling in left side. Examination showed enlarged and cystic ovary, and a secondary operation is under consideration. Again, an incision might have removed a beginning cyst, which developed within a year.

The following two cases had the second operation with the following results. Both were neurasthenics.

CASE VI. M. A., thirty-five years. Married, no children. Operation July 19, 1898, for "dragging on right side" and sterility. Curettage. Trachelorraphy; right cystic ovary and occluded tube removed, suspensio uteri. Many adhesions between uterus, adnexia, omentum, and intestines. Left side freed and left. Good recovery from operation, but not relieved. March, 1901, Dr. Johnson did a second and complete operation, removing remains of right tube by V-shaped incision into horn of uterus, also removing left tube and ovary, and appendix by inversion. More adhesions were broken up, and uterus suspended. 1904. Uterus in position but great pains in right side, occasional vomiting, and not relieved. *Query*: Was the first operation too conservative, or would the results have been better if the entire right ovary and tube had been removed and the left resected?

CASE VII. M. E., thirty-six years. Married, four children. Pain in back and vagina. Cannot sit down without pain. Retroflexion. Operation July 5, 1898. Curettage. Both tubes and ovaries found apparently normal and free from adhesions, and were allowed to remain. Ventral fixation. No relief. Aug. 13, 1898; coccyx removed by Dr. C. A. Porter, as several of the staff diagnosed it as the probable source of continued pain. Still no relief. September, 1899, patient returned from her home, and a complete hysterectomy, with the removal of the appendages also, proved her salvation, and everything relieved.

In such a case, the last operation should have been the one of election, and not the conservative operation.

CASE VIII. P. K., sixteen years. Single. Pain in stomach, back and left side, radiating down left leg. Retroversion, and mass close to uterus on left, size of pigeon's egg. Operation Aug. 28, 1902. Pelvis full of adhesions. Abscess of left ovary fixed in broad ligament removed. Right ovary and tube which was patulous with no pus in it, were freed from adhesions, and allowed to remain. Recovery good. Pathologist's report, "Gonorrheal Abscess." Pain began on right side and continued for a year, when a secondary operation was done, removing the right ovary and tube, which proved to be a lighting up of the gonorrheal infection.

Had I known the facts, which were denied at the first operation, I would have removed one ovary and both tubes.

Conclusions drawn from all observers agree that, in young women who are desirous of having children, part of the ovarian tissue should be preserved, even at some risk. They also affirm that resection of an ovary is not a cause *per se* of secondary operations, or of increased mortality.

Therefore in doubtful cases, I go so far as to advocate the exploratory incision. (1.) It has not been proved to increase the danger. (2.) It is a wise proceeding when the other ovary is cystic or contains a papillary growth. (3.) It may prevent a secondary operation. (4.) It should prevent removal of a normal ovary. (5.) It may disclose a growth within or beginning cystic formation which can be easily excised. (6.) It is a conservative operation, consuming but little more time.

Ultra-conservative operations have not proved successful in my hands.

Medical Progress.

PROGRESS IN OTOLOGY.

BY PHILIP HAMMOND, M.D., BOSTON.

EXTERNAL AUDITORY CANAL. — ECZEMA.

RANDOLPH [1] believes in abstaining from the use of water, and finds great relief from the use of either yellow oxide of mercury, or salicylic acid in the form of an ointment (2%). For the itching which so often accompanies this disease, he sometimes adds a few drops of carbolic acid to the salicylic ointment, and the application of solutions of nitrate of silver, ($\frac{1}{10}$ or $\frac{3}{10}$) to the canal is strongly advocated by Mangan.[2] Where there is vesicular eruption the skin may be dusted with a drying powder such as zinc oxide, calomel, or subnitrate of bismuth.

FURUNCLES.

Sack [3] employs the following method in the treatment of furunculosis: The canal is first thoroughly cleansed and dried, and then a cotton tampon, previously dipped in a solution of carbolated glycerin, is pushed tightly into the ear. This is allowed to remain from a few hours to a day, the object being to exert considerable pressure on the inflamed part of the canal. Incision should be practiced only when there is definite abscess formation.

Reich [4] claims superior results in the treatment of furunculosis from the use of hot dry air. There seems to be no deleterious action upon the skin from its use, there is an increased hyperemia, promoting phagocytosis, and rapid absorption of infiltration.

An affection of the ear which seems to attack Europeans living in the tropics has recently been described by Müller [5] as ossifying otitis externa. Inspection shows a narrowing of the external canal, with great infiltration of the soft parts, closely simulating hyperostosis of the external meatus. This swelling in many cases disappears rapidly when moist compresses are applied. In no case was the middle ear found involved, and in only one was there exostosis of the canal.

MIDDLE EAR.

In the treatment of acute inflammation of the middle ear, Brunel [6] advocates local bleeding during the early and painful stage, leeches being used for this purpose. He also uses a carbolated glycerin solution ($\frac{1}{10}$) in the ear, at the same time shrinking any hypertrophy in the nares by the use of frequent inhalations of mentholated oil. The danger of inflation at this stage of the inflammation is pointed out by Randolph who believes, as does also Coussieux,[7] that a mixed infection may in this way be produced which will be worse than a suppurative process due to one organism.

[7] Ann., des mal. de l'oreille, etc., May, 1903.

Botey [8] insists that after paracentesis of the drum membrane no irrigation be used immediately, but that a small wick of sterile gauze be introduced, drainage being kept up in this manner. Even after removal of ossicles he employs the gauze drain, believing that in this way the entrance of infectious germs may be prevented, and that only when they have already gained admission should we try to inhibit their growth or destroy their activity.

S. MacCuen Smith [9] states that we are more apt to have intra-cranial complications following influenza than with the exanthemata, and the infection in these cases is so insidious that it may be well advanced before the complication is discovered, and in this way occur even when the physical symptoms denote marked improvement in the general condition. Early and free incision of the drum should be made in these cases.

DISTURBANCES OF HEARING IN ACUTE SUPPURATIONS OF THE EAR.

Ostmann,[10] from a careful examination of a series of cases of acute suppurative inflammation of the middle ear, believes that the inflammation is not confined to the tympanic cavity solely, but that the labyrinth is often affected, because of the disturbance of hearing for the upper scale. He accounts for this phenomenon in the lighter cases by the existence of a slight hyperemia, and thinks that in the severer forms there is undoubtedly a new formation of connective tissue. To detect these changes in the hearing it is necessary to employ some instrument capable of producing the high notes, and Ostmann regards the recently modified Galton whistle as in every way suitable and necessary for this examination. Without such careful inquiry into the physical changes of the ear it is impossible to give an intelligent prognosis regarding recovery.

In a consideration of the aural affections of infancy, Morse [11] emphasizes the following points: Otitis media is extremely common in childhood, and of great importance in differential diagnosis. It should be looked for in all doubtful cases where the symptoms cannot otherwise be easily explained. Inflammation of the ear is not necessarily associated with ear-ache, and the putting of the hand to the ear is common even when the ear is not diseased. Tenderness around the ear is an extremely unreliable guide. The only satisfactory way to examine ears is with a speculum, one smaller than usually sold with most sets being required. Among the common manifestations of otitis media are serious constitutional symptoms, suggestive of meningitis, pneumonia, gastritis, etc.

TUBERCULOUS OTITIS MEDIA.

Grimmer [12] observes that the tuberculous process in the tympanic cavity may reach quite an advanced stage before the external surface presents any pathological change. The reason for multiple perforations of the drum he attributes to the greater resistance of the middle or fibrillary layer to the destructive process, as this yields only after the mucous layer has ulcerated. According to this authority, primary tuberculosis of the ear is very rare, involvement of the ear almost always following some general infection. The characteristic symptoms are absence of pain, caries, and multiple perforations. The granulations are pale and bloodless looking, instead of red, as usual.

DISEASES OF THE EAR AND LIFE INSURANCE.

Burger [13] believes the ordinary examiner unable to properly estimate the risk involved in accepting the application of a person having aural disease. Particular attention should be paid to the suppurations of the middle ear, as these are most liable to prove dangerous. His conclusions are that an applicant for life insurance should unquestionably be refused when he has chronic suppurative otitis media with any of the following complications:

(1) Tuberculosis, or cholesteatoma formation.
(2) An inflammation of the attic or mastoid.
(3) Encroachment of the process on the bone.
(4) Facial paralysis, vertigo or hemicrania.

TREATMENT OF MIDDLE EAR.

Bezold [14] is strongly opposed to packing the canal with boric acid powder or gauze, and alludes to some twenty cases which he has seen in the past few years which were treated in this way. Maceration and infiltration of the canal are promoted, and pus is apt to be backed up in the tympanum. A review of the cases which he has observed shows four cases of empyema of the mastoid, two cases of gravitation abscess in the neck, two of caries of the mastoid, and one of necrosis of the labyrinth.

McKernon [15] suggests the use of crystals of carbolic acid in the treatment of chronic suppurations of the ear. The canal is filled with the crystals, the patient being in a recumbent posture, and they are allowed to remain for several minutes. After removal, alcohol is used to counteract the influence of the caustic on live tissue, while the diseased area is cleansed and stimulated. But little pain is said to attend this procedure.

Lednev [8] believes that the best results in the treatment of otorrhea are obtained from the use of iodoform. He reports twenty-three cases treated in this way, with cure in all but one.

Haug [16] has experimented with anesthesin in inflamed ears, mixed with alcohol and glycerin, or alcohol and water, and carried into the ear on a piece of gauze. Painful affections of the ear, especially of the external canal, seem to be relieved in from two to five minutes, lasting for at least two hours. Apparently its use exerts no influence on the course of the disease, and it does not seem to lessen the pain of paracentesis.

PREVENTION OF SERIOUS COMPLICATIONS OF EAR DISEASES.

In a paper on this subject, Hiram Woods [17] states that comparatively few cases of otitis media are seen by the aurist in their incipiency, yet early recognition may be necessary to save life, or at any rate to preserve the hearing. Relief of pain presents itself as the first duty of the physician, and he who trusts to the use of narcotics for this purpose is probably losing valuable time. Pain alone as a symptom of acute suppurative otitis media is of little value. The only satisfactory way of ascertaining the condition of the tympanum is by objective examination of the membrane, and when bulging occurs, indicating infection of the middle ear drainage by incision should be at once called for. Meierhof [18] believes that few cases which have the benefit of early expert treatment require major operation. He also insists on the importance of early and free drainage of the drum cavity.

Alexander [19] has used constant heat in the treatment of mastoiditis. He applies it by means of an apparatus similar to Leiter's coil. The patient is put to bed, and the apparatus used for from one to seven hours, the temperature of the water being from 111 to 114. Eighteen cases are reported, and of these, seven seem to have benefited from the use of the heat. Three did not tolerate the coil, and in the remaining cases, while the heat was grateful, it was subsequently necessary to operate.

Bezold [14] has noticed that the more severe cases of mastoiditis, and particularly those cases having protracted suppuration from the middle ear, are apt to have large pneumatic cells, usually remote from the antrum. The empyema may become localized here, even after the tympanic perforation has closed, and remain latent for a considerable period of time. He makes it a rule to operate when a suppuration has persisted for more than two months, and he has always found large cavities filled with pus and granulations.

Various contrivances for applying treatment to the Eustachian tube in the chronic catarrhal diseases of the middle ear continue to interest many writers. Rourse [20] employs a sound for mechanical dilatation, although he generally introduces some medication along with this, such as a glycerin-iodine mixture, passing this well up into the tympanic cavity. The sound is left in place for five minutes and then withdrawn. Reference to the electric bougie is also made by several.

Urbantschitsch [21] reports further observations upon a series of old catarrhs of the middle ear treated by galvanism. Some cases which had not yielded to any other treatment were apparently helped, but in many, but slight if any improvement was noticed.

LUMBAR PUNCTURE FOR TINNITUS.

Babinski [22] reports eight cases so treated, in all of which marked improvement of subjective noises and hearing was noticed. In every one of the cases the tinnitus disappeared following the first puncture, and the results seemed to be reasonably permanent. One case which was kept under observation three months showed no recurrence.

Chavasse and Mahu [23] in speaking of lumbar puncture, believe that it is of the greatest value as a means of diagnosing intra-cranial troubles of otitic origin, and that the operation is practically harmless. If, on examining the fluid after having used the centrifuge, it is found to contain either bacteria or polynuclear leukocytes, or both, we have a meningitis. If the liquid is clear and contains quantities of lymphocytes, we probably have a tubercular meningitis.

THIRD DAY. THURSDAY, JUNE 9.

SYMPOSIUM ON GALL-BLADDER DISEASES.

ETIOLOGY OF CHOLECYSTITIS AND CHOLELITHIASIS.

DR. WALTER L. BIERRING, of Iowa City, Ia., in his consideration of this subject said it was necessary to recognize that this viscus constituted one of the most vulnerable points for infection in the abdominal cavity, and in this respect was analogous to the Fallopian tube and the appendix, in which latter structure, infective agents were more or less constantly present in its lumen normally, while the gall bladder was generally free of micro-organisms; furthermore, infection of the gall bladder concerned itself more with the contents than the walls, the sterile bile becoming a culture medium for micro-organisms, while in appendix infections the coats were more prominently involved. The liability of gall-bladder disease was due mainly to its position, between the bacterial hordes of the intestine and the liver, exerting a very important rôle in the immunity possessed by the liver. Results of experimental infection demonstrated that a great many pathogenic micro-organisms flourish in the bile quite vigorously, though at one time the bile was supposed to act as a bactericide. Clinical and experimental observation showed that infection occurred in two ways: (1) By way of the blood, descending or hematogenous, (2) ascending or by way of the common bile duct. The effects of stoppage of the bile by gallstones or foreign bodies favors the growth of bacteria. The etiologic relation of cholecystitis and cholelithiasis has been found to be so close that that which pertains to the etiology of gallstones would be contributory and in most instances causative of cholecystitis. Cholelithiasis, he said, was very rare in early adult life, occurring more frequently after the age of forty. It was far more frequent in women than men, — child bearing, tight lacing, sedentary habits and constipation probably explaining this fact. From the accumulated experimental and clinical knowledge of the pathogenesis of gallstones, Dr. Bierring made

[22] Soc. méd. des hôpitaux de Paris, Apr. 24, 1903.
[23] Rev. heb. de laryng., d'otol., etc., Oct. 24, 1903.

the deduction that while the essential cause usually is cholecystitis, there were other factors at work besides infections, and special consideration should be given infectious diseases and states of altered metabolism which promote a change in the quality of the bile chemically, so as to constitute an irritant. Cholecystitis and cholelithiasis he believed to be secondary affections, and, if it were possible to eliminate such influences as age, improper wearing apparel, lethargic habits, constipation, gastric and intestinal catarrhal disorders, cholelithiasis would soon become a very rare disease.

DISEASES OF THE GALL BLADDER AND BILE DUCTS, IN RELATION TO DISEASES OF THE GASTRO-INTESTINAL TRACT.

Dr. Bertram W. Sippy, of Chicago, read this paper, and said that owing to the close anatomical proximity of the gall bladder and bile ducts to certain portions of the gastro-intestinal tract, disease of one of these structures may be readily transmitted to the other. Disorders of the stomach and intestine arising from disease of the gall bladder and bile ducts he divided into those of nervous or reflex origin, and those due to a direct extension of the anatomical diseases. Of the nervous disorders he said the functional activity of the stomach and intestine was influenced in a reflex way by disease of the biliary tracts, but no serious permanent effect was likely to result; while the direct extension of anatomic disease from the bile tracts to the stomach and intestine might be fraught with most serious consequences. From personal observation and study he has found that pyloric and duodenal obstruction from cholecystitis was serious when co-existent with pyloric stenosis. In reference to the management of duodenal and pyloric obstruction arising during or immediately following an attack of cholecystitis, his advice is not to operate until the patency of the pylorus is tested by rest and rectal feeding, except in those cases in which immediate operation is necessary, on account of the seriousness of the local inflammation, when operation should be directed to relieving local inflammation. Gastro-enterostomy should rarely be performed at the same time, except when is there evidence of old pyloric or duodenal obstruction. If the obstruction does not diminish with rest and rectal feeding, operation for cholecystitis may be combined with gastro-enterostomy if the condition of the patient permits. He has found great difficulty in differentiating ulcer of the stomach from gallstones at times. Gallstones usually pass from the gastro-intestinal tract with the feces, but a stone may occlude the lumen of the bowel sometimes, with fatal results. The most common seat of obstruction was near the ileo-cecal valve. He has found it of great value in diagnosis to remember that there is not a single symptom in gastric or duodenal ulcer that might not be present in cholelithiasis and *vice versa*. In conclusion he said that in the majority of cases a fairly accurate differential diagnosis could be made between the two conditions by carefully studying the whole clinical picture. Mistakes might occur when evidence was faulty or incompletely elicited, or when too much stress was laid upon some individual symptom.

DIAGNOSIS OF CHOLECYSTITIS AND CHOLELITHIASIS.

Dr. Parker Syms, of New York City, enumerated the important diseases of the gall passages. They were: (1) inflammatory disease of the gall bladder and gall ducts with or without stone; (2) gallstones in the gall bladder and gall ducts with or without inflammation; (3) inflammatory condition of the region surrounding the gall passages causing obstruction by pressure or distortion; (4) neoplasm of the gall passages, benign and malignant, with or without gallstones and with or without inflammatory disease. The prominent symptoms produced by gall-passage disease were: pain, tenderness, fever and chills, vomiting, change of pulse rate, collapse, tumor, jaundice, urinary changes, blood changes, stools. The pain is colicky, occurring most often when the stomach is empty; tenderness was localized, he said, to the region involved, which is usually opposite the juncture of the ninth rib with its costal cartilage; fever was of an acute type, rapidly subsiding as it rose; vomiting was of a reflex character coming on with the pain and independent of nausea; pulse was accelerated and tension increased; collapse occurred in severe attacks; tumor might be felt below the free border of the ribs; jaundice might be present or absent, depending upon the amount of obstruction to the flow of bile into the intestine; urinary changes were of interest in determining the presence and degree of jaundice; blood changes also aided in determining the presence and degree of jaundice, and the amount of leucocytosis aided in determining the presence of suppuration; stools showed the presence or absence of bile; so far, x-ray examinations had been unsatisfactory. Bile passage disease should be distinguished from the following conditions: gastric ulcer, appendicitis, renal colic, pancreatitis, phlebitis portalis, angina pectoris, empyema, subphrenic abscess, malignant disease of the pylorus, duodenum, pancreas, liver, kidney, etc., all of which he described. For the purpose of aiding in a more accurate diagnosis and estimate of the conditions present, the author embodies a diagnosis chart of diseases of the gall bladder and ducts.

THE TREATMENT OF CHOLECYSTITIS AND CHOLELITHIASIS.

Dr. Lucius W. Hotchkiss, of New York City, called attention to the growing tendency to place diseases of the gall bladder and bile ducts within the category of surgical affections, thus establishing the foundation of rational treatment. This treatment he divides into two classes; first, the medical or palliative, and second, the surgical or radical and curative. He quotes the opinions of experimenters some of whom believe that gallstones may be dissolved by administering sodium glycocholate; or alkalis and bile salts with a rich diet. The treatment by olive oil has not fulfilled the hopes of its discoverer as a specific. Hence the *rationale* of the treatment which aims to relieve congestion, and increase the flow of bile, he states, is perfectly sound. In the treatment of the disease he believed the great point to be determined was the border line between balneological and surgical procedures, *i. e.*, when the former should cease and the latter be begun. He believed that as greater certainty in diagnosis was reached there would be less call for the more difficult and dangerous operations upon the common duct, and a decreasing number of cases requiring cholecystenterostomy. The danger in operation lay principally in delay. Choledochostomy, choledochectomy, choledo-enterostomy, he thought, were possible only in rare conditions, and operations upon the hepatic duct were still in their infancy. Reference shows, he states, that American surgery has played no unimportant part in the pioneer work of the operative treatment of gallstone disease, and in the later developments of important modifications in technic. Consideration of the treatment of certain cases showed that cases seen in the first mild attack quickly subside under medical treatment; cases seen

in subsequent mild attacks were ideal ones for cholecystectomy; cases with repeated severe attacks in which cholecystostomy was always justifiable and the operation of choice; cases which for a few days show evidence only of mild local infection, suddenly developing signs of peritonitis and sepsis which required early operation; cases of common duct obstruction by calculus, in which it was advisable to treat expectantly for a week or two. He says, in conclusion, that the treatment in these cases must ultimately be surgical, and it must be admitted that medical science had discovered no sure solvent for gallstones, or devised any means other than surgical for the drainage of the gall bladder and biliary ducts.

ERGOT IN GENERAL PRACTICE.

DR. ALFRED T. LIVINGSTON, of Jamestown, N. Y., aimed to demonstrate in his paper that inefficient tone of unstriated muscular fiber was a common and serious element of disease; that it was important to guard against, or to correct, such abnormal state of that tissue. His secondary object was to indicate a drug which would accomplish the work desired. The abnormal disturbance of blood distribution depended, he thought, upon a relaxed state of the muscular coat of the blood vessels. The location, degree and persistence of such vascular relaxation, together with the influence of irritants or etiological factors, determined a variety of diseases, most of which would not occur if there were a good degree of tone in all vascular walls. A relaxed state of unstriped fiber in the bowel and other hollow organs, produced disorders indicating a stimulating or toning of unstriped muscular fiber. He made the statement that only a small percentage of humanity had a good state of tone of all the unstriped fiber of the body, thus being more subject to disease. In treating his subject the author classified his subject under the head of (1)Disorders of blood vessels, speaking first of inflammation of the arteries, veins and lymphatics for which affection his prescription was rest for two to five months and daily injections of ergot. Septic inflammation of veins and lymphatics had repeatedly yielded to treatment. The serious and fatal elements of febrile diseases were treated in detail. He said the evidence afforded by the action of ergot in shock was that the condition was not so much a paralysis of vasomotor centers, as it was a tremendous disturbance of the equilibrium of the circulation; and the indication was, therefore, primarily, to contract these dilated and engorged vessels and again establish an active circulation; ergot was the agent that would do this. From all that he had said, it would be recognized that he regarded the toning of relaxed unstriped muscular fiber as important in a great variety of diseases, and of vital import in many instances. Ergot will do this, he asserted.

DR. J. O. STRANAHAN, of Rome, N. Y., spoke of the excellent use of ergot in the insane institutions of New York.

DR. HERMAN GRAD, of New York, reported the excellent results he had obtained from the use of ergot before, during and after surgical operations, in greatly relieving the nausea and vomiting which so often followed the administration of anesthetics.

DR. JAMES J. WALSH, of New York, referred to the cases in Dr. Wakefield's service in which ergot had been of great value. He referred to a certain relaxation of the blood vessels in the abdominal region and said that the general observers had claimed that two thirds of the blood of the body could be contained in the abdominal vessels. Therefore, in certain cases, by toning up the abdominal vessels, as by the administration of ergot, the circulation could be made better.

DR. ALEXANDER LAMBERT, of New York, said that last year there had been over 8,000 cases of alcoholism at Bellevue Hospital, and that while the death-rate in nine years had been about 3% in those patients with a wet brain condition, etc., he had been able to reduce the death-rate by ergot, 44%.

THE DIFFERENTIAL LEUCOCYTE COUNT AS AN AID TO THE DIAGNOSIS OF FEVERS.

DR. WILLIAM KRAUSS, of Memphis, Tenn., read this paper and presented the following conclusions: (1) It is not so much the absolute increased per cent of large lymphocytes which is diagnostic of malarial infection as the relative increase over the small lymphocytes. (2) In cases of malarial infection without much fever and without quinine history, the polynuclears are markedly diminished and the large lymphocytes very much increased in proportion. (3) In the absence of an adenopathy, possibly also of influenza and measles, the above finding is positive evidence of present or very recent malarial infection. (4) During the rise of a malarial fever or as a result of quinine therapy, the polynuclear leucocytes may reach 80%, but in that event the large lymphocytes exceed in number the small ones. (5) In malarial hemoglobinuria any of the various blood findings, characteristic of malarial fever, may be present in any stage, and there is no evidence now at hand to explain this. (6) Malarial and typhoid fevers can be more positively differentiated from fevers of sepsis, pneumonia, rheumatism, malignant tumors, etc., by the differential leucocyte count than by the hemocytometer, and it can be done on dried films, away from the bedside. (7) Malarial infection makes a strong impress upon the leucocytic relation, no matter what other disease it is associated with. (8) It is not safe to rule out typhoid fever when the malarial variation is found, but, as it calls for antimalarial medication, the therapeutic test may decide before a Widal would appear. (9) In a gradually developing fever, the absence of marked increase in large lymphocytes or polynuclears during the first week justifies a preliminary diagnosis of typhoid fever.

(To be continued.)

Recent Literature.

Treatise on Diseases of the Skin for the Use of Advanced Students and Practitioners. HENRY W. STELWAGON, M.D., Ph.D. Third Edition. W. B. Saunders, 1904.

It is but little more than a year since we had the pleasure of noticing the appearance of a second edition of Dr. Stelwagon's textbook. In the third edition, which appeared in January of this year, very few changes or additions naturally have been found necessary. Owing to the prominence of the x-ray and Finsen light treatments, as well as the high-frequency current, a reference has been made to these methods.

The Extra Pharmacopœia of Martindale and Westcott. pp. xxiv+809. Eleventh Edition. London: H. K. Lewis. 1904.

This small book in its eleventh edition has been brought up to date. Many drugs have been omitted from consideration, allowing the addition of three hundred new remedies.

CONSUMPTION IN NEW ENGLAND.

The American Statistical Association has recently published a paper by Dr. S. W. Abbott, secretary of the Massachusetts State Board of Health, on "The Decrease of Consumption in New England." The paper is largely statistical, and embodies facts of the most striking interest to students of the problem of tuberculosis. The New England states have for years had the advantage of a fairly accurate system of vital statistics, extending for different periods in the several states, but for the last twelve years existing in all. The occupations and social conditions of the people in these states vary widely, as well as the population, and the rate of its increase during the past fifty years. Vermont has been the most stationary as regards population, whereas the manufacturing states, of which Rhode Island and Massachusetts are the examples, have been more decidedly affected by immigration than the others during the last ten years. Italians, Scandinavians, Germans, Southern Russians and Canadians have been large factors in the increase of population. These facts are of interest for future studies of problems of tuberculosis, but as yet the effect of this immigration upon the prevalence of the disease is not to be determined.

Dr. Abbott sets himself the following questions to consider: The prevalence of consumption at the present time; its decrease in the last years of the nineteenth century; the comparative mortality of the sexes from consumption and the relative decrease in each sex; the comparative mortality from consumption at the different ages of life and the relative decrease at each age. Some of these questions it is possible to answer satisfactorily, whereas others can be estimated merely. Regarding the per cent of mortality from consumption in New England, complete figures are available for the years 1892 to 1901 inclusive. This includes a total of 99,002 deaths in these ten years, or an annual mortality of 18.81 per ten thousand living inhabitants. Of the various states the mean death-rate has been greatest in Massachusetts, followed by Rhode Island. The reason for this is to be found in density of population, as Dr. Abbott has previously shown in a consideration of the geographical distribution of the causes of death in Massachusetts. He finds that, the mortality of densely settled districts being taken as one thousand, districts of medium density show 810, and thinly settled district, 727. It was also shown that deaths from consumption diminished steadily from the seacoast districts toward the western portion of the state. In estimating the diminution in the death-rate from the disease, the extraordinary fact is disclosed that deaths have declined in Massachusetts from 3901 per million inhabitants in 1851 to 1595 in 1902. The death-rate from the disease in 1902 constituted but 37.3% of that prevailing in 1853. A comparison of these figures with those in England for a similar period shows essentially the same conditions, although the entire mortality from the disease was less than in Massachusetts. If such figures are to be regarded as an augury for the future, it is clear that tuberculosis is somewhat rapidly tending toward extinction. Dr. Hillier, in a recent paper, has predicted its extinction in England and Prussia within about a generation. Dr. Newsholme is quoted as saying that there is more hope for the almost complete extermination of tuberculosis than of any of the acute infectious diseases, with the possible exception of typhus and smallpox. Von Behring has likewise expressed a similar opinion.

Regarding the third proposition, as to comparative mortality from consumption in the two sexes, it appears that in 1851 in Massachusetts the mortality among females was much greater than among males, being 45% greater. The tendency has been toward a steady decline in the death-rate in both sexes, as already pointed out, but a much more rapid decline among females than among males. In 1902 the conditions were reversed, and the male death-rate had become 12% greater than the female. Finally, the matter of the age incidence of consumption also shows interesting figures, with general improvement all along the line, but particularly in the later periods of life. Dr. Abbott's general conclusions

are that the death-rate from consumption in New England at the present time is somewhat less than twenty per ten thousand living inhabitants, that the death-rate has diminished largely in all the New England states, in some as much as 50% in the half century, and that this decrease is going on now more rapidly than in earlier years. The death-rate of women has particularly decreased, and, as just stated, the incidence of the disease has decreased in greater proportion in the old than in the young.

Such statistical papers as this to which we have called attention do more than a vast amount of theoretical discussion in bringing home to the people at large the actual facts regarding tuberculosis. Dr. Abbott shows conclusively by figures, the general accuracy of which cannot be doubted, that tuberculosis has diminished markedly in the last fifty years, and that its ultimate extinction is by no means chimerical. The whole agitation regarding the subject, and particularly the attempt to educate the masses, is doing much toward a completion of the campaign so satisfactorily begun. We are glad in this connection to call attention to a communication from Dr. Knopf, which appears in another column of this issue, on "The National Association for the Study and Prevention of Tuberculosis." After many vicissitudes, it appears that a strictly representative national association has been formed, which will do much toward concentrating effort and directing investigation toward the most profitable ends. The gentlemen composing the association as its official representatives are all associated in the professional, and to a less degree, in the popular mind with the problems of tuberculosis. We cannot question, therefore, that this association will fulfil its onerous function in the most satisfactory way possible.

A DEPARTURE IN THE TRAINING OF NURSES.

AT the graduating exercises of the Nurses' Training School of the Boston Children's Hospital, recently held, certain suggestions regarding the training of nurses were presented, which are of interest not only to the nurses themselves but also to the profession at large. Dr. R. W. Lovett spoke for the medical staff, and pointed out certain projected changes in the training of nurses at that hospital to which we wish to call attention. He alluded to the fact that the ordinary training school for nurses is usually an appendage to a hospital rather than an independent educational institution, and that therein the schools which educate women for other professions are very far in advance of the training schools for nurses. Dr. Lovett then proceeded to sketch the history of the training school at the Children's Hospital, and the previous development which it had from time to time undergone.

Among these changes were the lengthening of the course to three years, a reduction in the daily duty from twelve to eight hours per day, and a discontinuance of the payment of nurses on the ground that the instruction obtained was equivalent to their work. He showed how the whole question of nursing has become elaborated with the development of medicine, and brought out the neglect of the proper systematic training in fundamental branches. The announcement was then made, and it is to this we desire to call particular attention, that an arrangement has been effected by means of which Simmons College, devoted to the training of women in practical technical work, is to co-operate with the hospital in the early training of the nurses. Hereafter, instruction during a period of four months is to be given each nurse in the branches of anatomy, physiology, chemistry, bacteriology and sanitation, this instruction to be wholly at Simmons College. Thereafter the more practical side of nursing will be taken up much as heretofore in the hospital wards. In spite of the somewhat brief period of preliminary instruction, it was pointed out that the lengthening of the probation period is a step of importance, that the training given in a properly equipped institution for fundamental branches will be of great value in inculcating proper habits of observation, and that ultimately it may be possible to extend this preliminary course. Professor Sedgwick also spoke on the subject, and in his capacity as a member of the corporation of Simmons College promised the hearty co-operation of that institution in the scheme which has been elaborated.

So far as we have followed the somewhat extraordinary development of training schools for nurses during the past ten years, this step is one of the most fundamentally important which has been suggested. The idea of improved preliminary instruction, the suggestion that the nurses should pay rather than be paid for their services, and the general elevation of the calling to a profession, have naturally been discussed from many points of view. So far as we know, however, an actual plan, such as this suggested for the Children's Hospital, has hitherto not been

put into practice, although various steps in that direction have been taken. The experiment on the face of it would certainly seem worth trying, and we have no doubt that it will prove a success in augmenting the education of the nurses on various theoretical matters in which they are supposed at the present time to be versed but often are not.

We have from time to time commented on the development of nursing, and have expressed a certain skepticism as to the ultimate product of the increased educational facilities. We certainly can have no objection to education of any sort, provided only it does not take the place of that for which the nurse alone exists — the care of the sick. We must not lose the nurse in developing the profession of nursing.

THE FOURTH OF JULY.

As our national holiday approaches, speculation as to the effect of recently attempted legislation and much popular discussion on the subject of the celebration of the day is justified. The attempt to abolish noise is evidently quite impossible and quite without the bounds of legislative enactment. We are inclined to think, however, that the widespread feeling on the subject will have a certain influence in restraining the excesses to which we have been accustomed. The plea which is annually put forth that some restraint on the noise-making propensity be enforced in the neighborhood of hospitals cannot be too strongly emphasized. The positive discomfort, to put it in the mildest way, which bedridden and debilitated patients must suffer ought, at least, to have a deterrent influence even upon the young. In this connection it is a trifle discouraging to observe in the daily press that a member of our city government has introduced an order into one of the legislative branches seeking permission to begin the noise-making at midnight on the third of July, to continue unabated for twenty-four hours. The matter of tetanus no doubt this year, as heretofore, will receive a large amount of comment and protest after the fact. There seems however some evidence to show that a systematic attempt to keep certain danger dealing weapons and explosives out of the hands of the public will be forthcoming

MEDICAL NOTES.

Post-Graduate Teaching in Germany. — It is announced that hereafter towns in Germany having hospitals of reasonable size may create institutions for post-graduate clinical teaching. The nearest universities will supply the members of the teaching staff, in return for which the university concerned is to pay the cost of maintenance of certain patients sent to its clinics. The object of this system is to utilize the clinical material of large cities which do not themselves support a university.

Radiology at the University of Vienna. — It is announced that the science of radiology has been officially recognized in the faculty of medicine in the University of Vienna by the appointment of several men as docents in the subject.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, June 29, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 45, scarlatina 14, typhoid fever 15, measles 41, smallpox 0.

William Osler, LL.D. — Prof. William Osler of Johns Hopkins University received the honorary degree of LL.D., at the annual commencement of Harvard University, held June 29.

Harvard Medical Alumni Association. — The annual meeting of the Harvard Medical Alumni Association was held at the Harvard Medical School, June 28, with an attendance of about fifty members. Dr. D. W. Cheever addressed the association on the subject of the Boston Medical Library. Councillors were elected as follows: Dr. C. M. Green, Boston; Dr. Elliott P. Joslin, Boston; Dr. William B. Coley, New York.

NEW YORK.

Seaside Hospital of St. John's Guild. — The Seaside Hospital of St. John's Guild at New York, Staten Island, was opened for the season on June 20, and it is stated that the largest number of patients ever received on the opening day was admitted. The floating hospital of the Guild has not yet commenced its trips, but a nurse and orderly are in attendance on the boat conveying mothers and children to the Seaside Hospital.

New York Water Supply. — Urging that means be devised to test public sentiment on the question of asking Governor Odell to call a special session of the legislature to pass a water supply bill for New York City, Mayor McClellan recently sent a long communication to the Board of Aldermen, and by the board it was referred to the committee on water supply with the understanding that a public hearing

should be held on the matter as soon as possible. In this message, which is an intelligent discussion of the whole subject, the Mayor states that in signing the Smith bill (which prohibits the city from obtaining any water supply from Dutchess County, on the east bank of the Hudson), the Governor excluded New York from utilizing the most valuable immediate source of supply. He expresses some doubt, however, as to whether the same legislature would be willing to give the city relief. "As we stand now," continues the message, "the city is dependent to a great extent upon the continuance of an abundant water supply from natural sources. Should this supply of nature at any time undergo any considerable diminution for two successive years, the city would suffer a calamity almost indescribable. . . . The importance of a reservoir connection with streams in Dutchess County as a part of the chain of our supply system lies in the fact that such connection would not only furnish a large quantity of wholesome water, but it could be used, by extension, to draw from streams beyond that county which, on account of the quantity and the quality of the water obtainable there, would not justify the expense of an independent aqueduct. These waters, it is asserted by competent authorities, would be worthless to the city unless they could be commingled with the waters of Dutchess County. . . . The prosperity of the city, as well as the health of its inhabitants, is largely dependent upon an abundant and wholesome water supply, and I would suggest, therefore, that this matter should receive your most earnest consideration."

Obituary.

NATHAN SMITH DAVIS, M.D., LL.D.

DR. NATHAN SMITH DAVIS of Chicago died in that city June 16 at the age of eighty-seven years. He was born in New York state and received his medical education at Fairfield in that state. His practice began in Vienna, N. Y., and was continued in Binghamton, and later in New York City. In 1849 he removed to Chicago, accepting the chair of physiology and pathology at the Rush Medical College. Dr. Davis' name is chiefly identified with the foundation of the American Medical Association as far back as the year 1845, when he brought about a convention for the discussion of medical education, from which the American Association has grown to its present proportions. He was also prominent in the foundation of various scientific institutions in Chicago, and at one time had a national reputation in his profession. He was at various times the editor of several medical journals, and in 1883 he became editor of the *Journal of the American Medical Association*. During the later portion of his life a certain tendency to controversy, which had stood him in good stead earlier in his professional career, became a bar to his continued recognition. He will, nevertheless, be remembered as a man of strong personality and high ideals as well as a physician of great merit.

Correspondence.

THE NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

NEW YORK, June 21, 1904.

MR. EDITOR: I am in receipt of a number of inquiries from all over the United States and from abroad concerning the outcome of the various meetings which have taken place in Baltimore, Philadelphia, New York and Atlantic City in regard to the formation of a national tuberculosis association. Although your esteemed paper brought out a short paragraph concerning the Atlantic City meeting, it must have escaped the notice of many of my correspondents, and I ask you, in the interest of the cause, to kindly publish the following in the next issue of the JOURNAL.

An American national organization for the study and prevention of tuberculosis has been formed at last. The constitution and by-laws of this new society were adopted on Monday, June 6, at Atlantic City. The objects of the organization, as stated in its constitution, are as follows: (*a*) The study of tuberculosis in all its forms and relations; (*b*) the dissemination of knowledge about the causes, treatment and prevention of tuberculosis; (*c*) the encouragement of the prevention and scientific treatment of tuberculosis.

The following are the officers of this association: Dr. Edward L. Trudeau of Saranac Lake, N. Y., is the first president; Dr. William Osler of Baltimore and Dr. Hermann M. Biggs of New York are its vice-presidents; Dr. George M. Sternberg of Washington, D. C., late surgeon-general, is its treasurer; and its secretary is Dr. Henry Barton Jacobs of Baltimore. The board of directors, in addition to the officers above named, consists of Dr. Norman Bridge of California; Dr. S. E. Solly of Colorado; Dr. John P. C. Foster of Connecticut; Dr. George M. Sternberg of Washington, D. C.; Dr. Arnold C. Klebs and Dr. Robert H. Babcock of Illinois; Dr. J. N. Hurty of Indiana; Dr. William H. Welch, Dr. William Osler, Dr. H. B. Jacobs and Dr. John S. Fulton of Maryland; Dr. Henry M. Bracken of Minnesota; Dr. William Porter of Missouri; Dr. Edward O. Otis and Dr. Vincent Y. Bowditch of Massachusetts; Dr. Frederick L. Hoffman of New Jersey; Dr. Hermann M. Biggs, Dr. S. A. Knopf, Dr. Edward L. Trudeau and Mr. Edward T. Devine of New York; Dr. Charles L. Minor of North Carolina; Dr. Charles O. Probst of Ohio; Dr. Lawrence F. Flick, Dr. Mazyk P. Ravenel, Dr. H. S. Anders and Dr. Leonard Pearson of Pennsylvania; Dr. M. M. Smith of Texas; Dr. George E. Bushnell of the United States Army Hospital, and Surgeon-General Walter Wyman of the United States Marine Hospital.

Its membership is to consist of three classes:

(*a*) Members — those who are elected by the board of directors and who pay annual membership dues of $5. (*b*) Life members — those who pay $200 and are already members of the association. (*c*) Honorary members — persons distinguished for original researches relating to tuberculosis, eminent as sanitarians, or as philanthropists who have given material aid in the study and prevention of tuberculosis.

The government of the association, the planning of work, the arrangement for meetings and congresses, and everything that appertains to legislation and direction are to be in the hands of the board of directors, and committees are to have the power to execute only what is directed by the board.

The board of directors is empowered, however, to appoint an executive committee of seven members to which is entrusted the executive work of the association. This committee, chosen at the meeting in Atlantic City, consists of Dr. Edward L. Trudeau, Dr. Henry Barton Jacobs, Dr. Edward O. Otis, Dr. Mazyk P. Ravenel, Dr. Arnold C. Klebs, Dr. John N. Hurty and Mr. Edward T. Devine.

The board of directors is empowered to appoint representatives in the International Committee on Tuberculosis. It was decided at the meeting of organization, that this representation was to be headed by Dr. William Osler, and his associates will be selected later. The board is authorized, also, to appoint such committees as may be necessary for scientific and educational work, and for the holding of meetings and congresses.

Drs. Osler, Trudeau, Biggs, Devine, Barrier, Huber, Knopf and others addressed the meeting on the scope of the work which was before the association. The addresses of the various speakers were received with enthusiastic applause, but the ovation given when Dr. Trudeau appeared on the platform surpassed anything the writer has ever been privileged to witness before. It was spontaneous, genuine, and lasted for minutes. It was a grand tribute from the vast assembly, not only to the pioneer of the sanatorium treatment in American, but to the grand qualities of Dr. Trudeau as a physician, scientist and humanitarian. Dr. J. M. Barrier of Delhi, La., in speaking of the fearful mortality from tuberculosis among the negroes, urged the new society to take up also the work of prevention of tuberculosis among the colored population of the United States.

Concerning the character of the new organization, I may be permitted to quote in conclusion the opinion of a layman, the editor of *Charities*, the organ of the New York Charity Organization Society:

"There are two conspicuous and equally gratifying features of this national movement. It is thoroughly representative of the leaders of the medical profession; and at the same time there are ample evidences of their determination to make the association of direct practical value in legislation, in the education of the public, and in bringing about a co-ordination of philanthropic, medical and educational agencies for the conquest of the great scourge.

"While the scope of the association has not been officially outlined, it is evident from the stirring addresses made on the evening of the first meeting, that it will work directly for the better education of the public as to the means by which tuberculosis is communicated; for the erection of hospitals and sanatoria; for the adoption by local boards of health of such measures as have been so effective in reducing the death-rate from the disease in New York City; for the formation of local committees and associations in various communities, and for the intelligent co-operation of state and municipal authorities, private, voluntary agencies, and the medical profession.

"The question as to whether a special journal shall be established was left over for later consideration; but either through a special periodical or through the use of the medical or the lay press, the association will aim to bring about a practical and beneficial interchange of experiences, and a more intimate knowledge on the part of those who are at work in any community of the measures which have been found effective elsewhere. The executive committee was empowered to select an executive secretary, who will probably be a layman, and as soon as the condition of the association's treasury warrants it, a determined and aggressive campaign will be opened.

"It will be a source of pride and gratification, not only to physicians, but to all who have taken a sympathetic interest in the warfare against consumption that there is now a national body to which local associations and committees, hospitals and sanatoria, legislatures and local municipal administrations may turn with confidence for the last word on any disputed subjects, and for encouragement and sympathy for all good work on lines which experience has approved as promising of good results."

The majority of the vast audience present at the Atlantic City meeting were enrolled as members of the new organization.

S. A. Knopf, M.D.

RECORD OF MORTALITY
For the Week ending Saturday, June 18, 1904.

Cities.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 2,843; under five years of age, 726; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 687; acute lung diseases 254, consumption 317, scarlet fever 26, whooping cough 10, cerebrospinal meningitis 61, smallpox 2, erysipelas 11, puerperal fever 10, measles 28, typhoid fever 29, diarrheal diseases 124, diphtheria and croup 68.

From whooping cough, New York 3, Philadelphia 4, Pittsburg, Worcester and Lawrence 1 each. From smallpox, Philadelphia and Baltimore 1 each. From cerebrospinal meningitis, New York 53, Baltimore 1, Providence 1, Boston 2, Worcester, Cambridge, Beverly and Westfield 1 each. From typhoid fever, New York 7, Philadelphia 7, Baltimore 1, Pittsburg 11, Springfield, Salem and Clinton 1 each. From erysipelas, New York 4, Philadelphia 1, Baltimore 1, Pittsburg 2, Providence 1, Boston 2.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,287, for the week ending June 4, the death-rate was 14.6. Deaths reported 4,277; acute diseases of the respiratory organs (London) 73, whooping cough 125, diphtheria 40, measles 217, smallpox 2, scarlet fever 30.

The death-rate ranged from 5.5 in Kings Norton to 34.9 in Wigan; London 13.2, West Ham 13.2, Brighton 14.9, Southampton 13.4, Plymouth 12.3, Bristol 12.9, Leicester 12.3, Nottingham 12.4, Birkenhead 17.3, Liverpool 17.9, Bolton 15.1, Manchester 17.7, Salford 17.8, Bradford 14.4, Leeds 16.3, Hull 13.8, Sheffield 14.2, Cardiff 15.7, Rhondda 16.2, Merthyr Tydfil 15.1, Hanley 16.3.

METEOROLOGICAL RECORD.

For the week ending June 18, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

W. A. ANGWIN, assistant surgeon. Ordered to the naval hospital, Mare Island, Cal.

EXAMINATION FOR ARMY MEDICAL SERVICE.

THE examination of applicants for commission in the Medical Corps of the Army will be materially modified after July 1, 1904, when the amended regulations governing the matter will go into effect. Immediate appointment of applicants after successful physical and professional examination — the latter embracing all subjects of a medical education — will be discontinued; thereafter applicants will be subjected to a preliminary examination and a final or qualifying examination, with a course of instruction at the Army Medical School in Washington intervening.

The preliminary examination will consist of a rigid inquiry into the physical qualifications of applicants and written examination in the following subjects: Mathematics (arithmetic, algebra and plane geometry); Geography; History (especially of the United States); Latin grammar and reading of easy Latin prose; English grammar, orthography, composition; Anatomy; Physiology; Chemistry and Physics; Materia Medica and Therapeutics; Normal Histology. The subjects in general education above mentioned are an essential part of the examination, and cannot under any circumstances be waived.

The course of instruction at the Army Medical School will consist of lectures and practical work in subjects peculiarly appropriate to the duties which a medical officer is called upon to perform. While at this school, the students will be held under military discipline, and character, habits and general deportment closely observed.

The final or qualifying examination will be held at the close of the school term, and will comprise the subjects taught in the school together with the following professional subjects not included in the preliminary examination: Surgery; Practice of Medicine; Diseases of Women and Children; Obstetrics; Hygiene; Bacteriology and Pathology. General aptitude will be marked from observation during the school term. A general average of 80 per cent in this examination will be required as qualifying for appointment, and candidates attaining the highest percentages will be selected for commission to the extent of the existing vacancies in the Medical Department. Candidates who attain the requisite general average who fail to receive commissions will be given certificates of graduation at the school, and will be preferred for appointment as medical officers of volunteers or for employment as contract surgeons; they will also be given opportunity to take the qualifying examination with the next succeeding class.

Admission to the preliminary examination can be had only upon invitation from the Surgeon General of the Army, issued after formal application to the Secretary of War for permission to appear for examination. No applicant whose age exceeds thirty years will be permitted to take the examination, and the authorities at the War Department desire it distinctly understood that this limit of age will be rigidly adhered to. Hospital training and practical experience are essential requisites, and an applicant will be expected to present evidence of one year's hospital experience or its equivalent (two years) in practice.

The first preliminary examination, under the amended regulations above referred to, will be held about August 1, 1904; those desiring to enter the same should at once communicate with the Surgeon General of the Army, Washington, D. C., who will be pleased to furnish all possible information in regard thereto.

RECENT DEATHS.

JOHN H. DORN, M.D., a retired New York physician, died suddenly from cardiac disease, in London, on June 17. Dr. Dorn was born in Johnstown, N. Y., in 1842, and served for the first two years of the Civil War as a member of a New York regiment. He then began the study of medicine, and was graduated from the Albany Medical College in 1865. His professional life was spent in New York City, and from 1875 to 1896 he was a police surgeon. He retired from active practice about eight years ago, largely on account of his health.

THEODORE FRELINGHUYSEN BRECK, M.D., M.M.S.S., died in Springfield, June 25, 1904.

CHARLES EVERETT VAUGHAN, M.D., M.M.S.S., formerly of Cambridge, died in Santa Barbara, Cal., June 24, 1904, aged sixty-eight years.

BOOKS AND PAMPHLETS RECEIVED.

The Practical Medicine Series of Year Books. Comprising ten volumes on the Year's Progress in Medicine and Surgery. Issued monthly. Under the general editorial charge of Gustavus P. Head, M.D. Vol. V. Chicago: The Year Book Publishers. 1904.

Uric Acid. An Epitome of the Subject. By Alexander Haig, M.A., M.D., Oxon., F.R.C.P. Philadelphia: P. Blakiston's Son & Co. 1904.

Society Report, American Medical Association, Section on Medicine. By J. M. Anders.

The Clinical Study of Blood-Pressure. A Guide to the Use of the Sphygmomanometer in Medical, Surgical and Obstetrical Practice, with a Summary of the Experimental and Clinical Facts Relating to the Blood-Pressure in Health and in Disease. By Theodore C. Janeway, M.D. Illustrated. New York and London: D. Appleton & Co. 1904.

Arteria Uterina Ovarica. The Utero-ovarian Artery or the Genital Vascular Circle. Anatomy and Physiology, with their Application in Diagnosis and Surgical Intervention. By Byron Robinson, B.S., M.D. Illustrated. Chicago: E. H. Colegrove. 1903.
